KNOWLEDGE
AN ILLUSTRATED
MAGAZINE OF SCIENCE
PLAINLY WORDED—EXACTLY DESCRIBED

LONDON: FRIDAY, NOVEMBER 4, 1881.

CONTENTS.

TO OUR READERS.

"KNOWLEDGE" is a weekly magazine intended to bring the truths, discoveries, and inventions of Science before the public in simple but correct terms—to be, in fact, the minister and interpreter of Science for those who have not time to master technicalities (whether of Science generally or of special departments).

Knowledge will contain *Original Articles* by the ablest exponents of Science; *Serial Papers* explaining scientific methods and principles; *Scientific News* translated into the language of ordinary life; a *Correspondence Section* (including columns of *Notes and Queries*) for free and full discussion, and especially for inquiry into matters which the readers of original articles may find difficult or perplexing; and *Reviews* of all scientific treatises suitable for general reading. In addition to these portions, there will be a section for Mathematics, and columns for Chess and Whist (regarded as scientific games), conducted on a novel plan intended to render these portions at once useful to learners and interesting to proficients.

I have long regarded the material benefits derived from Science, great though these unquestionably are, as small by comparison with those to be derived from Science as a means of mental and moral culture. Nearly ten years have passed since, recognising this, I pointed out the necessity for such a journal as the present. We have none doing the work which Knowledge is intended to perform.

But I felt that before attempting to conduct such a Journal, I should obtain as wide an experience as possible of the wants of the class of readers for which it is intended. During the last ten years I have come in contact, as lecturer and writer, with tens of thousands belonging to that class. The experience I have thus gained is altogether exceptional. From letters addressed to me during my lecture-tours in Great Britain, the United States, Canada, Australia, Tasmania, and New Zealand, as well as those almost equally numerous written to me from other countries, I have learned the nature of the difficulties which commonly perplex scientific students and the readers of scientific treatises. I believe this experience must prove of great value to me in conducting Knowledge.

The tone of the articles will be that which I have found most useful in lecturing and writing. The general public do not want Science to be presented to them as if they were of intelligence inferior to their teachers. But they cannot be expected to take interest in statements couched in abstruse or technical terms. Nor is Science degraded when plain untechnical language, such as we propose to use in Knowledge, is employed; when, for instance, instead of speaking about the "mean equatorial horizontal solar parallax," a writer refers to the sun's distance; or when a race of men is not described as "microseme and dolichocephalic," but as small-faced and long-headed.

Discoveries and inventions communicated to scientific societies at home and abroad will not be presented until they have been translated from technical language which to the general reader is mere jargon.

The price of Knowledge is lower than that which has heretofore been assigned to periodicals of the same class. It is trusted that those who approve of the plan above sketched, and wish to see the Magazine firmly established, will help to

"Let knowledge grow from more to more,"

by making its existence known to their friends. In this and other matters cordial co-operation from all quarters is invited.

Richard A. Proctor.

SCIENCE AND RELIGION.

By the Editor.

MANY seem to imagine that the tendency of Science, especially in its more recent developments, is irreligious. Some give a special reason for this strange opinion, namely, the inconsistency which they conceive to exist between some of the results to which modern Science unmistakably points, and ideas which have been derived from poetical descriptions found in the Bible. So far as this particular form of objection is concerned, Science need be at no pains to formulate a reply. It would be as reasonable to do so, I conceive, as it would be seriously to answer such a question as this: "How can the Darwinian theory of the remote cousinship of man and monkeys be reconciled with Job's statement (Job, xxx. 29), 'I am a brother to dragons'?" or this: "How can the views of modern medical men about the intestines be reconciled with Job's assertion (Job, xxx. 27), 'My bowels boiled and rested not'?" Moreover, the world is not interested (or should not be) in hearing the views of Science as to the real meaning of words which theologians, after much time and trouble given to a matter lying

specially within their province, are not at one in interpreting. But when the question is of the truth of those scientific views which are oppugned, or as to the bearing of Science generally on Religion, the case is different. Science may reasonably answer questions relating to the influence of scientific discoveries on the human mind.

The great objection raised against modern science appears to be in the main this, that it enlarges unduly our ideas of the vastness of God's domain in space, of the immensity of the time periods during which He acts, and in fine, of His inconceivable power and wisdom. We may admire the wisdom of the Almighty, as shown in the pebble, or the rock, in the flower or in the tree, in the insect or the animal, nay, we may even so far extend our vision as to recognise the laws under which a stratum, or a forest, or a race of animals, perhaps even a continent, or a flora, or a fauna, had their origin and passed through their various stages of development. But we must not extend our survey further. To see God's hand in these, His wisdom in the laws by which they are formed, is to be religious and good, but to trace His power and wisdom on a larger scale is to be irreligious and wicked. Evolution on the small scale we may admit without harm; but to see evolution in the dev lopment of a world or a world-system, and still more toesee evolution throughout the entire universe as revealed to man, this is "to set God on one side in the name of Universal Evolution."

It is unfortunate that those who take this view of the general scope of modern scientific research had not been careful at an earlier date to explain, when admitting the growth of a tree, a forest, or a flora—of an animal, a race, or a fauna, according to natural laws, and even explaining (as many of them did) the wonderful nature of the laws according to which such growths took place, that they wished it to be clearly understood that in thus recognising the action of law they were rejecting the idea that the Almighty fashioned the plant or the animal, the forest or the race, the flora or the fauna, or indeed, aught (animate or inanimate) the development of which man is able to study through all its stages. Because, if it had been clearly understood that wherever they recognised growth and development as the results of law, they were assured such results could not possibly be attributed to the Almighty, Science might perhaps, (though it seems unlikely) have been deterred from researches leading to the distressing conclusion that there is development according to law on the greater scale as well as on the less; nay, that to all appearance law prevails throughout the entire domain of the Almighty in space and during the entire period of time in which he acts—that is, throughout infinity of space, and during eternity of time.

As regards the actual evidence of the vastness of space and the immensity of time throughout which the action of law extends, it may suffice to say that only the very ignorant or the very dull can for a moment entertain doubt. Unless the evidence given by earth and heaven has been specially devised to mislead man, or unless the reasoning powers bestowed on man by God have been given but to lead him astray (conceptions alike blasphemous and unreasonable), there can be no manner of doubt that on the one hand the universe is infinitely larger than it was supposed to be before the days of Copernicus and Kepler, Galileo and Newton; or that, on the other hand, our earth has lasted, and will last, thousands of times as long as had been supposed before its structure had been examined; the solar system millions of times as long as had been supposed before its movements had been studied; the galaxy of stars yet longer; the higher order of systems to which that galaxy belongs for periods so vast, that to all intents and purposes they extend (in our conception) to absolute eternity—in the past as in the future.

As to the influence which a result such as this should have upon men's minds, it should perhaps suffice to say that those who believe that the Almighty is all-wise as well as all-powerful ought not to fear lest the discovery of truth from the study of His universe should produce evil effects.

But I go much further than this, and say that of all possible forms of teaching, those derived from or based upon science must be most beneficial in the religious sense, not using the words science and religion in their ordinary narrow significance, but in their widest and noblest. "Doubtless," as Herbert Spencer has well said, "science is antagonistic to the superstitions that pass under the name of religion; but not to the essential religion which these superstitions merely hide. Doubtless, too, in much of the science that is current there is a pervading spirit of irreligion; but not in the true science which has passed beyond the superficial into the profound." Or, as Huxley has even more pointedly remarked, "True Science and true Religion are twin-sisters, and the separation of either from the other is sure to prove the death of both. Science prospers exactly in proportion as it is religious, and religion flourishes in exact proportion to the scientific depth and firmness of its basis. The great deeds of philosophers have been less the fruit of their intellect than of the direction of that intellect by an eminently religious tone of mind. Truth has yielded herself rather to their patience, their single-heartedness, and their self-denial, than to their logical acumen." To which may be added the noble saying of Carlyle, that "to know the Divine laws and harmonies of this universe must always be the highest glory of a man, and not to know them the greatest disgrace for a man."

But we may fairly go even further than this. We need not be content to defend, or merely to justify, or even to laud, Science in its relation to Religion. We may assert without fear of valid contradiction that the neglect of science is irreligious. For what is such neglect (where men have time and leisure for the work) but the refusal to study the works of the Creator? And in what position, logically, does a man stand who praises the Creator in words, but declines to study His creation? "Suppose," says Spencer, "a writer were daily saluted with praises couched in superlative language. Suppose the wisdom, the grandeur, the beauty of his works were the constant topics of the eulogies addressed to him. Suppose those who unceasingly uttered these eulogies on his works were content with looking at the outside of them, and had never opened them, much less tried to understand them. What value should we put upon their praises? What should we think of their sincerity? Yet, comparing small things to great, such is the conduct of mankind in general in reference to the universe and its cause."

The study of science implies the surest belief that God's works are worth study, the fullest recognition that the author of those works is worthy of our reverence. It is the truest kind of homage, in that it is not homage expressed merely in words, but homage shown in work, in service, in sacrifice. The man of science, in fine, refuses to offer to the Almighty "the unclean sacrifice of a lie." He offers him instead (in the search for truth) the sacrifice of time, of labour, and of thought. His very questions imply the fulness of his faith:—

> *This* is his homage to the mightier powers,
> To ask his boldest question, undismayed
> By muttered threats that some hysteric sense
> Of wrong or insult will convulse the throne
> Where Wisdom reigns supreme.

THE RELATION OF FOOD TO MUSCULAR WORK.

By Dr. W. B. Carpenter, F.R.S.

[In an article on the "Use and Abuse of Food," republished in my "Pleasant Ways in Science," there is a passage in which Liebig's mistake about the relation between nitrogenous or flesh-forming food and work is quoted without being corrected. I was not aware when the article was written (1867) that scientific experiments were in progress which were eventually to completely expose the fallacy of Liebig's position. When the article was republished these experiments had long since been brought to a satisfactory issue. Although the point does not importantly affect my essay regarded as a whole (for the material of a machine, as well as the source of its working energy must be kept in repair, and the workman does not get less good from his food because he takes it under a misapprehension as to the particular benefit it will do him), the mistake is one which should have been corrected. The interpreter of scientific statements, too technical for general comprehension, must not be content with presenting correctly and intelligibly the accepted teaching of an authority in any special branch of science. He must assure himself, as time passes, that the teaching which was regarded as sound when the subject was first dealt with, has not undergone correction in the mean time. If I had done this in the present case (as I have in general been careful to do), the error in question would not have appeared in the pages of "Pleasant Ways in Science." The following exceedingly interesting paper, by Dr. Carpenter, puts the matter in the proper light. He speaks, I need hardly say, "as one having authority." I may point out that it is one of the great advantages of a journal like the present that errors into which even the most careful will fall from time to time, will here be corrected at once. In the columns of a monthly magazine correspondence would be inconvenient, even if permitted. Here the freest questioning and discussion is invited, and it is particularly desired that those having special knowledge of a subject will call attention to, and correct, any statements which may appear to them erroneous.—Ed.]

PART I.

THAT "the evil which men do lives after them," is often exemplified by the continued prevalence of scientific doctrines accredited by the authority of great names, long after their fallacy has been demonstrated by the subsequent researches of other inquirers to the satisfaction of all competent judges. For, if these demonstrations be not presented to the world under the sanction of a like authority, the old errors are continually reproduced by popular expositors, and unquestioningly accepted by ordinary readers.

Having met with a notable instance of this kind not long ago, in the reproduction, as an accepted physiological verity, of the doctrine of Liebig as to the direct dependence of muscular energy on the expenditure of nitrogenous food, I think that a journal which aims to communicate positive "knowledge" to its readers may be an appropriate medium for a brief statement of what are now accepted by all scientific Physiologists as the facts of the case.

It is no derogation to the well-established fame of Liebig as one of the greatest Chemists of his day,* to affirm that when he passed out of his own domain into that of Biology, he made many and flagrant mistakes. Looking back after an interval of nearly forty years, at his "Organic Chemistry in its Relations to Physiology and Pathology," I am really astonished at the reckless audacity of some of his assertions; as, for instance (1st edit. 1842, p. 219), that "we know with certainty that the nerves are the conductors of mechanical effects, and that by means of them motion is propagated in all directions;" and that "the heart and intestines do not generate the moving power in themselves, but receive it from other quarters." He might just as well have said that "we know with certainty that when a charge of gunpowder or dynamite is exploded by an electric spark, it is the conducting wire that supplies the energy which rends asunder the rock." For nothing was even then more certain, than that the heart, intestines, and all other muscles furnish, in virtue of their own contractility, the power (or, as it would now be called, the "potential energy") which produces their mechanical effects, this being simply called into action by the nervous stimulus.

Another most noteworthy example presents itself in Liebig's denunciation of the "germ-doctrine" of fermentation and contagion, which was then being built-up on the basis supplied by the microscopic discoveries of Cagniard de la Tour on the fungoid nature of yeast, and of Audouin and Milne-Edwards on the like character of the Muscardine-disease of silkworms. "A theory," he says (3rd edit. 1846, p. 212), "of the cause of fermentation and putrefaction, which is utterly fallacious in its fundamental principles, has hitherto furnished the chief support of the parasitic theory of contagion. The advocates of this theory regard putrefaction as a decomposition of organic beings caused by infusoria and fungi, and consider every putrefying body as a breeding-place for infusoria or a nursery for fungi; and where organic bodies putrefy over a large surface, the whole atmosphere, according to this view, must be filled with the germs of these infusoria and fungi. The germs of these organised beings are, in this theory, the germs of disease or of the causes of disease." Yet it is this very doctrine, the complete establishment of which by the admirable researches of Pasteur, and of those who have followed in the line of inquiry which he so clearly marked out, has not only given the true interpretation of the phenomena of Fermentation, but, in its application to Pathology, is now serving as the basis for "preventive" medicine and "antiseptic" surgery. And I feel sure that Liebig himself, had he lived into the present era, would have been quite ready to admit its truth; for he was the last man to persist in views no longer tenable, merely because he had himself advanced them. "There is no harm in a man's making mistakes," he used to say, "but great harm in his *making none*, for he is sure not to have worked." And Professor Hofmann records having been exhorted by Liebig "not to keep in your house from night till morning an error you have become cognisant of."

Now Liebig's chemical division of food-materials into plastic, or "tissue-forming," and respiratory, or "heat-producing," was unquestionably an immense advance; and the basis of it is still universally recognised as sound. I can myself remember the time when it was a question whether the nitrogenous components of the blood, and the tissues formed at their expense, can be built-up in the animal body, with the aid of atmospheric nitrogen, out of starch, sugar, fat, and other non-nitrogenous hydrocarbons. Chemistry had not then shown the almost exact conformity of many Vegetable compounds to the albumen which was regarded as the fundamental constituent of Animal food; and while it was by Mulder that the doctrine of the *protein*-compounds was worked out, which, with some modifications, is now generally accepted, it was by Liebig that the impossibility of supposing that animals can form their tissues out of anything else than the "proteids" originally generated by Plants, was first definitely insisted on. He was not aware, however, that the formation of "protoplasm" requires *fat* as well as proteids; and that thus fat is to some extent a tissue-food. But he was unquestionably right in affirming that animal tissues cannot be manufactured out of *saccharine* compounds (as starch and sugar), unless these have been previously

* See "The Life-Work of Liebig," by Prof. Hofmann, the "Faraday Lecturer" for 1875.

changed into fat—a change whose possibility he went far to prove,—and then only in the same measure as fat itself. And he quite correctly assigned as the ultimate destination of the great bulk of the non-nitrogenous components of food, the being (so to speak) "burned" within the body, by combination with oxygen taken in through the lungs; their hydro-carbons being exhaled by these organs in the form of water and carbonic acid. But he assumed that the only purpose served by this oxidation was the production of *heat*, affirming that all the *mechanical force* exerted by the Animal body is the product of a transformation of *living* muscular fibre into *dead*, the "vital force" which was possessed by the living tissue being "expended in the shape of motion." The oxidation of the dead material he seems to have regarded as only a consequence of its loss of power to resist chemical agencies, and as a means of its removal,—serving, at the same time, as an additional source of heat. And rightly judging that this chemical metamorphosis should show itself by the increased excretion of urea in the urine (the kidneys furnishing the channel through which most of the nitrogenous "waste" is carried out of the body), he appealed, in support of his doctrine, to what he supposed to be the fact of such increase, and its proportion to the amount of work done.

Notwithstanding the general acceptance of Liebig's doctrine among the Physiologists of that time, there were those who saw that it was attended with considerable difficulties, notably as regards the amount of work done by man and animals upon a very small allowance of nitrogenous food. It was well known, for instance, that Bengalee labourers (who, for their size, are very fair workers*) live all but exclusively on rice, which consists almost entirely of starch; a pound of this, with a little ghee (butter), or a small bit of fish, constituting their ordinary diet. And it appeared from the carefully conducted experiments of Mr. Joule, of Manchester, that the quantity of work done by a grass- or hay-fed ox (taking into account that done by its heart *within* its body, as well as that done *outside* its body) was more than could be accounted-for by the metamorphosis of the nitrogenous constituents of its food.

Mr. Joule was at that time engaged upon an inquiry into the Mechanical equivalent of Heat, which led him to suspect that the combustive oxidation of the non-nitrogenous constituents of food might be a source of *mechanical power*, as well as of heat. But this doctrine was first definitely stated, and shown to be one expression of the great general fact (or law) now known as the Conservation of Energy, in the "epoch-making" treatise published in 1845, by Mayer; who urged (1) that the chemical force contained in the ingested food and in the inhaled oxygen, is the source of the motion and heat which are the two products of animal life; and (2) that the production of these forces varies in amount with the chemical changes to which it is due. The animal body, he maintained, is comparable, in these respects, to a steam-engine, in which work is being done, and heat produced, by the combustion of fuel; and he calculated that the quantity of carbon burnt off by the body in a day (as measured by the amount of carbonic acid given off in the expired air) is far more than sufficient for the whole day's work,—about four-fifths of it being used in the production of heat, while the remaining fifth suffices for the production of the muscular force ordinarily exerted within and without the body. He affirmed that "the muscle is the instrument by which chemical change is transformed into mechanical effect, not the material which is itself transformed;" and he regarded the blood stream that flows through the capillaries of the muscle, as bringing both the fuel and the oxygen needed to burn it. With the prevision which marks true genius, Mayer asserted that as soon as experimental methods should become sufficiently perfect to render it possible to determine with precision the amount of chemical change, either in the whole animal body or in a single muscle, during a given period, and to measure the production of heat and the work done during the same period, the result would show a definite correlation between them.

This (as will be shown hereafter) has been completely verified by subsequent research; the only point in which Mayer's doctrine has been found to need correction, being one of secondary importance.

(*To be continued.*)

* I have been informed by an engineer who superintended the construction of part of the Bengal system of railways, that the average quantity of earthwork done by a native labourer on the above diet is about *two-thirds* that of a highly-fed English "navvy."

ARE WOMEN INFERIOR TO MEN?

A FRENCHMAN named Delaunay has recently published a pamphlet, the object of which is to show that women are intellectually and physically inferior to men. At the outset it should be noticed that this M. Delaunay must not be mistaken for the great French astronomer Delaunay, (who died some nine years ago). The point requires noting, because the present Delaunay has ere this dealt with statistical evidence relating to astronomical matters, endeavouring to prove therefrom that the planets Jupiter and Saturn exercise a marked influence on the phenomena of earthquakes. It is hardly necessary, perhaps, to say that the proof was hardly so perfect as M. Delaunay imagined. In fact, his reasoning would not have attracted attention if his name had not sounded like that of a very eminent astronomer, of whose death many had not heard.

M. Delaunay now devotes himself to the task of showing that those who regard the two sexes as intellectually or morally equal, are absurdly sentimental. He seeks to show that women are in a lower stage of development than men, on grounds which he describes as purely anthropological, though he should rather, it would seem, have described them as biological, since his inferences respecting the tests of development are derived quite as much from the study of other animals as of men. He admits that among certain lower forms of life, as insects, some fishes, and reptiles, the females show a superiority to the males; but among the higher races of vertebrates (backboned animals) it is different. Among birds and mammals (he might have added marsupials, or pouched animals, as kangaroos, opossums, &c.), the male is nearly always superior to the female. The inference is, that whereas in lower races the female is superior to the male, the male is equal to the female in races more advanced, and superior to the female in all the superior species. "The supremacy of the female is *therefore*," he says, "the first form of the evolution undergone by sexuality, while the supremacy of the male is the last form." The conclusion is calculated to be so satisfactory to men that they may be permitted, perhaps, to pass over the manifest weakness of the reasoning. The law, which should be universal to be of avail, is admitted to be only general; and it is noteworthy that the reasoning really points to the conclusion that the higher the race, the lower relatively is the female: so that it would seem that the first

point to be established by one who would prove his nation in advance of others, should be the inferiority of the women of his race. If this were really so, we imagine that there are some races of men, not supposed to be far from the very forefront of human progress, who would not care, at such a cost, to establish their claims to a high position.

M. Delaunay is careful to show why he thinks the female inferior to the male in the higher races. First, we find that among birds and mammals, including man (who shares with the pig, the monkey, the dog, &c., the privilege of breast nourishment), the nutritive phenomena are more intense than in the female. Man eats more than woman; and he is, therefore, incontestably her superior. "Yet, although she eats less, the woman is more of a *gourmande*, and eats more frequently." (This may be proved by comparing aldermanic feasts and club dinners with the favourite forms of feminine gourmandism.) "Next we observe that the breathing of men is more intense than that of women. For an equal height he has a greater capacity of chest, and a larger thoracic index than the woman" (a greater breathing capacity). "He also absorbs more oxygen, though his breathing is slower." (Why should not this be regarded as a proof of inferiority? Suppose a woman were writing, and should put it this way, Woman requires less oxygen than man, and is therefore superior to him; how then?) "The temperature is higher in man than in woman, and the pressure of the blood greater, though the pulse is less frequent." This, again, might be quoted the other way by women. It would be almost as logical to say, Man is superior to woman because he wears a beard, and the hair on his head is shorter than hers.

It appears that the frame of man, as compared with that of woman, proves incontestably his superiority. He has a heavier skeleton, absolutely as well as relatively. "The woman in all the physical characteristics of her skeleton is intermediate between the child and the man, according to Topinaud." Must we then rank the elephant as man's superior? his skeleton is certainly heavier than man's, not only absolutely but relatively. "The woman is not so right-handed as the man; the pre-eminence of the right side over the left is not so marked with her as with the male." Charles Reade would probably regard this as evidence of superiority rather than inferiority; and many men who have not been thought inferior to their fellows, but the reverse, have been at no small pains to train the left side to equality, or as near equality as they could attain, with the right side.

Worse remains, however, to be told. "The male externally is always larger than the female. The woman is not so heavy as the man, although she would often appear larger on account of the development of the adipose system, which in her is greater than the man."

The next point, if established satisfactorily, would be rather more to the purpose. "In all our Hindo-European races," says Topinaud, "the woman is more prognathous than the man," that is, her jaws are relatively more projecting than those of man. This would be a strong point, because there really appears to be a correlation between the position of the jaws in animals and the capacity (relative, of course,) of their brains. But it would be desirable to have all the particulars by which the peculiarity referred to has been established. It would be easy to select classes either of men or of women who would be very unfair representatives of their sex taken as a whole; and though I would be far from saying that anything of this sort has been done, I would note that it is a much more difficult matter than many would suppose (who have not tried) to obtain a large number of either sex who could be regarded as absolutely free from class influences. The task would be easier if men and women pursued similar avocations. As they do not, the statistics collected by Torpinaud may, for aught that appears, have tended, if rightly interpreted, to show that such and such avocations either affected intellectual development, or were selected by persons of inferior intellect, rather than anything specifically distinguishing men from women."

A similar objection applies, but yet more strongly, to M. Delaunay's next point. He says that, "according to his own researches, woman is more flat-footed than man, and has a foot less arched (a sign of inferiority); hence the preference of women for high-heeled boots." It is a rather bold assumption that the form of the feet thus indicates intellectual development. But assuming that it were so, I apprehend that the statistics of feet-forms would show very different results according to the classes that might be selected. Supposing, for instance, M. Delaunay had measured the feet of a few hundred waiters, and compared them with those of a few hundred opera-dancers, he might, perhaps, have inferred either that opera-dancing conduced far more than waiting at table to intellectual development, or else that women were far superior to men. I do not say that a selection so unlikely to lead to a correct result as this has actually been made; but we require to know much more than we do about M. Delaunay's statistics before we can accept his conclusion, even if we admit that the mental and moral qualities can be deduced from the shape of the feet. The fancy for wearing high-heeled boots may reasonably be regarded as showing that women regard a high instep as a natural feminine beauty, to be enhanced where present or imitated where wanting; that, in fact, women are more particular in this respect than men. So viewed, it would no more prove that women are commonly flat-footed than their wearing chignons or switches would show that they commonly have shorter hair than men. In fact, M. Delaunay's argument here is decidedly unfavourable to his theory, if a high instep really is a proof of intellectual superiority; for women try more to enhance those qualities which they regard as feminine, and therefore attractive, than those which they share with men.

"The female voice is sharper than that of the male. Both in wild and domesticated animals the male has the muscular system more developed than the female." All this may be granted; but it proves nothing to the purpose. The bull has a deeper voice than man, and the gorilla has the muscular system far more developed; but we do not infer that the bull or the gorilla stands higher in development on either account than man.

"The movements are more precise in man than in woman." (What movements?) "Among pianists of the two sexes the mechanism reaches a much higher degree of perfection in men." As musicians, whether we consider composition or execution, women certainly are surpassed by men; and I may note among the absurdities of our system of education that almost every girl in the middle and upper classes "learns the piano" (save the mark!) though not one in a hundred has any natural aptitude for music, while among boys music is comparatively neglected. There is little, however, in feminine execution to justify the statement that their movements are less precise. On the contrary, numbers of girls acquire wonderful precision in playing; only, unfortunately, most of them want that aptitude for music which can alone make mere perfection of digital mechanism of any account. It is not easy, however, to see why musical skill should be regarded as a test of mental or moral qualities. I am disposed, on the contrary, to consider that women in our day are handicapped by their musical education; and that pro-

bably, if so many were not compelled (without musical talent to help them) to waste many years of their life in the weary work of "practising," we might have better opportunities of learning what women are capable of in other ways than we are actually afforded. Music, at any rate, is one of the weak points of modern feminine education, if not its worst feature. Even as musicians, women would be far likelier to show power, if only those who possessed aptitude for music received a musical training. How can the real musician among fifty girls get any chance, when she has to go through, with the forty nine who are not musicians, the weary music killing work of our present system of so called musical training? (Is not this matched, however, by the existing systems of classical and mathematical training for boys, irrespective altogether of any aptitude for classical or mathematical work?)

We come next, in M. Delaunay's paper, to the more important question of cranial capacity and form: for certainly (setting aside, of course, phrenological absurdities), the shape and size of the brain are more likely to indicate mental and moral capacity correctly, than are the shape of the feet, the tone of the voice, and the muscular development. As, however, my limits are already exceeded, I leave the rest of M. Delaunay's paper to another occasion.

So far as we have gone, M. Delaunay's arguments remind us, more than we should have thought possible in a scientific *brochure*, of the reasoning in a humorous article which appeared a year or two ago in the *New York Times*, wherein it was gravely argued that the inferiority of woman to man is proved conclusively by women's habit of sitting on the ground to take off, or to put on, their shoes and stockings. In fact, I am not sure that M. Delaunay might not find more in favour of his theory in this argument than in any of his own that have thus far been considered.

COMETS.

THE year which was to have seen the end of the world, because of planetary conjunctions and perihelion passages, because Mother Shipton had said so (or was said to have said so), and because the ascending gallery in the Great Pyramid is 1882 inches long (so that the year 1882 is to introduce a new era), has been remarkable in astronomical annals for the number of comets which have been seen. Already six have been numbered, and the year is not over yet. Something still remaining—more, indeed, than we are always ready to admit—of old superstitions respecting comets, has led many to regard the coincidence as full of meaning. Others, not quite so credulous, have supposed that though comets *may* not come in flights of half-a-dozen together to portend the end of the world, they may yet affect our weather in some way; perhaps directly, as the moon is supposed to do (with very little reason); perhaps indirectly, by acting on the sun. To the astronomer the appearance of so many comets—some of them large ones—has been full of interest, because he hopes by the application of the new methods of research discovered within the last quarter of a century to solve some of the mysteries with which the whole subject is still fraught, despite a number of interesting discoveries which have recently been made.

A brief inquiry into some of the facts which have been discovered respecting comets, and a discussion of some of those peculiarities which still remain among the greatest mysteries of science, will probably prove acceptable at the present time, when comets attract so much interest and attention.

Elsewhere in the solar system we meet with relations not differing greatly in kind from those presented by our own earth. We see a set of globular bodies revolving around the sun in nearly circular orbits, nearly in one plane, and all in the same direction; we find that these globes rotate upon their axis—still in the same direction; they have, apparently, atmospheres proportioned to their dimensions; and many of them are attended upon by bodies resembling our own moon. And therefore, without entering upon the vexed question of the plurality of worlds, we are able to pronounce that, *if* these globes are inhabited, dwellers upon them have, like us, their years, their days, their seasons; a sun rising in the east and setting in the west; twilight and moonlight; air and vapour; winds and rain; all things, in fact, as it would seem, necessary to their comfort and convenience. Here and there—as in the zone of asteroids and the rings of Saturn—we meet with novelty of arrangement or configuration; but even then we find a stability, either of figure or motion, which renders such objects comparable, so to speak, with those we are accustomed to.

But with comets the case is wholly different. When we have said that these objects obey the law of gravity, we have mentioned the only circumstance—as it would appear—in which they conform to the relations observed in terrestrial and planetary arrangements. And even this law—the widest yet revealed to man—they seem to obey half unwillingly. We see the head of a comet tracing out systematically enough its proper orbit, while the comet's tail is all unruly and disobedient.

The paths followed by comets show no resemblance either to the planetary orbits or to each other. Here we see a comet travelling in a path of moderate extent and not very eccentric; there another which rushes from a distance of two or three thousand millions of miles, approaches the sun with ever-increasing velocity until nearer to him than parts of his own corona (as seen in eclipses), sweeps around him with inconceivable rapidity, and makes off again to where the aphelion of its orbit lies far out in space beyond the most distant known planet, Neptune. Some comets travel in a direct, others in a retrograde, path; a few near the plane of the earth's orbit, many in planes showing every variety of inclination. Some comets regularly return after intervals of a few years; some after hundreds of years; others are only seen once or twice, and then unaccountably vanish; and not a few show by the paths they follow that they have come from interstellar space to pay our system but a single visit, passing out again to traverse we know not what other systems or regions.

The ancients believed comets to be of the same nature as meteors, or shooting stars—either in the earth's atmosphere, not far above the clouds, or, at all events, much lower than the moon. These views are, however, much less ancient than the more correct views maintained by the Pythagoreans. Their doctrine was that comets are planetary objects, having long periods of revolution. From whom this opinion was derived is uncertain. Like other opinions attributed to Pythagoras, it was doubtless obtained from Eastern philosophers; but of what country—whether Egyptian, Persian, Indian, or Chaldæan—we have no means of learning. Apollonius, the Myndian, ascribes the opinion to the Chaldæans. He says they spoke of comets as of travellers penetrating far into the upper (or most distant) celestial spaces. Seneca and Pliny held similar views, exhibiting in this respect, says Humboldt, the imitative faculty of the Romans. But the Greek

philosopher preferred to look for a theory of the universe in the conceptions of his own brilliant and imaginative mind. As if to show future ages how little was likely to be achieved by the highest mental powers without the habit of patient observation, he endeavoured to educe a system of philosophy from fancies, and to found it upon syllogisms. Aristotle—who may be considered the typical philosopher of the Greek school—included comets in the wide range of phenomena which he claimed the privilege of explaining. To him was due the opinion mentioned above—an opinion confidently maintained during the many centuries in which the philosophy of Aristotle held sway over men's minds. To him, also, was due a yet more remarkable opinion, the view, namely, that the Milky Way is a vast comet which continually reproduces itself! Xenophanes and Theon, in the fifth century, adopted a rather singular view of the Aristotelian theory of comets, when they spoke of these objects as "travelling light-clouds."

To these fancies the ancients added the idea that the shapes of comets indicated their character as portents. Thus in Fig. 1 five views of comets are shown, as an arrow-head, a sea monster, a sword, a lance, and in flames.

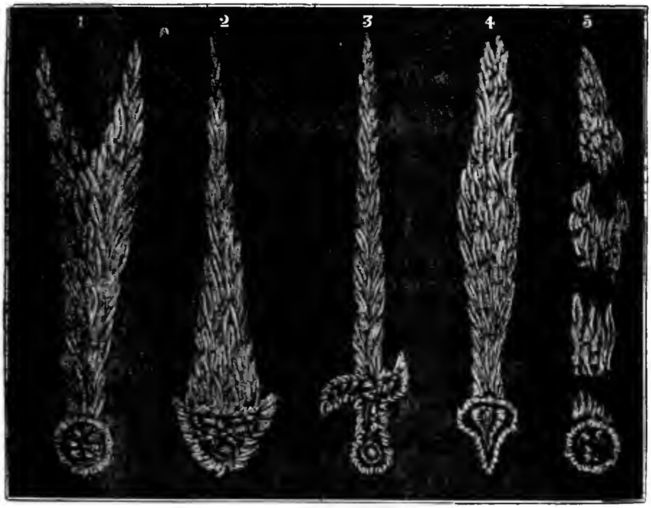

Fig. 1.—Various fanciful views of Comets, according to Pliny. From the *Cometographia* of Hevelius.

Tycho Brahe was the first to express doubts respecting the views of Aristotle. From a careful series of observations, he demonstrated that the orbits of comets are certainly situated beyond the moon's orbit. He thought the orbits must be circular, for he lived at a time when none but circular orbits were conceded to the celestial bodies. Dörfel, a native of Upper Saxony, proved that the orbits of comets are either very elongated ovals, or parabolas, and that the sun occupies a focus of the curve. It happens, singularly enough, that this discovery was effected but a year or two before Newton propounded the theory of gravitation. Newton himself examined the orbit of the great comet of 1680 (known as "Newton's comet") and others; and he found that they all accord with the law of gravity.

But before long, Newton's friend and pupil, Halley, effected a yet more remarkable discovery. In hopes of confirming Newton's views by results founded on actual observation, he collected all the records of comets which seemed entitled to confidence, and attempted—as well as his meagre materials would allow him—to calculate the elements of their orbits. In this way he computed the paths of no less than twenty-four. Among these, three presented a remarkable similarity. One appeared in 1531, and was described by Appian; another appeared in 1607, and was observed by Kepler; the third was traced by Halley himself in 1682. The equality of the intervals between these epochs led to the suspicion that the same comet had appeared three times. And Halley found, on searching historical records, that a comet appeared in 1305, another in 1380, and a third in 1456. Combining these appearances with those mentioned before, he thought he had satisfactory evidence of identity. For he was sufficiently familiar with the results which might be expected to flow from the law of gravity, to be aware that *absolute* regularity of motion was not to be expected in a body traversing the solar system in an eccentric orbit, and swayed from its proper path by the attraction of such giant planets as Jupiter and Saturn. Indeed it happens, singularly enough—one out of many remarkable coincidences in the history of comets—that the comet of 1830 was *not* Halley's comet, which really appeared in 1378, a date bringing in a yet greater discordance in the intervals than Halley had suspected and accounted for. With remarkable acumen—since no means existed in his day for anything like accurate computation—he not only pointed out the possible influence of the great planets in disturbing the comet in past revolutions, but he made a rough approach to an estimate of the effect that they would have on the period of its next visit. "Instead of appearing in August, 1757, as it would if its period remained unaltered, it will not appear," he said, "until the end of 1758, or the beginning of 1759, for it will be retarded by the action of Jupiter. Wherefore," he adds, with a pardonable anxiety to secure the credit of his ingenious investigations, "if it should return, according to our prediction, impartial posterity will not refuse to acknowledge that this was discovered by an Englishman."

As the time for the fulfilment of the prediction approached, an intense interest was excited in the minds of astronomers. In 1757, Clairut, Lalande, and Madame Lepaute undertook the computation of the epoch at which the comet might be expected to return. They applied methods of investigation invented by Clairaut himself. It resulted from their laborious computations that April 13, 1759, was fixed on for the epoch at which the comet should attain its closest approach to the sun, or, as it is technically expressed, should pass its perihelion. But Clairaut was careful to allow a month either way, on account of unavoidable omissions in the calculation, and for the effects of unknown forces, "such as the action of some planet too far off to be seen" (a happy anticipation of modern discoveries).

And now the heavens were swept diligently by all the telescopists of Europe, each eager to be the first to

announce the discovery of an object whose appearance or non-appearance was to confirm or to disprove the Newtonian theory. It was actually discovered, however, without telescopic aid, by a Saxon farmer, George Palitsch, on Christmas-day, 1758. It reached its perihelion on March 13, 1759, confirming at once the accuracy of Clairaut's computation, and the justice of his caution in assigning rather wide limits of error.

It was now evident that comets travel, like the planets, in determined paths; and also, that the investigation of their motions is a subject worthy the study of the ablest mathematicians, and sufficient to tax their highest powers. An account of their labours would be out of place in such an article as the present; but we recommend the subject to the notice of the agricultural student, as one of the most interesting chapters in the history of modern science.

One comet, however, discovered not long after astronomy had achieved this triumph, seemed at first to teach a different lesson. In 1770 a comet appeared whose path turned out to be not a long oval or parabola, as had been the case with all the orbits yet examined but an ellipse of moderate extent, and not very eccentric. The orbit lay also much closer than usual to that thin slice of space (so to speak) within which the planets are observed to move. Lexell, who computed the path, found that the period of the comet was about five-and-a-half years. Its return was carefully watched for, *but no one has ever seen the comet since.* The cause of its disappearance, and also of its sudden appearance—for this was equally remarkable, when we remember that so conspicuous a comet could not have been circulating long in its small orbit without discovery—was carefully inquired into. The result was singular. On tracing back the path of the comet, it was found that it must have passed very near to the great planet Jupiter. "It had intruded," says Herschel, "an uninvited guest into his family circle—actually nearer to him than his fourth satellite." Accordingly, the comet's path, originally a long oval, had been bent into a curve of less extent. Having once entered on this new path, the comet was free to follow it—always returning, be it noticed, to the point at which it had started on it—so long as Jupiter was not interfered with. But it happened, unfortunately for the stability of the comet's motions, that, after going twice round the new path, it again presented itself near Jupiter's track, when the planet (which had meanwhile gone once round his orbit) was not very far from the scene of his former encounter. He accordingly again exerted his influence upon the unfortunate comet, and this time dismissed it on a path which will not admit of its approaching the earth near enough to be seen.*

Let us return, however, to Halley's comet.

It so chances that the comet which was the first to show full obedience to the law of gravitation, was one which exhibited in a very remarkable and significant manner the characteristics which distinguish comets from other heavenly bodies, and make them so mysterious to the student of science. At the return of Halley's comet, in 1836, all that had signalised the return in 1759 was repeated, but the mathematical triumph was far greater. Damoiseau, Rosenberger, and Pontecoulant calculated the comet's return to perihelion within two or three days, instead of a month, and the time when it passed this point of its orbit corresponded, within a few hours, to the mean of their several estimates. On the northen heavens where it was first seen, the comet presented a remarkable appearance, with a long and brilliant tail stretching over an arc of many degrees upon the sky. When it had passed from our northern skies, it was carried (after a short interval, during which it was lost to view in the sun's rays) to the southern heavens. Sir John Herschel, and Maclear (Astronomer Royal at the Cape), were prepared to receive it; but when first observed by them it showed none of the features which made it so remarkable in our skies. It had no tail and scarely any head. In fact, Sir John Herschel, in one account, says, that as first seen it could only be distinguished from a fixed star by its motion. The study of its gradual change of aspect from that time threw so much light on the nature of comets' tails and other appendages (or at any rate of that particular comet's tail) that Sir John Herschel, not accustomed to be over confident, said there could be no doubt as to the true interpretation of the observed phenomena. What these phenomena were shall be considered further on.

* It must be noticed, however, that Leverrier, who very carefully re-examined the question, was led to question the accuracy of the results recorded above. Admitting that Jupiter had twice disturbed the comet, he thinks there is no certainty (for want of sufficiently accurate observations) respecting either the original path of the comet, or that in which it is at present circulating unobserved—if, indeed, it has not been *absorbed* by Jupiter.

ILLUSIONS.

By Thomas Foster.

THE senses are the means by which, directly or indirectly, all observations are made, and science can only make real advance in so far as it is based on observation and experiment. It is most important, therefore, that either our senses should be trustworthy in their action, that is should give us true information, or (if they neither are absolutely trustworthy originally nor can be so trained as to become so) that we should be able to test and to correct their indications.

Now it very soon appears, when we put the matter to the test, that the direct evidence of the senses is not to be accepted without careful cross-examination. The science of our day may be regarded as having been established in opposition to the apparently obvious evidence of the senses. Take, for instance, astronomy. Nearly everything that the eyes tell us about the heavenly bodies, and nearly all that the sight and touch tell us about the earth (so far as astronomy has to deal with the earth as one of the planets) is false. Not one of all the stars we see in the skies is really where we see it. The earth seems flat, large, and fixed; it is really a globe, small compared with the seemingly small stars, and it is moving in many ways, not one of which the senses correctly appreciate. It is the same with other sciences.

We are not concerned, however, to discuss here how far the apparent teaching of the senses has to be analysed before its real meaning can be understood. The examples illustrating this would cover the whole range of science. For instance, to show how the real place of a star can be determined—more or less exactly—from its apparent place in the sky, we require to discuss the laws of refraction, aberration, the proper motion of stars, and a number of other matters. In such cases as this, though what the eye tells us is in a sense incorrect, the eye is supposed to do its work correctly. The eye tells us *truly* that the rays received from the star by it have come in such and such a direction, and what science has really to do is to determine in what direction those rays must have set out in order after various changes of direction, due to the various media through which they passed, to reach the eye situate on a moving and rotating body like the earth, in the direction which they had, or at least seemed to have—or, more

strictly, in order to produce an image of the star on such and such precise part of the retina.

But there are many cases in which the senses seem actually to convey false information, the eye telling us wrongly about the shape, size, position, &c., of an object, the touch deceiving us as to its form and qualities, the hearing, the smell, the taste, each in its own way deceiving us. It is such cases as these that I propose to examine. It is most important for the student of science that he should be aware of the various forms of error into which the direct action of the senses may lead him. I could cite instances where, for want of precisely such information, the student of science has been at the pains to explain a phenomenon which had no real existence, or which was precisely the reverse of reality. Mr. Proctor mentions somewhere a case where a French astronomer (Chacornac), was careful to explain *why* the edge of Jupiter's disc is brighter than the middle, the fact being that the middle is brighter than the edge, the apparent brightness of the edge being a mere delusion. It may be added that the discussion of the class of illusions referred to is full of interest. The reader will find that the careful consideration of the cause of illusions will generally suggest other illusory experiments, sometimes more striking than those here described. There are few occupations more interesting as pastimes, and at the same time more instructive, than the invention and testing of various forms of illusion.

It should be mentioned at the outset that such illusions as these are wrongly called sensory illusions. As Huxley points out, "there is no such thing as a fictitious or delusive sensation. . . . . But the judgments we form respecting the causes and conditions of the sensations of which we are aware, are very often erroneous and delusive enough; and such judgments may be brought about in the domain of every sense, either by artificially-contrived combinations of sensations, or by the influence of unusual conditions of the body itself." He adds, "mankind would be subject to fewer delusions than they are if they constantly bore in mind their liability to false judgment. Men say, 'I felt,' 'I heard,' 'I saw' such and such a thing, when, in ninety-nine cases out of a hundred, what they really mean is, that they judge that certain sensations of touch, hearing, or sight, of which they were conscious, were caused by such and such things." It is precisely this lesson which I want to enforce in the present series of papers.

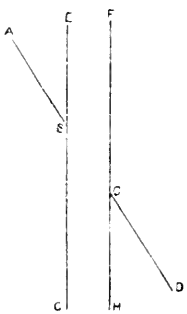

Fig. 1.

The simplest illusions are those affecting straight lines, causing them to appear crooked, or curved, or *vice versa*.

Take, for instance, the case illustrated in Fig. 1. Here the parts of the broken line AD appear to be parallel, but not—as they really are—in the same straight line. The part CD seems lower than the true prolongation of the part AB. The explanation of this is not so obvious as in some less simple cases which I shall consider further on. Manifestly, the mind recognises that, owing to the interposition of the space EH, the point where the prolongation of AB should appear must be lower down than B, but it underestimates the allowance to be made on this account. This is equivalent to saying that the eye under estimates the breadth of the strip EH. Why this should be? It seems to me it is because the space EH appears to lie above the plane containing AB and CD, so that the real breadth of EH is unconsciously judged to be less than it really is: for, of course, a strip nearer the eye than EH is would *seem* broader than EH if really of the same breadth, and if seeming *no broader* than EH, would really be of less breadth. The eye judges that EH *is* nearer, and infers unconsciously that it is of less breadth than EH really is.

Let us test this explanation, first seeing whether a strip which breaks a curve, as EH breaks the straight line AD, really seems nearer to the eye than the curve.

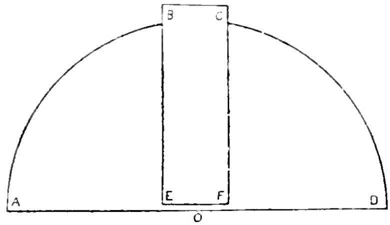

Fig. 2.

Describe a semicircle AD (Fig. 2) broken at BC, and between B and C draw the outline of strip BF as in the figure. We see at once that the space BF appears to be nearer the eye than the portions ABE, CFD. Doubtless the judgment unconsciously reasons that the strip which breaks the outline ABCD must lie upon the semicircle and hide the portions wanting.

Again, it seems to me and to some others, but not to all to whom I have shown Fig. 2, that the figure formed by carrying on the curves AB, DC, to meet over space BC would not be a complete circle, but somewhat contracted horizontally. This would correspond with the above explanation of the illusion illustrated in Fig. I. As, however, all eyes do not recognise this second illusion of Fig. 2, let us modify the experiment, noting that the same eyes which might not recognise an illusion apparently affecting breadth only, would readily be affected by an illusion affecting direction. (We may remember what Brewster points out in dealing with one of the illusions mentioned in his Natural Magic, that in many cases it is the most observant eye that is affected by an illusion. In the present case the eye which has the best power of estimating breadths would be the one most affected by illusion as to the breadth of the space BF.)

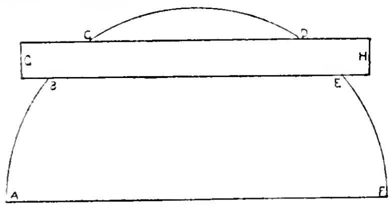

Fig. 3.

Draw then the strip GH, Fig. 3, crossing the semicircle ABDF as shown. Here the curve CD seems to belong to a smaller circle than that of which it really forms part. It looks as though the curves AB, FE caried on beyond the strip GH would lie about considerably outside CD.

It will be found that if the parts CD, BE of the sides of

the strip GH are erased, the illusion ceases. The erasure restores, as it were, the space GH to the level of the paper to which it really belongs.

The case illustrated in Fig. 1 is commonly regarded (but without sufficient reason, or, indeed, any assigned reason) as belonging to the class of illusions illustrated in Fig. 4 (first noticed by Zollner). Here the lines AB, CD, EF, GH, &c., which are really parallel, appear to converge alternately towards AC, DF, EG, HL, and KM. This illusion is different from that of Fig 1, as affecting the apparent directions of lines, whilst the other does not (parallel lines are regarded by geometricians as in the same direction).

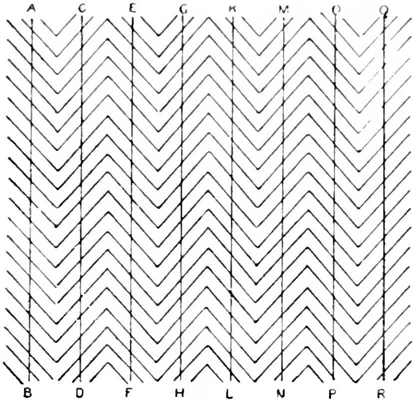

Fig. 4.

The illusion of Fig. 4 appears to result from the attention being drawn unduly to the circumstance that the vertical lines pass athwart the other sets at an angle, so that the angle is, as it were, exaggerated. The eye notices, for instance, that AB passes the parallels in order from right to left, the uppermost parallel crossed by AB being farther to the right than the lowest, and thus the idea is conveyed that B, instead of being a point vertically below A, is to the left of such a point. So D seems to the right of a point vertically below C, and so on.

The illusion of Fig. 4 admits of being varied and, in some cases, strengthened by substituting waving lines of various forms for the diagonal hatching. Several cases of this kind will be shown in the next number. I conclude this paper with a few simple illusions, affecting not only the direction and position of lines really straight, but also their straightness, making them appear as curved lines.

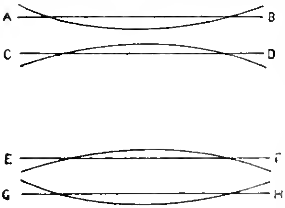

Fig. 5.

The lines AB, CD of Fig. 5 appear to be curved so as to be nearer at the middle than at either end; while the lines EF, GH, in the same figure, appear to be so curved as to be farther apart in the middle than at either end. Obviously, the eye unconsciously notes the varying distance between the really curved lines and the straight lines, and attributes part of the change of distance to a curvature of the really straight lines.

This form of illusion may be modified, as shown in Fig. 6. Some find the apparent curvature produced by the arrangement of Fig. 6 stronger than the other. For my own part, I find the apparent curvature of the lines AB, CD strongest in Fig. 5, that of the lines EF, GH strongest in Fig. 6.

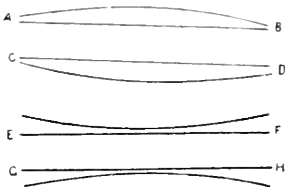

Fig. 6.

The illusion seems intensified in the case of lines AB (Fig. 7), which seem to be convex towards each other; the symmetry of the pair of curves lying between these parallels ought theoretically to restore the idea of parallelism. The lines EF and GH in the same figure may be made to seem either parallel or concave toward each other, according as the eye takes together the curves which approach EF and GH (respectively) nearest, or the concentric pairs; for the two curves which lie between EF and GH produce opposite effects on each of the lines EF, GH.

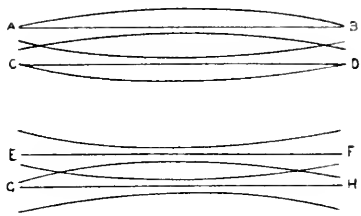

Fig. 7.

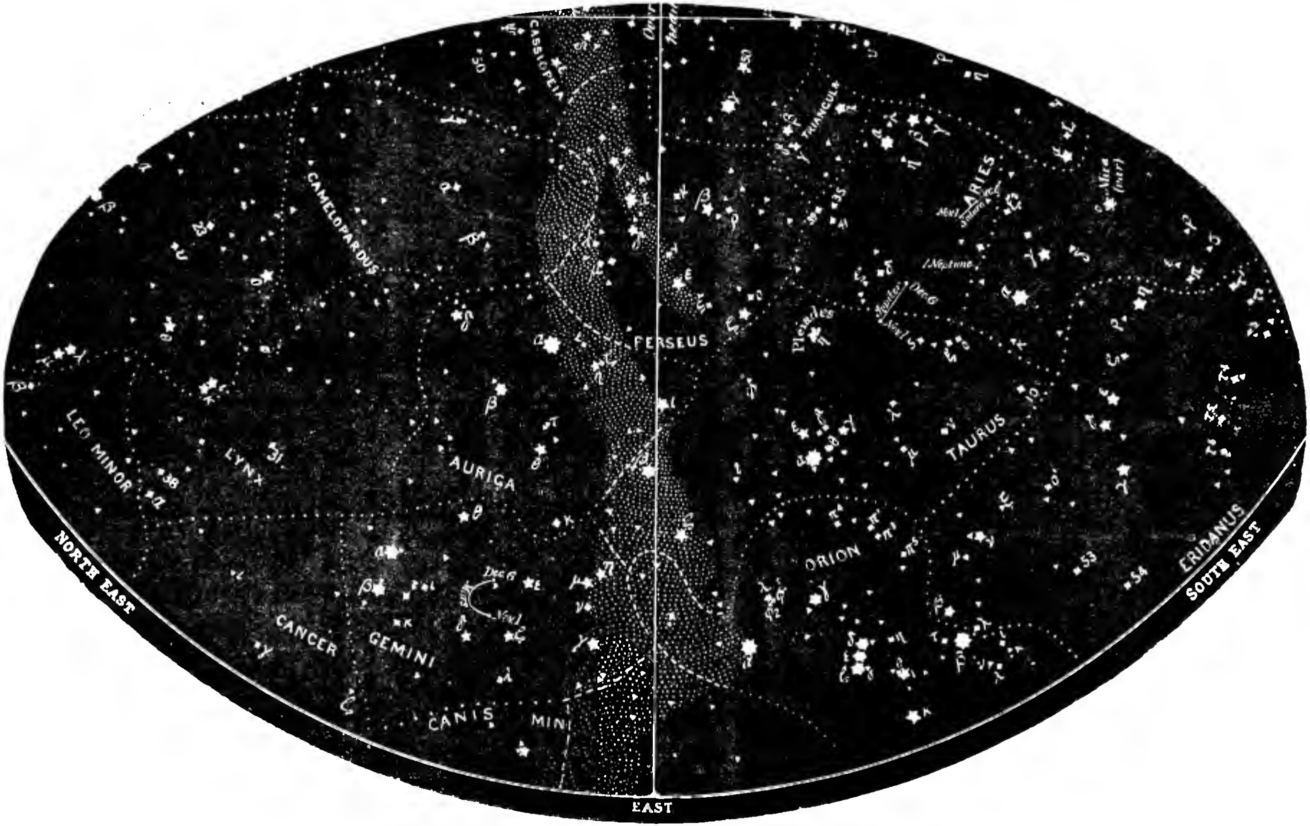
Next week I shall consider other cases of apparent curvature, but in the meantime I may note that I shall be glad to hear from readers who have noticed illusions akin to these, or may have been led to other explanations than those I have suggested.

What is a man,
If his chief good, and market of his time,
Be but to sleep and feed? A beast, no more.
Sure, He that made us with such large discourse,
Looking before and after, gave us not
That capability and godlike reason
To fust in us unused.—*Shakespeare.*

Electrical Exhibitions and the Government.—Our correspondent probably reflects the general opinion of British exhibitors in Paris when he says that "the conduct of our Government has prevented our country from holding the place it deserved to hold among European nations in an industry which promises before long to be one of the utmost importance." But it is perfectly well known to foreigners, and also to ourselves, that the British exhibitor, so to speak, must swim without corks. He may not make so large a show as some of his rivals; but what he does show is even more likely to be over-estimated, as being the result of his unaided efforts, than to be undervalued in consequence of any unfair comparison with those who have enjoyed advantages which he does not possess. The difference between the conditions which surround British and foreign exhibitors is thoroughly understood by all who are interested in understanding it; and we do not believe that a steady adherence to the general rule of Government non-intervention, although it may detract from the prettiness or completeness of a display, will ever be really detrimental to the interests of a national manufacture.—*Times.*

THE EASTERN SKIES IN NOVEMBER.



This Map shows the position of the stars in the Eastern Skies:—

On October 30, at 11½ o'clock. | On November 7, at 11 o'clock. | On November 14, at 10½ o'clock. | On November 22, at 10 o'clock. | On November 29, at 9½ o'clock.
On November 3, at 11¼ o'clock. | On November 10, at 10¾ o'clock. | On November 18, at 10¼ o'clock. | On November 25, at 9¾ o'clock. | On December 3, at 9¼ o'clock.

The movements of the planets Mars, Jupiter, Saturn, and Neptune, which are travelling in this part of the stellar heavens at present, are indicated by the lines marked respectively with the names of these planets. The planet Mars, it will be noticed, passes, during this month, what is called a stationary point; he is advancing (moving from right to left) till Nov. 17, after which he retrogrades. But he does not really come to apparent rest, owing to the wide spread of the loop he forms between his stationary points. Jupiter, Saturn, and Neptune are all three retrograding. They are in opposition, or exactly opposite the sun, so that they come to the south at midnight on the following days:—Saturn on Nov. 1, Neptune on Nov. 7, Jupiter on Nov. 13.

DARWIN ON MOULD AND WORMS.*

No man of science of our day understands better, or applies more thoroughly, than Darwin, the principle laid down by Lord Bacon, that "Man, as the minister and interpreter of nature, does and understands as much as his observations on the order of nature permit him, and neither knows nor is capable of more." To one who rightly apprehends this, the fundamental principle of modern scientific research, small things and great, so only that they illustrate the order of nature, are alike worthy of study. He may carry his survey over the depths of space, or into the structure of a microscopic creature; he may extend his view into the remote past and the distant future, or he may limit the range of his vision to phenomena taking place in a second or in a yet shorter time: but only in so far as his purpose is to determine the order of nature's works, is he the true minister and interpreter of nature. The modern student of science, following this principle, is in strong contrast with the philosophers of the Greek school, who, little disposed to pursue observations, evinced, as Humboldt has said, "inexhaustible fertility in giving the most varied interpretation of half-perceived facts;" and, as Bacon himself said, "Laid their whole stress upon intense meditation, and a continual exercise and perpetual agitation of the mind;" and so were led to frame systems on insufficient knowledge, and to explain false systems by false hypotheses. Doubtless, a philosopher of that school would have looked with contempt on a Darwin studying the movements of plants, the ways of bees, the breeds of pigeons, and analysing the play of features in joy or in sorrow, in anger or in pleasure. It would have seemed to him far worthier to educe from his moral consciousness ideas as to the true position of worms in the scale of being, than to devote years to the actual study of their ways and works. But by the humbler and more laborious method the student of science in our day manages to attain, or at least approach, the truth; the more brilliant philosopher of the olden school educed from his active mind multitudinous errors.

Darwin's latest treatise, on Vegetable Mould and Earthworms, affords perhaps the best illustration of his method of all the works that he has yet published. His "Origin of Species" and "Descent of Man" mark an epoch in science; but such a work as the present illustrates the way by which the new paths have been entered. It is true no one can read those epoch-making works without recognising in every page the kind of work on which their author's mind has been engaged while establishing his theories, or the tone of modern scientific thought. But results have there to be touched on which, in a work like his "Monograph on the Cirripedia," "The Movements and Habits of Climbing Plants," and, above all, the present treatise, are exhibited in detail.

Forty-four years ago Darwin announced the first results of his study of the formation of vegetable mould, in a paper read before the Geological Society of London. In the interval which has elapsed since then he has been accumulating the stores of knowledge about mould and mould makers which are presented in the work now before us.

Perhaps the most remarkable results of Darwin's observations is the "stupendous work" accomplished by creatures so small and weak. It was objected against the views which he published in 1837, that worms could not possibly bury to a depth of several inches fragments of cinders, burnt marl, &c., which had been strewn over the surface of meadow land. But now Darwin is able to speak confidently of their burial of the remains of Roman villas and pavements. He shows also how ancient encampments and tumuli have been gradually lowered by the agency of worms. Grass-covered slopes undergo perpetual denudation through their operations, the covering of grass remaining all the time intact, and even the inclination of the slope remaining unchanged. It may well seem incredible to the superficial reasoner, that creatures like worms,—small, weak, and soft-bodied—should produce such results; nay, results far greater in the course of time, changing as they do the entire aspect of a country. It is this inability, as Darwin well remarks, "to sum up the effects of a continually-recurring cause, which has often retarded the progress of science, as formerly in the case of geology, and more recently in that of the principle of evolution." When men like Sir John Herschel or Sir Charles Lyell have spoken of the effects of slowly-acting causes in modifying continents and seas, they have been ridiculed by the thoughtless, who cannot see how the downfall of rain, the slow movement of rivers, the play of waves on shore-lines, can produce such results. In like manner the biologist is ridiculed who, noting small changes in various races in short periods (or even in periods which to our conceptions seem long), points to the effect of such changes when multiplied during the lapse of those long periods of time of which the earth's crust tells us. But our author has shown how even creatures so tiny and weak as the coral animal have made large islands and long lines of sea-resisting reef, by constant labour; and now he shows how under our very feet the despised earthworm is changing the form and nature of the land we live on. When we learn that the rich dark mould in which vegetation thrives best, is made by worms, we see that not only the aspect of a country, but the condition of its inhabitants, and even its history, have been modified by their work. So that we may accept in its widest significance his remark that "it may be doubted whether there are many other animals which have played so important a part in the history of the world as have these lowly creatures."

The study of the habits of worms in this work is full of interest. As in nearly all the author's books, the language is clear and simple. It may be said indeed of this treatise, presenting the fruit of observations so long continued on a subject apparently so little promising, that great though its scientific value unquestionably is, it is better fitted than nine-tenths of our works of fiction to while away a weary hour. It merits, however, more than mere reading. It is a work not to be tasted merely, but to be chewed and digested.

We shall hereafter return to this work, to consider more at length some of the interesting results of Mr. Darwin's researches.

* "The Formation of Vegetable Mould through the Action of Worms, with Observations on their Habits." By Charles Darwin, LL.D., F.R.S. (London: John Murray, 1881.)

Applications of Electricity.—The public hardly realise, as yet, a tenth part of the uses to which electricity can be readily and conveniently adapted; and exhibitions will furnish the best possible means of rendering them familiar with these uses, which, in many cases, are of an essentially domestic character. Electric bells, for example, although almost universal in large hotels, offices, and public buildings, make way but slowly in private houses, notwithstanding their many advantages. Telephones, in like manner, are far less numerous than they ought to be; and many forms of electrical arrangement quite common in the United States, and found to have great value in saving labour, are scarcely at all in use among ourselves. The electric light is not yet employed in many places for which it is eminently suitable; and its employment is still impeded by difficulties of detail which a larger demand would set aside.—*Times.*

Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

I AM very anxious that Correspondence should become a distinguishing feature of this magazine. I wish all readers to feel that in these columns, including the section for Queries and Replies, they have a means of resolving doubts which may occur to them in scientific study or investigation, when reading articles on science in magazines and journals, and in studying the pages of this magazine itself. Our space will indeed be too limited to permit of our dealing with all such questions as occur to students; so that simple and easily-resolved questions cannot occupy space in these pages, which could be better employed. Those who ask such questions must not be angry if they find a reply in our "Letter Box" couched in very brief terms. Still the wish of myself and others, who will join with me in conducting these columns, will be to leave, if possible, no question unanswered. And as we shall in many cases leave reply to readers who may have special means of information on particular subjects, so also shall we often join the ranks of those who ask questions.

A valued correspondent, who will, I hope and believe, help largely in dealing with difficulties which come into these columns for discussion, advises (see letter 1) that paradoxers should be rigidly excluded at the outset. He has had a very wide experience in this matter; but mine has been even wider, and I must confess to still feeling some tenderness for paradoxers. So many of them have originally been victims of ill-written text-books, difficulties left unexplained, and so forth, that hopeless though the attempt may seem of putting them on the right track, I do not yet feel disposed to give it up entirely in every case. In these pages the honest paradoxer, at any rate, may at least state his difficulties; but space will not be given to him to urge theories in defiance of known facts or established doctrines. I shall venture to ask that even those who are surest of their ground in meeting paradoxers will deal tenderly with these weaker brethren. The paradoxer finds it hard enough to give up a theory which he has, perhaps, nursed for years in the belief that it was legitimate, without being badly ridiculed or harshly rebuked. (*Nescit vox missa reverti;* were it otherwise there are few words of my utterance I would more wish to recall than those in which I have exposed, with unnecessary energy, mistakes which might equally well have been corrected in a gentler manner.)

In more equal arguments, where, perhaps, each party to the discussion has some truth on his side, a greater liveliness of tone may, perhaps, be permissible. Yet, after all, it is nearly always [illegible] who is in error.

On [illegible] to exclude from [illegible] whether [illegible].

HINTS TO CORRESPONDENTS.

1.—Believing as I do [illegible] laid down in your prospectus is a sound one, and that, if it be carried out in its integrity, KNOWLEDGE cannot fail [illegible] before it, I would, with your permission, [illegible] put on record certain ideas of mine in connection with one department of your journal. I mean the "Correspondence Column." I am moved to do this from the consideration that the perusal of the similar portion of such of your contemporaries and predecessors as have had anything like a kindred aim with that which you profess, has led me to the conclusion that of all parts of a scientific paper this is the most apt to degenerate into the weakest, unless a tight hand is kept upon those whose chief glory it is to see themselves in print. Amid many earnest students and seekers after knowledge, whose legitimate thirst for information it should be at once the duty and the privilege of the man of science to gratify, are always to be found men who, under pretence of seeking instruction, will obtrude their own "fads" on the public, and unless restrained in the outset, speedily develop into paradoxers of the most aggravated type. Or again, there are the people who put solemnly on records things which are as "familiar in their (and other peoples') mouths as household words," and who will tell you that two and two make four, as though it were a direct and immediate revelation from Heaven. Furthermore, we have the gentlemen who conceive that anything in the shape of the observation of a phenomenon, no matter in how slipshod a style it is described, must necessarily be of the highest scientific interest. These are the people who write to the papers and say that "while crossing Salisbury plain on Friday night between nine and eleven p.m., I noted a sudden illumination of the sky, which, I have no doubt, proceeded from a falling meteorite; inasmuch as, on turning round, I observed a bright object as big as a good-sized stone just disappearing on the horizon." Or "happening to look at the sun on Monday I could detect two spots on it." I would appeal to any who has studied the quasi-scientific correspondence which appears from time to time in different journals, whether I am caricaturing no inconsiderable part of the letters which, in some occult way, their editors suffer to pass? The people, too, who take counsel on matters of almost purely personal interest, who "have built a greenhouse 8 ft. by 4, and will feel obliged if any of your readers will tell me how to keep it stocked with plants throughout the winter." The youths entering into competitive examinations, who wish to be told how to simplify the fraction $a + \frac{a}{+3}$ and so forth. All these occupy space which should be devoted either to those who have something really to learn or something to teach. The person, though, to be rigidly excluded and forcibly ejected from the pages of every scientific periodical whatsoever is the paradoxer; the man who has sparred the circle with a two-foot rule and a bit of string; who has been down into the Essex marshes with a drainage-level and shown, conclusively, that the earth is as flat as a pancake; or he who, by dividing the number of days in the year by the height of the Lord Hill Monument at Shrewsbury, finds the number 3·1416, and forthwith proclaims that Mr. Haycock, the architect must have been "inspired!"* There is a record, more or less authentic, of a man, that his servant ran up to him in great trepidation, exclaiming, "Oh, sir, there is a bailiff down stairs!" "All right," was the response of the master of the house, "ask him to take a chair." "He has taken six already, sir," replied the servant. Upon a cognate principle I would, in *limine*, try to deprecate the offer of a chair in these pages to any paradoxer whatsoever. Depend upon it, should such be made, it will be found that he has taken his "six already."

I am, Sir, yours, &c.,

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

IS THE SUN HOT?

2.—In your lecture on the Sun we are told that the sun is himself hot, and the source of heat for this earth, just as a fire is the source of heat for a room. Now, I would ask how this can possibly be the case, and I would take the very illustration you employ to show how entirely erroneous is the idea that the sun can be the source of the earth's heat, in the sense, at least, in which you speak. If I

* For an amusing travestie of such reasoning, see "The Tichbone Riddle" further on.—*Ed.* KNOWLEDGE.

draw nearer to a fire in my room, I get more of its heat I find myself warmer. But we know perfectly well that by drawing nearer to the sun we get colder instead of warmer. The tops of lofty mountains are nearer to him than the valleys and the plains which lie around their base. Yet, while it is warm in the valleys and the plains, it is intensely cold at the tops of the mountains so cold that if the mountains are high enough (*and are so much nearer the sun*) the snows never melt there. How can this be if the sun warms the earth as a fire warms a room? Again, if we go up in a balloon, we find that the greater the height to which we ascend the colder is the air.

Indeed, if meteorologists are right in saying, as they do, that the highest clouds, the feathery cirrus clouds, are composed of particles of ice, it becomes simply absurd to maintain that the sun is himself an intensely hot body, for those clouds can be seen on summer days in the full blaze of a solar heat (if that view of his nature were correct). I do not myself understand how meteorologists can have sufficient reason for maintaining that cirrus clouds are composed of ice crystals, unless they believe with me, that the sun is not himself hot (though, of course, he is the source of heat to the earth, acting, I believe, upon the atmosphere in such a way as to generate much heat where the air is dense, and very little where the air is rare); in fact, when I hear the statement made that the cirrus clouds are composed of particles of ice, I recognise another illustration of what I regard as the undue confidence of scientists. They tell us in the same page that cirrus clouds are formed of snow crystals, and (see the accounts of Glaisher's balloon ascents) that even when a balloon is at its highest, the cirrus clouds are still far above, looking no nearer than they appear as seen from the earth's surface. How, then, can the idea that the cirrus clouds are composed of ice crystals be other than a theory, and a very wild theory in my judgment, to be entertained by the very same men of science who believe that the sun is a fire warming the earth?

Although I do not profess to be an astronomer or a meteorologist, I have for many years given great attention to the subject on which I now write; and I have collected together a number of considerations which all tend to show that the solar rays only generate heat when they act in combination with the atmosphere. I would invite readers of KNOWLEDGE to study this question apart from any preconceived ideas they may have, and uninfluenced by the names of so-called authorities in science.

In one respect the theory which I have given above, besides being obviously in better accordance with observed facts than the accepted one (which is, indeed, entirely opposed to them), is much more acceptable to those who recognise the mind of a Supreme Being of infinite wisdom in all the workings of creation. For, observe, if the accepted theory is true, by far the greater part of the sun's rays are wasted. I think Tyndall has stated that more than two thousand millions of rays pass away from the earth for each ray which falls upon it, and that even taking all the planets together, only one ray falls on some planet for two hundred and thirty millions which pass into space and are utterly wasted. Now, what low, and, therefore, what utterly incorrect ideas are given of the great Creator's plans, by a theory which thus tells us that only an exceedingly minute fraction of the work done by the vast orb which He has set to rule and illuminate our solar system is of any use to that system? What should we think of a man who wasted £999 out of an income of £1,000? Yet that would be but a small waste compared with that which scientists assure us is going on in the case of our own sun; and, by parity of reasoning, this waste is repeated millions of times among the millions of solar systems of which astronomers tell us. For my own part, I cannot believe that the picture thus given of the Creator's ways, in the case of these the noblest of the orbs He has made, can be a true one.—I am, sir, yours faithfully, ANTI-GUEBRE.

["Anti-Guebre's" tone is rather dogmatic for one who desires to oppose what he regards as scientific dogmatism. His questions shall not remain unanswered; but we prefer to wait until either he or others who consider the theory of the sun's heat untenable shall have given more of their reasons for want of faith.—ED.]

CAN ICE-YACHTS SAIL FASTER THAN THE WIND?

[3]—I have seen it stated that the American ice-yachts often travel faster than the wind, and I have been told that in the *Newcastle Weekly Chronicle* you have explained that, though before the wind one of these yachts cannot go faster than the wind, which is, indeed, obvious, yet with a beam wind they will go faster than the wind—sometimes twice as fast. Surely there must be some mistake here. Everyone who has considered the usual explanation of the way in which a ship sails with a side wind knows that the driving force exerted by such a wind is but a part—often but a small part—of the driving force which the same wind would exert on a ship sailing directly before it. In determining the effective force of such a wind we first resolve the full force into two—one perpendicular to the sail, the other parallel to the sail; each of these is less than the full force, being represented by the two sides of a right-angled triangle, while the full force is represented by the hypothenuse. The latter of these, the force parallel to the sails, produces no effect. The force perpendicular to the sail is then resolved into two, one perpendicular to the ship's course, which produces only leeway, the other parallel to that course, which is the only part of the wind's force effective in propelling the ship. Each of the two last-named parts is less than the force perpendicular to the sails, which is itself less than the force of the wind. *A fortiori*, the effective propulsive force of a side wind is less than the full force, and must, therefore, produce a smaller velocity; in other words, the ship sails faster before any given wind than on any other course. What is true of a ship sailing at sea must be equally true of a ship sailing on ice. It seems to me, therefore, sheer absurdity to assert that an ice-boat can go faster than the wind, when we know that, sailing before the wind, she can never have a velocity quite equal to that of the wind.

If there is any flaw in this reasoning I should be glad to have it pointed out. UPSILON.

["Upsilon's" difficulty is a very natural one, and his reasoning seems at a first view just. It is, however, incorrect. It is quite true that regarding a ship as at rest, a wind of given velocity cannot exert a more effective influence than that which it produces as a stern wind. But the same is not true when the ship is in motion. If "Upsilon" compares the two cases—an ice-yacht running before the wind at the same rate as the wind, and one running at the same rate with the same wind abeam—he will see that whereas in the former case the wind exerts no driving action at all on the ice-yacht, there still remains in the latter case a driving force; so that unless the frictional resistance balances this force, the velocity of the yacht will increase. I leave this as an exercise for "Upsilon," but if he should find any difficulty with the problem I will give a fuller explanation, with an illustration or two later.—ED.]

THE BIRMINGHAM AND MIDLAND INSTITUTE.

SOME EGOTISTICAL REMINISCENCES, BY W. MATTIEU WILLIAMS.

AN intellectual festival was held in Birmingham on the 20th of last month, when a breakfast party, including the Mayor, his brother, the President of the Board of Trade, Dr. Siemens, and other notables, filled the Town Hall, the guests afterwards making procession to inspect and inaugurate the new extension of the Midland Institute; and in the evening another meeting was held in the Town Hall to distribute prizes to the students, and listen to the thoughtful address of Mr. Siemens on the scientific training of artisans.

This Institute having been established for the purpose of doing for the Midland metropolis nearly the same work as KNOWLEDGE promises to do for all English-speaking peoples, a short sketch of the working progress of the institution by its first teacher cannot be out of place in the first number of this magazine.

In 1854 Birmingham was in a condition of intellectual destitution that to a young native of the present day must be difficult to conceive. A Mechanics' Institution had been tried, and had failed. Various other minor efforts of the same kind had met with the same fate, and the old Philosophical Society that at one time had done honourable work, and was, if I remember rightly, associated in its beginnings with the great Priestley and his friends, was dying of inanition, little remaining but its physical home, at No. 7, Cannon-street. It seemed as though the infamous outrages upon Priestley by the "Church and King" mob had left a blighting curse upon the intellect of the town.

But in spite of this there were a few men of strong faith; there was Arthur Ryland, the now justly recognised father of the Institute; there were Captain Tindal, Sir F. E. Scott, Follet Osler, John Jaffray, William Matthews, and others, who refused to despair, and they united to do something worthy of so important a centre as Birmingham. They held meetings, subscribed money, and induced others to do the like. Charles Dickens gave readings in the Town Hall, which left a clear profit of £339. 16s. A comprehensive scheme was drawn out, including a "General Department," to supply the usual elements of a Literary and Scientific Institution for the well-to-do classes, and a "School of Industrial Science," since named "The Industrial Department," in which should be supplied systematic instruction, including "Chemistry," as applied to the various Manufactures and Agriculture, Mechanics, Metallurgy,

Mineralogy, and Geology, Ventilation of Mines, and Mining Engineering." Besides these, there were to be "Museums common to both Departments," and "arrangements for associating the School of Design with the new Institute."

The first beginning of the practical work of the Institute was the formation of three classes, "Class A, Physics; Class B, Chemistry; and Class C, Physiology." They were conducted by myself in the building of the old Philosophical Society in Cannon-street, where I had already delivered an introductory lecture, and commenced work in October, 1854. Six months later I added to these two junior classes (day and evening) for Elementary Physics, and two "Female Classes" for the same subject applied especially to household matters, and other extensions gradually followed.

The public meetings and general agitation of the subject throughout the town brought many students, who began with the enthusiasm of novelty, and held on for awhile, especially in the Chemistry Class, where the first twenty lectures devoted to the metalloids, and including the brilliant combustion experiments, seldom failed to comply with Brande's formula for a successful chemical lecture, "a flash, a bang, and a stink." When, however, we came to the common metals and their prosaic salts, there was a sad falling-off, in spite of the local importance of the subject.

This alarmed the Council, but being behind the scenes myself, I understood it. Presently, however, some truly alarming symptoms appeared. I found that we were exhausting our material, that the whole population of Birmingham only contained a very limited number of artisans and others who could appreciate the advantages and the pleasure of systematic study of science; that we had already nearly satisfied their limited demand, and that the rate of growth of a new generation of students was ruinously slow. The further I extended my inquiries and the greater the efforts made by the best men in our Council to recruit the classes, the more clearly and seriously was the difficulty presented.

What was to be done? Must we follow the too common example of substituting clap-trap for sound instruction in order to maintain an appearance of success, or should we stand firmly by our original intent and continue to supply solid instruction even to a beggarly number of students? Mr. Ryland, the majority of the Council, and myself agreed in choosing the latter alternative, but in spite of this it was evident that the Institution had arrived at a very critical stage of its existence, and my anxiety was considerable, having been so continually warned by "practical" men that "this sort of thing" had been tried again and again in Birmingham, and had always failed in the long run, however promisingly it may have begun.

The time had now arrived for proposing a scheme that I had been considering for some time past, and, accordingly, on one of my Sunday afternoon visits to Mr. Ryland, I laid before him the project of superadding to our regular courses of solid instruction occasional single lectures of a very popular introductory character, which anybody, however ignorant, might attend, and thus possibly be cured of the common mental epidemic of supposing that science is necessarily dry and repulsive, and ultimately be tempted to become students in the classes.

Mr. Ryland cordially approved, and we anxiously discussed the question of free admission, or a small charge of twopence, or threepence, or one penny at the doors, and finally decided on ONE PENNY. Mr. Ryland suggested the name, PENNY LECTURES, then a new one, as "Penny Readings" were yet unknown. He laid the project before the Council. It was adopted, and on Jan. 22, 1856, I commenced the first course of twelve penny lectures, the printed prospectus of which is now before me.

It was a general outline of natural phenomena, taking in what is now commonly taught as "Physiography." The success of the experiment was complete; the theatre was filled—at some of the lectures not only the seats were all occupied, but the platform was covered with a standing audience. The course was repeated "by special desire," and thenceforth, until I left Birmingham in 1864, I continued them every Tuesday during the session, with an occasional break, when Mr. George Dawson, or others, volunteered to occupy an evening. The subjects were various, in many cases determined by the limited stock of apparatus then within my reach, as, without ample demonstration, success was impossible. My object was to make the lectures as attractive and as *unsatisfactory* as possible, to awaken curiosity, but not to satisfy it there.

They had the desired effect. All classes of people, and of all ages attended them, the little boys in the front row being especially conspicuous. The classes steadily improved, instead of declining, as heretofore, and I am able to prove how they were fed by the statements of some of my best pupils, who told me how they were tempted to have a pen'orth on passing, then another, then to go every Tuesday, and finally to become what I then found them to be. If space permitted I could state some interesting personal details, among others, of the case of two notorious Birmingham burglars who regularly attended the Penny Lectures until the force of professional circumstances terminated their studies; of other Penny Lecture auditors who now stand well as scientific and technological experts and teachers of science; and how, through Isaac Smith, one of my most enthusiastic penny and class pupils, his uncle, Sir Josiah Mason, was induced to become the munificent founder of the "Mason College," which is doing for those who can afford to study during the day, what the Institute does for evening pupils.

Penny Readings followed the Penny Lectures, as the first initiation of the Literary Classes, and the highly successful Penny Arithmetic Lessons, by Mr. Rickard, revived the mathematical department, which, at about the date of the first Penny Lectures, had declined so seriously that an attendance of three, two, and even only one pupil was not uncommon in the Algebra Class. The present prosperity of the Institute is largely due to the remarkable energy and ability of Mr. Rickard, who proves himself a true teacher by throwing as much effort, earnestness, and enthusiasm into the simplification of simple addition as in the exposition of quaternions or the differential calculus.

When I left Birmingham the Council wisely appointed as my successor, both in the classes and the penny lectures, Mr. C. J. Woodward, who had proved the value of the Institute by first hearing a penny lecture, then entering the classes and gaining the Society of Arts gold medal while yet very young. He still works with untiring zeal and ability, and that simple-minded love of his work that is so contagious to pupils. His extended chemical laboratory and new physical laboratory are so commodious that they rival those of our great universities. A staff of able teachers has followed, and are now working admirably. In the general glorification of founders, patrons, &c., which justly occupied the recent meeting, there was a serious omission, viz., to do honour to the labours of such men as W. Matthews, George Dawson, Sam. Timmins, Dr. Badham, and others, who worked as unpaid volunteers in the pioneer labour of teaching classes when the Institute was too poor to pay professional teachers. The Institute now counts 2,688 students in the industrial department, against the 85 with whom I commenced, and 2,564 members in the general department. It has branches and affiliated institutions in every important suburb of Birmingham. Besides these, there is an "Institute Scientific Society," where original papers are read and discussed, and possessing a good lending library of scientific books; also a "Union of Institute Teachers and Students," for promoting the welfare of the Industrial department.

These, with the unrivalled Board schools, the King Edward's school and its branches, the great free library and public reading rooms and the Mason College, are effecting a wonderful transformation of the hardware metropolis, which will probably render it the most intellectual town in England.

I must not touch upon what may be termed the external history of the Institute, the visit of the great and good Prince Consort to lay the foundation stone of the building, and the many other public incidents connected with its growth; these will be duly recorded in "The Institute Book of Glory," promised by the hon. secretary; but I cannot conclude without a word or two respecting the analogy before-named between the work of the Midland Institute and that of KNOWLEDGE.

If Mr. Proctor were just emerging from Cambridge in the full-blown pride of newly-acquired Academical honours, I should despair of the success of this important effort to diffuse scientific knowledge among all classes of men, women, and children; but learning by the prospectus lately placed in my hands that he has been taking lessons from his own pupils, I have no doubt that he will successfully apply them.

Had I commenced as an Academical purist, with a cut-and-dried course of instruction framed on academical lines, the first classes of the Birmingham and Midland Institute would have failed, with serious consequences to the whole project. In like manner any attempt to popularise science by presenting to non-technical readers mere technical abstracts of technical papers or essays, must of necessity fail again, as it has failed before.

As an example, I may mention the fact that in my first Physics class not one of about forty students, mostly adults, knew what was a parallelogram or a diagonal. How, then, could I teach them the composition and resolution of forces? Such questions I had to ask and solve continually, and though I have not seen Mr. Proctor since his return from the Antipodes, I have no doubt that, during his lecture tours, similar questions have been thrust upon him, and that he has found answers for them, and will proceed accordingly.

The translation of the Latin word "Science" into plain Saxon "Knowledge" is a good beginning, and as Science, thus translated, is the natural food of the intellect of all human beings, there can be little doubt of the success of a well-conducted, non-pedantic (or, I would rather say, anti-pedantic) effort to supply the natural demand.

COLOUR OF SUNLIGHT.

PROFESSOR LANGLEY threw out, several years ago, the idea that our sun is in reality not a white sun, but a blue one, his apparent whiteness being due partly to the absorptive action of his own atmosphere, but partly to that of our own air. It should be noticed, in considering this view, that our sun is probably akin to the stars which we regard as yellowish. Capella, for instance, is decidedly yellow by comparison with Vega. The spectrum of Capella has been shown by Dr. Henry Draper to be so similar to that of the sun that the eye can detect no difference. Arcturus, which is somewhat more markedly yellow and, indeed, is regarded by some as orange-yellow in colour has a spectrum very closely resembling that of the sun, but still not exactly the same. The great value of Dr. Draper's evidence on this point, like that of his evidence respecting the presence of oxygen in the sun (as shown by the comparison of the solar spectrum with that of our own air), is that it can be studied by all who choose to examine the photographs which he has obtained of the spectra for comparison. On the same small piece of glass are shown the spectrum of Capella and the spectrum of sunlight reflected from the surface of a planet, and the identity of the lines belonging to the two spectra can be seen at once. Now, Professor Langley, pursuing the idea which he threw out several years since, has been able to show that our sun, though we regard him as a white sun, and though, seen from a greater distance, so that he appeared as a star, he would probably appear yellowish, is yet a blue, or at least a bluish sun. We see that the sun appears red, or orange, or yellow (according to the state of the air) when setting—that is, when seen through a long range of our own atmosphere. Such action as our air exerts on the sun when he is high above the horizon is similar in character, though less in degree; it serves, therefore, *pro tanto*, to render the disc of the sun yellower than it really is. Again, the edge of the sun's disc is markedly less luminous than the middle, though to ordinary eyesight the difference is generally rendered undiscernible by the sun's great lustre. Of course, in reality the same amount of light is emitted from that part of the solar surface which at any moment lies near the edge of his visible disc as from that part which lies near the centre. The apparent difference can only be due to the effect of absorption exerted by the solar atmosphere—the line of sight passing through a greater range of this atmosphere when directed toward the edge than when directed toward the middle of the disc. (In passing, I may note that the difference of absorptive action is proof, not, as Kirchoff erroneously supposed, of the depth, but of the relative shallowness of the solar atmosphere.) Now, anyone who studies a photograph of the solar disc—as, for instance, that excellent photograph by Rutherford, which forms the frontispiece of Schiller's German translation of "Le Soliel"—will have noticed that the darkening toward the edge is much more marked there than it is in the ordinary telescopic disc of the sun. It follows that those rays which produce the photographic image of the sun (chiefly the blue, indigo, and violet rays) are more affected by the absorption of the solar atmosphere than those which form the ordinary visual image of the sun. His atmosphere then acts more strongly to absorb the rays belonging to the blue end of the spectrum than the rays belonging to the red end. The sun's apparent colour, therefore, is less blue than his real colour. If his atmosphere were suddenly removed, he would change from his present white or whitish-yellow colour to bluish, or perhaps greenish, precisely as the setting sun, if the air between the eye and him were suddenly removed, would change from his apparently ruddy hue to the white colour of the overhead sun. In this way it has been, only by detailed experiments instead of by general reasoning, that Professor Langley has established the theory that our sun is really blue, his apparent colour being due to the effect of absorption exerted by his atmosphere of vapours, chiefly metallic.

THE *TRIBUNE* RIDDLE.

THE mystery of the *Tribune* Building* has long baffled the investigations of our most learned archæologists. Putting aside as unworthy of consideration certain wild theories of its purpose, there remain three leading theories, each one of which has its able advocates. By these we are told that the building was designed either for a tomb, or for religious purposes, or for an astronomical observatory.

The first of these rests on a comparatively slight foundation. The most elaborate research has failed to show that there is anything buried beneath the *Tribune* Building, except beer.

* The office of the New York *Tribune*.

The carefully [illegible] written by Prof. Veranda Brown in support of the theory that the *Tribune* Building represents the history of the Jewish and Christian religions, and contains a precious prophecy as to the future religious belief of mankind, has a certain degree of plausibility which will always commend itself to imaginative men. As is well known, the plan of the building is unlike that of any other architectural work, in the curious and arbitrary way in which it is divided into different stories. The lower part consists of four stories and a basement. According to Prof. Brown, this basement represents the patriarchal period before the time of Moses, and the four stories represent the Jewish nation under Moses, under the Prophets, under the Kings, and under the Roman Empire. The last story is smaller than the others, thus typifying the declining condition of the Jewish state, and the marble capitals of its pilasters indicate the luxury and splendour of the Roman Empire. Above the Jewish division of the building we find a second series of three stories, representing the first three centuries of the Christian era. The uppermost one of these is gorgeously ornamented with polished granite columns, with Byzantine capitals—constituting an unmistakable reference to the conversion of CONSTANTINE, the fixing of his capital at Byzantium, and the triumph of the Christian religion. Next we find three more stories, each containing five windows. These typify the fifteen centuries which have elapsed since the conversion of CONSTANTINE, and bring the record of the Jewish and Christian religions down to the present time.

Where the seventh story, or the third century of our era, begins, the façade of the *Tribune* Building is divided into two large masses, one being precisely twice the width of the other. These undoubtedly represent the division of the Christian world into the two great Churches—the Latin and the Greek—the beginning of which division really dates back to the rivalry between the Bishops of Rome and Constantinople. Between these two great divisions rises the tower—a quadrangular structure, with clear-cut angles, and standing boldly out into the light. In this tower we recognise Protestantism. Smaller in size than either of the two great divisions that represent the Latin and Greek Churches, it reaches nearer heaven, and secures a greater share of both sunlight and clouds.

The upper part of the tower is, in Prof. Veranda Brown's opinion, prophetic in its teaching. Both the tendency of Protestantism to bring all things to the bar of reason, and the refusal of any two Protestant bodies to agree in their views of what is true, are prefigured by the clock which occupies the upper part of the tower, with its four faces that so stubbornly refuse to make the same profession of faith as to the time. Still higher than the clock we find the lightning-rod. There the tower has reached its fullest development—ending in a point—signifying "nothing," and a lightning-rod, of all things the most thoroughly scientific and materialistic. Prof. Verandah Brown, who is a pure rationalist, accepts with some scientific enthusiasm this architectural prophecy of the fate of Protestantism.

The astronomical theory of the building is ably advocated by Prof. Pritchard Roctor. He maintains that had the builders intended to erect an astronomical observatory, they would have designed a building which should have been both massive and high. Both of these conditions are found in the *Tribune* building. They would also have constructed a long, narrow tube of masonry through which to observe the stars. We find precisely such a tube in the *Tribune* Building, although the ignorance of the present day has perverted it to the use of an elevator. They would also, says the Professor, have constructed a subterranean chamber as a receptacle for water. The *Tribune* builders builded even better than the Professor knew, for they made a large subterranean chamber for the reception—not of water, but of beer. From these considerations he draws the conclusion that the *Tribune* Building was designed for astronomical purposes, and incidentally remarks that the arguments of Professor Veranda Brown are fallacious, inasmuch as he forgot to include the coal-cellar in his calculations, and the coal-cellar cannot possibly be brought into any intelligible relation with the Jewish commonwealth.—*New York Times*.

ULTIMATE STRUCTURE OF BODIES.—"As matters now stand," says Mr. H. C. Sorby, "we are about as far from a knowledge (by vision) of the ultimate structure of organic bodies as we should be of a newspaper seen with the naked eye at a distance of one-third of a mile."

Our Mathematical Column.

MATHEMATICAL columns in magazines are too apt to degenerate into puzzledom corners, collections of problems of considerable difficulty, but having no real interest, and not valuable as illustrating principles. We wish ours to be of real use to the student of mathematics, but still more to those who, when studying other branches of science, find that rightly to understand their subject they require to be familiar with certain special departments of mathematics. It must be confessed that most of our treatises on mathematical subjects pay little attention to the requirements of students of this kind. They are excellently adapted to prepare students for examination; because at an examination a student of algebra must not be surprised if he be asked questions relating to infinite series, a student of trigonometry if he be asked to establish Dr. Moivre's Theorem, and so forth. But they do not meet the wants of one who requires to know the methods and principles of algebraical, trigonometrical, or other forms of calculation. There is little in such works to show the *use and value* of the processes considered in them. Many a ready student has passed a fair examination in the differential calculus, who had not the remotest idea of the practical value of its methods, or that in hundreds of simple subjects of inquiry the calculus can be employed easily and advantageously. There is no occasion for mystery respecting the use of mathematical methods; but it would really seem, to read some mathematical treatises, as though the last idea in the world the student should associate with any mathematical subject was the idea that it may actually be useful. Even the problems which are given for solution are, for the most part, either useless or absurd.

This is not the way to render mathematical subjects inviting, or to encourage the student to master the difficulties which are inherent in them.

Of course, we cannot here give mathematical essays which can render the student independent of systematic treatises. Such treatises he must have, and must carefully study. But we hope to show that a number of departments of mathematical research, supposed to be either too profound, or of too little practical value to be worth taking up, can be readily and usefully studied. In every case we wish to come as quickly as possible to the practical application of the various methods we shall successively deal with.

We shall probably begin with a simple paper on the use of logarithms, seeking to show that, instead of being regarded as a mere mysterious collection of numerals, a book of logarithms should be considered the great simplifier of all forms of calculation. Scarcely anyone who has much to deal with figures, otherwise than in mere processes of addition or subtraction, should be without such a book; and a very brief study of the subject will suffice to enable anyone to make ready and intelligent use of the tables which a book of logarithms contains.

We may then discuss the Laws of Chance, the simple applications of Trigonometry, and other such matters, avoiding, as far as possible, those parts of a subject which a student can readily study in set treatises.

We shall be glad to receive problems of interest, either for solution or discussion, preferring, however, those which illustrate general principles to those which are merely, as it were, casual.

In many cases where problems are sent to us for solution, we shall only give hints, not complete solutions, believing that, so dealt with, they are likely to be of more use to the student than if a complete solution were at once given.

We need hardly say that this is not a suitable place for the discussion of very difficult mathematical problems, albeit those of our readers who do not take interest in mathematics must not be angry with us if from time to time we devote a column, or even a page or two, to matters of no interest, or even absolutely unintelligible to them. They must remember that each of our lighter essays here may be equally interesting to proficients in the subject dealt with; that, in fact, no one can expect *all* the contents of such a journal as the present to be interesting to himself individually. We shall endeavour, however, to keep within close limits all matter likely to be "caviare to the general."

SUNLIGHT AND HEAT.—The intensity of sunlight at the sun's surface is calculated to be 190,000 times that of a candle-flame; 5,300 times that of the glowing metal in a Bessemer converter; 146 times that of the limelight; 3·4 times that of the electric arc at the brightest yet obtained. The heat emitted by the sun in a single second would suffice to melt a shell of ice covering the entire surface of the earth to a depth of 1 mile 1,457 yards, or to burn a layer of anthracite coal 17·7 yards thick over the earth's entire surface. This would be equivalent to a consumption of about 16,436 millions of millions of tons of such coal per second.

Our Chess Column.

MANY weekly and monthly periodicals in this country and in others now contain a chess column, but it may be a question how far any general knowledge of the game is encouraged in this way. Usually these chess contributions are limited to problems, games between first-class proficients, and replies to queries, with occasional items of chess news. The problems are such as only good players can readily solve, so that the learner, unable to master them without an expenditure of time which he can ill spare, is rather deterred from the study of chess than otherwise by these masterpieces of chess strategy. The games, again, even when they are sufficiently annotated, are generally too profound to have much interest for the learner. He cannot see the purpose of moves whose real significance depends generally on results five or six moves at least in advance, and almost always on moves which are not played on either side. The chess expert recognises the beautiful positions, the brilliant attacks, the complex defences, and so forth, which would result if a particular move were not met in that way in which, in the game itself, it actually is met. A volume would be required to show all such results of each move played on either side by two first-class players; and the beauty of a game between two such players can only be properly appreciated by those who, as each move is played, can follow out the various consequences, according to the way in which the move may be met.

We wish to cater for a wider circle of chess players—for those who enjoy the game and can appreciate its beauties, while they have no ambition to be able to meet a Steinitz, a Blackburne, or a Zukertort without receiving odds.

It must be admitted that nine out of ten who call themselves chess-players know very little about the game. They move their pieces without any adequate idea of the value of position, or of the manner in which the powers of the various pieces can best be brought out. Of the importance of time, again, in chess strategy, they seem to have scarcely any conception. A player of this class will move his Queen out to some square where she can be attacked by a piece which in attacking her will take up a strong position, then to some other square where she can be similarly attacked by another piece, and, perhaps, after four or five such moves, be fortunate in being able to return her to her own square. He will then complacently remark that he must try some other way of opening his attack, utterly overlooking the fact that his opponent has gained four or five moves, and that even a single move early in the game often makes all the difference between a strong attack and an unsatisfactory defence. If such a player moves his Knight from King's Bishop's third to King's Knight's fifth, and on the opponent moving Pawn to King's Rook's third (attacking the Knight), finds no better move than to return him to his former position, he would be incredulous if told that he had thus lost all chance of winning against correct play. Yet there is scarcely an imaginable case, in the early stage of a game, where, if the game had been equal before this had happened, it would not afterwards have been seriously compromised. The opponent, be it observed, has made a move of great utility (though often too slow, except as in this case when a move is given away), while it is now his turn to play instead of the first player's, who stands just where he did before he rashly moved forth his Knight. (The opening, of which the accompanying game is an illustration, shows that, even when by venturing forth the Knight to the square in question a Pawn is gained, the counter attack, after the Knight has been driven back, compensates the second player fully for the loss. It also presents at move 33, a case in which loss of time is equivalent to loss of a game which might probably have been drawn.)

It seems to us that we may do something to encourage sound chess play by giving our readers chess material of a different kind from that which has usually been presented in chess columns. We propose to explain in a series of short papers the principal openings, discussing their advantages for attack and defence, and showing how the opening moves illustrate the general principles on which sound play depends. We shall illustrate these openings by games played by good players, but not played with quite so much study (and, therefore, not needing such skill for their interpretation) as the match games commonly selected for these columns. For this purpose we have made arrangements with the proprietor of the mechanical chess-player, Mephisto, to have games played with Mephisto specially for our chess columns. By an extension of Mr. Gümpel's kindness, the guiding spirit of that mysterious player has been persuaded to make his own comments on the game. It need hardly be said that only such games will be selected as have real chess interest. The multitudinous contests in which tyros have succumbed to Mephisto (and would have succeeded at the odds of a Queen) would be quite as much out of place here as in the

columns of the *Chess Chronicle*, humbler though our aim may seem.

We shall assume on the part of our readers a knowledge of the elements of chess play—the moves, laws, and so forth; and sufficient familiarity with the notation employed by English-speaking players, according to which the King (K.), the Queen (Q.), the Bishops (K.B. and Q.B.), the Knights (K.Kn. and Q.Kn.), and the Rooks (K.R. and Q.R.) are regarded as standing severally on the first square of a file, the other squares of which are numbered in order, the 2nd, 3rd, 4th, 5th, 6th, 7th, and 8th.

For our chess readers' amusement we give an illustration of weak chess play, which occurred within the last few days over our own chess-board. The first player had the idea that, knowing little of the usual openings, he might equalise matters by playing on a line entirely unrecognised by the books:—

MEPHISTO'S NOTES.

(a) This move constitutes the Two Knights' Defence.

(b) This move gives White if not a bad, at least a difficult, game to play; the continuation 6.B. to Kt.5. (ch.) is to be preferred.

(c) This move is stronger than the usual move P. to K.R.3 White threatens an attack with his Pawns on the hostile Bishop, thereby developing also his strong Queen's wing. P. to B.3. also provides a refuge for White's Knight on Q.4. in case Black should Castle, which would leave the Knight *en prise*.

(d) This certainly seems the most attacking line of play, in addition to which Black could also play P. to Q.R.4. to prevent the advance of the Queen's Pawns or P. to Q.Kt.4., or Castles.

(e) This is better than B. to R.4., which would result to the advantage of White, *e.g.* 11. $\frac{}{\text{B to R.4.}}$ 12. $\frac{\text{P. to K Kt.4.}}{\text{B. to Kt.3.}}$ 13. $\frac{\text{Kt. to K.5.}}{}$ with the better game.

(f) Threatening to win the Queen.

(g) This is the right move to stop any advance of the Black King's Pawn. Thus, for instance, 15. $\frac{\text{P. to Q B.5}}{}$ instead, would not be good; for 15. $\frac{\text{P. to Q.B.5}}{\text{P. to K.6}}$ 16. $\frac{\text{B. takes P.}}{\text{B. takes K.B.P.}}$ with the better game. White could not take the Bishop, for then Black would win his Queen by P. takes P. (ch.).

(h) Black has played P. to Q.R.4, with the intention of breaking up the Pawns on White's Queen's wing. If instead of P. takes P., as actually occurred, White should play P. to Kt.5, then P. to Kt.3 would stop White's Queen's Pawns. Black might, perhaps, also reply with P. to B.3. The variations arising out of this move are very numerous. The idea is the same as in 15. $\frac{}{\text{P. to Q R.4,}}$ namely to separate White's Pawns, and then attack them singly, *e.g.*:—

16. $\frac{\text{P. to Kt. 5}}{\text{P. to B. 3}}$ 17. $\frac{\text{P. to B.5 (or see A)}}{\text{B. to Kt. sq.}}$ 18. $\frac{\text{P. to K.6}}{\text{P. takes P.}}$

19. $\frac{\text{Q. takes P.}}{\text{Q. to Q.2}}$ 20. $\frac{\text{Q. takes Q.}}{\text{Kt. takes Q.}}$ 21. $\frac{\text{Kt. to Q.2}}{\text{B. to R.2}}$ 22. $\frac{\text{Kt. to Kt. 3}}{\text{P. to R.5}}$ with the better game.

A. It would be disadvantageous to take with the Queen's Pawn, thereby opening the file commanded by the Black Queen; therefore, 17.] $\frac{\text{Kt.P. takes P.}}{\text{P. takes P.}}$ If now White should play P. takes P., then Q. to B.2 would give Black a very good game, or if White should play, 18. $\frac{\text{P. to B.5}}{\text{B. to Kt.sq.}}$ 19. $\frac{\text{P. to Q.6}}{\text{B. to Kt.2}}$ 20. $\frac{\text{Kt. to Q 2}}{\text{Q. to B.sq.}}$ with the object of playing Q. to B.4, followed, perhaps, by Kt. to Q.2., Black should again get a good game.

(i) Threatening the capture of the Knight.

(j) By 19 Castles, White thought to evade Black's attack on the Queen's side, but only to exchange it for an attack on the King's side, the chance of which Black at once follows up by Q. to B.sq.

(k) White hopes to be compensated by his attack of R. to K.7 for this move.

(l) This is loss of time, as Black thereby advances his Pawns in support of the Bishop's Pawn. White cannot venture upon anything for fear of P. to B.7; if K. to K.3, then Black wins the White King's Pawn by Kt. to K.5 (ch.)! therefore, 33 R. to K.B.sq. at once was White's best play.

(m) This is hardly necessary; the object was to make the Rook available for support of the other Rook via R. to R. sq.

(n) This is weak again. R. to B.7 would have given White a good game; for, in reply to $\frac{}{\text{R. to B.4,}}$ White would play K. to Kt.3 with a fair chance of drawing.

(o) Black threatens to Queen his Pawn by P. to Kt.7 (ch.), which White cannot prevent.

KNOWLEDGE AND IGNORANCE.

"Ignorance is the curse of God,
Knowledge the wing on which we fly to Heaven."

THE PHILOSOPHY OF ANIMAL COLOURS.

By Dr. Andrew Wilson, F.R.S.E.

THERE is a suggestive passage in Butler's "Hudibras," which maintains that—

> "Fools are known by looking wise,
> As men find woodcocks by their eyes."

And if the axiom be correct, that a poet is only great when he is true to nature, it must be admitted that Butler has been singularly felicitous in this metaphor. Whoever has seen a woodcock in its ordinary summer plumage may form a good idea of the truth of the poetic remark. As that bird moves about amongst the fallen leaves of autumn, the greys, and browns, and yellows of its feathers mingle so beautifully with the like tints of its surroundings, that the animal is absolutely concealed from any view but the practised eye of the sportsman. As has been remarked of the bird in question, even the very conspicuous and ornamental tail becomes hidden from view in a most singular fashion. Below, these tail-feathers exhibit a white colour tinted with a silver sheen and marked with a deep black. Nothing more conspicuous than such an ornament can well be imagined; yet the tail and its belongings are, nevertheless, wonderfully concealed. For, as the bird reposes, these under lines and tints are placed downwards; and above, the ashen-grey tints mingle perfectly with the bird's surroundings. As the woodcock, therefore, rests amid its background of wood and its foreground of fallen leaves, every line of its plumage is made to assimilate so closely with the objects around, that the bird's presence, even a short distance off, is not suspected.

The woodcock is by no means alone in this harmony betwixt its plumage and its surroundings. The sand-grouse of the deserts, for instance, exhibit a like harmony. These birds cannot be detected, even as they run, amidst the sand of their haunts—so closely imitated in the dull tints of their plumage is the tone of the desert wild. The well-known case of the ptarmigan is even more extraordinary still. In summer the bird shows a plumage of pearly grey, which conceals it perfectly as it lies on its bed of Scottish heather, mingled with the lichen and its kith and kin. But when the winter snows descend and coat the hillsides with a mantle of white, then a kindly nature still contrives concealment for the ptarmigan in a fresh suit of colour. The pearly greys of the summer are replaced by a plumage of snowy whiteness, and, save for its dark eye, there is little risk of the discovery of the bird by the unwary or unpractised sportsman. The grouse and common partridge are not less perfectly protected. The hues of the grouse match the tints of the heather, and the partridge is almost as difficult to discover—say, in a ploughed field—as the ptarmigan on the hill-side. The birds just mentioned are all *rasorial* birds; that is, they are allied to the type of the common fowl, and are typically ground-livers. Their tints, therefore, assimilate with those of the ground and with ground vegetation; and whatever may be the ultimate philosophy which shows the origin of such harmonies, it is very plain that the utilitarian is bound to read "protection" in every line of the story. Escape from their enemies must be favoured by the correspondence in colour to which we allude. The harmonies of colour present the safest, and therefore the best foil, to the keenness of sight of the eagle, and to the agility of the falcon and its kind. It is different, indeed, with the songsters of the wood and grove. With well-developed powers of flight, and with a close refuge amid the foliage of the wood, the appearance of bright hues and tints in these birds is by no means disadvantageous. Another law—that of the development of colour in relation to sex—has taken precedence of the regulation of colour as a means of protection. If concealment be necessary, nature will teach the art of hiding in other ways than that whereby she contrives to make the partridge face danger with a stillness that almost rivals that of the stones, trustful in the harmony of her plumage that so closely matches her heather bed.

But there are wider fields open to the naturalist's survey of colour and its meanings. Suppose that we peer for a moment into the class of fishes, we shall find the adaptation of colour to surroundings illustrated in a very apt degree. Whoever has tried to spear a sole or flounder, for example, well knows that the excitement of the sport consists in the endeavour to follow out the axiom of Mrs. Glasse, and on the principle which that worthy lady laid down about "first catching your hare," to first catch your flounder. You cautiously and softly paddle out to shallow water in your punt, and you drift over the flat, sandy beach at a depth of from two to three feet. Below, the water is as clear as crystal. Here and there you see a lazy starfish on the march, exerting himself to the utmost, as he slowly extends ray after ray, and crawls at the rate of about a mile a month or so, by aid of his hundreds of sucker-feet. The sand-eels annoy you as they burrow downwards and send up little clouds of dust on your approach; but the flounders you came to spear—where are they? and echo seems but to answer "Where?" But the practised sportsman bids you learn (as in all other sciences and arts) the first lesson—namely, how to see and observe. As your boat creeps along, he points to what seems a mere sandy lump, but in which his keener eye has detected the merest wriggle of a fin. Dash! goes the spear, and up comes a flounder, and as you watch the ground, you see dozens, it may be, of similar sandy patches swimming off in rapid alarm. The flounder's "back"—it is really the *side* of the fish—on which it lies, is white enough, as we know; but the "other side" is as close a representation of a sandy patch as you can see or as you can imagine. Small wonder, then, that in flounder-spearing you experience the difficulties which nature throws in the way of capture through likeness in colour to the animal's surroundings. It is the same with sole, turbot, and with the skates and angel-fishes. Watch the

first flounder you see resting on the sandy bed of the Aquarium tank, and you will receive ample proof of the truth of the foregoing remarks. And should you chance to see the lazy "monk," or angel-fish, as it lies prone, heavy, and indolent in the highest degree in the flow of its tank, you may again understand something of the value of colour as a means of protection to animal life.

In the case of those "queer fishes," the little sea-horses, or hippocampi, with heads like horses, and with a body which, at large, reminds one most forcibly of some figure from the Heralds' College on a crest, concealment is effected in a slightly different fashion from that prevalent among the soles. Here the body, as a rule, possesses long streamers or fringes that mimic the seaweeds; so that, as the animal reposes, its body may well enough represent a stone, to which are attached fragments of marine vegetation. The Australian sea-horses, which live among red seaweeds, have streamers of that hue attached to their bodies, and the mimicry and imitation of their surroundings are thus very complete. Even their near neighbours, the pipe-fishes, with green bodies, when they fasten themselves to some fixed object, and "loll" in the water, may closely resemble an inert piece of green weed.

Amongst even the highest animals, protective colouring is common. A lion's hue matches the sand, as a tiger's stripes, according to Mr. Wallace, imitate very closely the foliage and trees amidst which it crouches. The camel's coat is sandy like its desert; and the rabbits offer as plain examples as any of the colour harmony in question. The polar bear is white, like the arctic fox in winter dress; and the nocturnal rats and moles are dressed in shades the opposite of the ghost-like hues that become so conspicuous at night.

THE SOUTH EUROPEAN VOLCANIC SYSTEM.

THERE are reasons for believing that all the volcanoes—and, indeed, all the regions of subterranean disturbance in Southern Europe—belong to a single volcanic system.

It is, indeed, rather difficult to define the exact relation between the different parts of a widely-extended volcanic region. At a first view it seems unreasonable to assert that if eruptions or other forms of disturbance in different places are simultaneous, this must be regarded as evidence that the two places belong to the same volcanian region, while a similar conclusion should be deduced from the fact that quiescence in one spot synchronises with disturbance in another, and *vice versâ*. For instance, it was noticed that during the often interrupted eruption of Vesuvius in 1868, Etna was more or less disturbed, until at length, as if in sympathy with the Neapolitan volcano, the Sicilian mountain gave vent to enormous streams of molten matter; and this of itself might be considered to afford satisfactory evidence of the existence of some sort of connection between Etna and Vesuvius. But on the other hand, we are told that when the great earthquake of Calabria took place early in 1783, the inhabitants of Pizzo remarked that the volcano of Stromboli, which is in full view of Pizzo at a distance of about fifty miles, smoked less and threw up a less quantity of heated matter than it had done for several preceding years. Then, again, on the same occasion the great crater of Etna gave out enormous quantities of vapour as the Calabrian earthquake began, while Stromboli seemed exceptionally active as the commotion of the earth in Calabria began to diminish; yet no eruption occurred from either of those great vents during the whole progress of the Calabrian earthquakes. Are we to infer from this, as in one place Sir C. Lyell seems to do, that the volcanic fires of Etna and Stromboli are "very independent of each other," or that the same mutual relation exists between them as between Vesuvius and the volcanoes of the Phlegræan Fields and Ischia, "a violent disturbance in one district serving as a safety-valve to the other?" Lyell completes the latter sentence, by the way, by adding, "both never being in full activity at once." But here it seems to us he loses the full value of the evidence which the various disturbances of the South European volcanic regions have afforded. Rightly viewed, both forms of evidence equally tend to show the inter-dependence, neither showing the independence, of different parts of this great region. If an eruption of Vesuvius begins precisely when an eruption of Etna seems for some cause or other to be checked, or diminished in activity, the circumstance seems in itself to suggest, if it does not prove, that the two vents serve to relieve one and the same volcanic region. If, again, Vesuvius and Etna both burst suddenly into violent eruption at one and the same time, surely that also is evidence that they belong to the same volcanian system.

There is no reason whatever for assuming that because a disturbance in one region may serve as a safety-valve for another, therefore both can never be in full activity at once. Experience has shown repeatedly that two regions of volcanic disturbance, the movements of which sometimes alternate, may at other times be simultaneously active.

But it may perhaps be asked, if this really is so, how can we possibly decide whether any two volcanian regions whatever are connected or distinct? For instance, when Chimborazo is active, Vesuvius is either active or at rest. If Vesuvius is active, the two vents may be said to be working simultaneously; and so the preposterous idea may be adopted that these two volcanoes, though separated by so many thousands of miles, relieve the same region of subterranean disturbance. If, on the other hand, when Chimborazo is active, Vesuvius is at rest, then the same absurd conclusion is derived from the consideration that the action of Chimborazo alternates with that of Vesuvius. In reality, however, plausible though this objection seems, it has no weight. The distinction between the simultaneity or the reverse of the action of Vesuvius and that of Chimborazo, and the associated or alternated efforts by which Vesuvius and Etna, or Etna and Stromboli, or Vesuvius and the Phlegræan Fields, relieve one and the same region of subterranean disturbance, is sufficiently well marked. Compare the dates of the eruptions of Chimborazo and Vesuvius with the actual range of time over which the observations extend, and no connection whatever can be observed between them. Vesuvius must, indeed, be either quiescent or at rest when Chimborazo is in eruption, but Vesuvius never (or only by the merest accident) begins to be disturbed when an eruption of Chimborazo commences; nor has an eruption of Chimborazo ever synchronised, except by the merest accident, with the cessation of an eruption of Vesuvius, or *vice versâ*. But whether we find that an eruption of Vesuvius ceases very soon after an eruption of Etna has begun, or that both volcanoes burst at once, or nearly at once, into eruption, the coincidence of contrasted conditions implies equally with the coincidence of similar conditions, that the two volcanoes are outlets of the same volcanic region.

In other large regions of subterranean activity we notice similar relations—namely, at times periods of well-marked oscillatory disturbance, and at other times periods of simultaneous action. We also find volcanic regions where the outlets are nearly always in action together at

times of disturbance, and other regions where alternations of activity are the only evidence of connection. Thus the Peruvian and Chilian volcanic regions have seldom, if ever, been simultaneously disturbed. A long period of disturbance in the Peruvian region, culminating in the terrible earthquake of Riobamba, was followed by a series of disturbances in the Chilian region, resulting in a permanent elevation of the whole line of coast. Then came disturbances in the Peruvian Andes, including the tremendous earthquake of the year 1868, which so shook the shores of Peru, that the sea wave then generated swept right athwart the Pacific to the shores of New Zealand, Australia, and the Asiatic continent. It is noteworthy that between the Chilian and Peruvian regions of disturbance there is a space in which no volcanic action has ever been observed; precisely as between the oscillating ends of a balance there is a region of comparative quiescence.

It certainly does not seem probable that these signs of disturbance in different parts of the South European volcanic region which have followed or accompanied the eruption of Vesuvius have been free from all connection with the activity of the great Sicilian vent. Certainly earthquakes in Sicily have been associated with the cessation of the outflow of lava from Etna. Nor can there be much doubt that signs of activity shown by Vesuvius after Etna has been in eruption, and *vice versâ*, indicate sympathy between the Neapolitan and Sicilian volcanic regions. It may seem extravagant to associate earthquakes in France or in the British Isles with the activity of the Italian volcanoes; but there are many reasons for believing that such slight earthquakes as do from time to time occur in these more northerly regions depend indirectly on the condition of the South European region of subterranean activity. It is certain that shortly before the great outburst of Vesuvius in 1868, an earthquake more marked in character than usual in this country shook the western parts of England. It is well known, too, that when another part of the great southern region of disturbance was affected, and Lisbon was laid in ruins, the lakes, rivers, and springs of England were disturbed in a remarkable manner; the water of Loch Lomond, for instance, suddenly rose, without apparent cause, against its banks, and then quickly subsided to its usual level.

THE RELATION OF FOOD TO MUSCULAR WORK.

By Dr. W. B. Carpenter, F.R.S.

PART II.

It has been shown that whilst Liebig regarded the production of Muscular Energy as an expenditure of the "vital force" of the muscle-substance itself—involving its death and chemical transformation, and requiring *nitrogenous* or tissue-food for its regeneration—Mayer attributed the production of that energy to the oxidation of a portion of the *non-nitrogenous* or respiratory food, regarding the muscular apparatus as the mere instrument by which that oxidation is made to produce Motion in place of Heat.

I shall now give a general account of the experimental inquiries by which Liebig's doctrine has been disproved and that of Mayer established. These have reference to the relation of the *amount of work* done by the body as a whole,—(1) to the relative consumption of the nitrogenous and the non-nitrogenous components of the food; (2) to the amount of Carbonic acid exhaled; and (3) to the amount of Urea passed off:—while (4) another set of experiments upon isolated muscles has demonstrated the dependence of the production of energy upon a change in the substance of the muscle itself, rather than (as Mayer supposed) in the blood passing through it.

1. If a man be carefully "dieted" for a time long enough to determine the amount of *nitrogenous* aliment adequate to repair the ordinary daily "waste" of his tissues, and the amount of *non-nitrogenous* aliment needed to maintain the heat of his body at its normal standard and keep him in healthful exercise, so that his weight remains the same at the end of the experiment as at the beginning—and he is then set to make a great addition to his daily exercise in the shape of walking, pumping, turning a machine, or the like—it is found that his body can be kept up to this extra work by an increase in the supply of *non-nitrogenous* aliment, with such a small addition to the nitrogenous as may suffice to make good the loss produced by the increased "wear and tear" of the machine itself.

2. All observations concur in showing an *immediate* increase in the exhalation of Carbonic acid, capable of being determined with rigorous exactness, when the body, previously at rest, is put into motion. The late Dr. Edward Smith made himself the subject of a long-continued and diversified series of researches upon this point, by the use of a portable gas-meter, through which he could breathe when walking or working at a tread-wheel, as well as when standing still, sitting, or lying: and he found not only that when continually "getting up stairs" on the tread-wheel he exhaled more carbonic acid than when walking, that when walking fast up-hill he exhaled more than when walking slowly on level ground, and that in the latter case he exhaled more than when standing still; but that he exhaled more when standing than when sitting, and more when sitting upright (without support to the back) than when lying so fully supported as not to put forth any muscular effort. Further, he found that when, in walking, he carried a weight even of a few pounds, the exhalation of carbonic acid was sensibly augmented; the increase being still greater when the weight had to be *raised* (as in walking up hill), as well as transported. These results have been confirmed by numerous other experimenters. They are in remarkable harmony with those long previously obtained by Mr. Newport, upon the relative amounts of carbonic acid exhaled by a bee at rest, and a bee "buzzing" under a glass.

3. The employment of more exact methods for the quantitative determination of Urea than that used by Liebig, has shown that he was altogether wrong in asserting that a corresponding increase is produced by muscular exertion in the quantity of that substance eliminated by the kidneys. An experiment which has now become "classical" was performed upon themselves by Professors Fick and Weslicenus in 1866; namely the determination of the respective quantities of urea eliminated by each of them for twelve hours *before*, for eight hours *during*, and for six hours *after* the ascent of the Faulhorn, whose height is about 6,500 feet. They took no nitrogenous food either for seventeen hours before the ascent, during the eight hours of the ascent, or for six hours after the ascent; but then took a good ordinary meal. The mean of the two determinations (between which there was a very close correspondence) gave for the twelve hours before the ascent, 0·62 gramme, being at the rate of 0·052 gramme per hour; for the eight hours of the ascent 0·40 gramme, or at the rate of 0·05 gramme per hour; and the same amount for the six hours following the ascent, being at the rate of 0·066 gramme per hour; while for the twelve hours after the subsequent meal, the mean amount was

0·48 gramme, or at the rate of 0·01 gramme per hour. There was thus a positive reduction in the amount of urea eliminated, which was probably attributable to the temporary abstinence from nitrogenous aliment; since the results of subsequent observations carried on for a much longer period upon men going through severe exertion upon an ordinary diet (as those made by Dr. Austin Flint, of New York, upon Weston, the pedestrian, during a five days' walk of 310 miles), show a slight total increase in the elimination, which is fairly attributable to the general "wear and tear" produced by the excessive strain put upon the machine. There is, then, no foundation whatever for the assumption of Liebig, that every exertion of muscular energy involves the death and disintegration of an equivalent amount of muscle-substance.

4. It now appears certain that the chemical change which is the source of Muscular energy occurs in the Muscle itself, not in the stream of Blood that courses through it. For the muscular tissue nourishes itself at the expense, not merely of the *protoplasmic* constituents of the food brought to it by the blood-current, but also of the *saccharine*; and, in addition, takes in oxygen which the red corpuscles of arterial blood bring to it from the lungs. A sort of explosive mixture is thus formed, which is "fired" (so to speak) by the nerve-discharge; a certain quantity of the saccharoid being thus caused to unite with the oxygen contained in the tissue, producing at the same time the *heat* which raises the temperature of the muscle, and the *motor force* exerted in its contraction; while the carbonic acid, which is the product of this oxidation, together with the residual water,* is conveyed away in the return-current of venous blood. But that this "explosion" (the term is only used figuratively, to indicate the *suddenness* of the chemical change, and its excitement by nerve-discharge) does not involve the destruction of the tissues, is evident from the consideration stated by Mayer, that the amount of work done by the heart (which is capable of very exact measurement) would require, if it involved the disintegration of the muscular tissue, a renewal of it at the rate of *a heart per week*. But muscle-substance constitutes no exception to the general rule that every tissue in the body has a term of life of its own: as we see in the rapid waste it undergoes when entirely thrown out of use. And it is the need of renovation thence arising, that gives rise to a demand for *nitrogenous* aliment; this being used to keep the machine, so to speak, in working order, not to serve as its fuel.

Again, it was formerly supposed by physiologists that the conversion of arterial into venous blood (which chiefly consists in the replacement of a portion of its oxygen by carbonic acid) takes place in the capillary network of the system generally; but we now know that it goes on at very diverse rates in different parts, and varies in the same part according to its functional activity. Now, this variation especially shows itself in the blood that passes through the Muscular substance; for when a muscle is at rest, the blood returned by its veins retains almost completely the character of that brought by its arteries; whilst, if the muscle be thrown into contraction by nervous or electric stimulation, the returning blood at once assumes the ordinary venous character—thus showing the dependence of its conversion upon the action of the muscle. We get a corresponding result by experimenting on a separated muscle; that of a cold-blooded animal being most suitable, as longest retaining its vitality when removed from the body. If the muscle of a Frog, placed in a closed chamber exhausted of all save watery vapour, be repeatedly called into contraction by electric stimulation, the chamber is found, after a time, to contain carbonic acid in a quantity proportionate to the number of such contractions, showing that some component of the muscle-substance has undergone oxidation; and since no other product of chemical action is discoverable, it may fairly be concluded that what has been given off from the muscle is part of the saccharoid matter which chemical analysis proves to have been previously stored up in its substance. The union of the saccharoid with the oxygen also stored up in the muscle, produces an amount of energy that can be determined (in the form of units of heat) by the quantity of carbonic acid found in the vessel. This energy, however, may express itself in motion as well as in heat; and the amounts of both may be determined with considerable precision—the former as units of *work* done, the latter as units of *heat* by which the temperature of the muscle is raised. Now, if the units of work be turned into their equivalent units of heat, and the two amounts be added together, they give a total so closely accordant with that deduced from the quantity of carbonic acid produced, as to afford the most striking confirmation of Mayer's prediction:—"Convert into heat," he said, "the mechanical product yielded by an animal in a given time, add thereto the heat directly produced in the body during the same period, and you will have the total quantity of heat* which corresponds to the chemical processes."

To sum up:—The *mechanical working* of the body of a living animal is as directly dependent as its *heating* upon the oxidation of the hydro-carbons of its food; and these may be most economically supplied by non-nitrogenous substances. On the other hand, the mechanism can only be kept in working order by the continual renovation of its substance (its very existence as a living whole involving the continual death and decay of its component parts); and for this renovation a supply of *proteids* is essential, with a certain admixture of *fat* to serve as material for protoplasm.

I have thought it worth while to enter somewhat fully into the particulars of this inquiry, since it affords an excellent example of the truly scientific methods on which Physiology is now being studied, and of the value of the results that are being obtained by their use. It is by such methods alone that the Physical and Chemical actions taking place within the living body can be so determined as to give to Physiology that place among the exact sciences which its earlier cultivators could scarcely venture to hope it would ever attain.

---

* The *saccharoids* may be regarded as consisting of carbon *plus* the components of water, so that the amount of energy (whether manifested in Heat or in Work) produced by their oxidation, is proportional simply to the quantity of carbonic acid generated. In *oleaginous* compounds, on the other hand, the number of oxygen atoms is not nearly equal to that of the hydrogen atoms; so that their oxidation generates not only carbonic acid, but also water. It is pretty certain that this metamorphosis, like that of saccharoid, takes place in the substance of the muscle, since it must be the chief source of energy in carnivorous animals, whose food contains no saccharoid. But we have no means of distinguishing the water thus generated from that which is otherwise present.

* It would appear from the experiments of Fick upon frog's muscles, that of the whole energy generated by the oxidation process, about five-sevenths show themselves as heat, whilst the other two-sevenths do the mechanical work. In the bodies of Man and other warm-blooded animals, however, the proportion of heat to work is ordinarily much larger; the former constituting about five-sixths of the total energy generated by the oxidation of the food, while the latter is only about one-sixth. Still, considered simply as a contrivance for doing mechanical work, the human body compares favourably with a steam-engine; the very best form of that machine only exerting about one-eighth of the power which is generated by the combustion of the coal it consumes, the remaining seven-eighths being wasted.

BRAIN TROUBLES.

IN these days, when the energies of the mind have become more important than those of the body, and when even the health of the body is chiefly of value because of its direct association with the health of the mind, it is well that all who have much brain-work to do should know and understand the symptoms indicating derangement or overwork of mental powers. Of course, in all cases where, through whatever cause, any specific mental malady is in question, the assistance of physicians who have given special attention to cerebral diseases must be obtained. But fortunately with most, even of those who work the brain hardest, no more real occasion arises (whatever some doctors would assure us) for medical advice respecting mind troubles, than commonly arises in the case of corporal troubles among men who pass their days in hard but healthy bodily toils. The saying that every man is either a fool or a physician at forty (thirty would, perhaps, be nearer the mark) may be applied at least as well to the case of the mind as to that of the body. It is as easy for one who is not the fool of the proverb to understand the signs which indicate mind-mischief, and to minister to the mind when out of sorts (not actually diseased), as it is for him to note the signs of bodily ill-health, and apply the remedies which experience has shown him to be appropriate. And here we would note generally, what it is one object of this article to indicate specifically, that the analogy may be carried somewhat further. There are few greater mistakes, so far as the body is concerned, than to imagine every little ailment to be a sign of actual disease, and to have recourse for such slight troubles either to medical advice, or (which may prove more mischievous still) to active medicines or other strong remedies. The physician of the proverb, that is, the man who, not being a fool, has learned to understand his own constitution under ordinary conditions, may be watchful, if he so pleases, of even the slightest indications of ill-health, general or local, so long as such watchfulness does not degenerate into hypochondria. But most of these indications should suggest to him only such changes of diet, exercise, hours of resting, and so forth, as his experience has found to be suitable, and should in the greater number of cases suggest negative rather than positive remedies even of this kind. Many signs of illness, indeed, which obtrude themselves on the attention even of those who watch themselves least in such matters, may far better be dealt with by the patient himself than by the physician. For instance, the present writer has learned to regard severe headaches of a certain type simply as affording evidence that certain articles of food (milk, butter, cheese, and the like) must either be given up altogether for several days, or taken in much-reduced quantity. When this course is followed, he is freed from all such attacks, until after the lapse, perhaps, of two or three months, a headache of this particular kind shows him that he has taken such articles of food in greater quantity than is desirable for one of his constitution. A doctor might prescribe with advantage for the cure of the attack itself, and there can be no reason why a person troubled by some severe attack of headache, muscular rheumatism, or the like, should not obtain from a doctor some active medicine by which to diminish the pain from which he suffers; but it is a far more important matter to ascertain the regimen by which such attacks may be prevented from occurring, and this is a matter which a man (not being the "fool" of the proverb) should manage for himself. Now what is true of bodily troubles is true of mental mischief, short of actual disease, though doctors who have learned, rather late, to leave men a good deal to themselves, so far as the former are concerned, are by no means ready to admit that mental troubles can also for the most part be remedied without calling in the physician. Writers like Forbes Winslow, and others who have dealt with obscure diseases of the mind, have done service in calling attention to certain signs of cerebral mischief which laymen might be apt to overlook; but they insist rather too strongly on these as indicative of actual disease, whereas it is within the experience of thousands that such signs, in the majority of cases, are no more to be regarded as necessarily indicating disease, than a passing feeling of nausea necessarily indicates an approaching fever, or than a pain in the bowels necessarily indicates an approaching attack of Asiatic cholera.

It should also be noted, that much mischief may be caused by suggesting that tricks and failings of the mind, which are quite common, are signs of serious cerebral mischief. Not long after the first edition of Forbes Winslow's treatise on "Obscure Diseases of the Mind" appeared, a friend of the writer's, who had begun to read the book only because of his interest in matters scientific, found that it possessed for him a strange fascination, because nearly all the phenomena mentioned by Winslow as indicative of approaching insanity were such as he had frequently noticed in his own case. Thereafter regarding these symptoms in the light in which they were thus presented, this unfortunate student of cerebral science found himself presently possessed by a strange terror lest the state which Winslow seemed to indicate as a necessary sequel of these familiar signs should be close at hand in his own case. The evil progressed until his mind was really endangered by these mistaken fears; but, fortunately for him (if madness is rightly regarded as the greatest of all evils), a series of misfortunes befell him which for a time altogether withdrew his attention from the mental phenomena which had so excited his fears. For two or three years he had to contend against great pecuniary difficulties, and to endure a series of domestic calamities of no ordinary order. Compelled to withdraw his attention from his own mind, he forgot that, according to the teachings of mental physiologists, he had been fairly on the way towards either mania or idiocy. Four or five years later, chancing to take down Forbes Winslow's book from his library shelves, he read with amusement the passages which had formerly excited his fears. He knew that the mental symptoms graphically described by Winslow still presented themselves from time to time—when, for instance, he was tired or unwell bodily—but he had learned in a very practical way that they are not quite so ominous as the mind-doctors assert. It is indeed possible (perhaps probable, or even certain) that no cases of acute mania may be noticed which have not been preceded by such symptoms; but assuredly these symptoms are not in every case—probably not in one case out of hundreds of thousands—the signs of actual mental disease, nor in one case out of millions followed either by acute mania or by apoplectic seizure, as in the exceptional cases dealt with by Dr. Forbes Winslow.

We propose hereafter briefly to consider some of the signs which show that the mind is temporarily out of order, requiring rest, relaxation, or change of employment. We may in some cases have to enforce the lesson we wish to inculcate by citing cases in which such symptoms have been followed by serious mental disturbance; but we wish at the outset to persuade our readers that, in far the greater number of cases, these signs suggest only the necessity for ordinary precautions, not for medical advice or active remedial measures.

(To be continued.)

COMETS.

Part II.

Most persons know that the name "comet" is derived from the word *coma*, or *hair*, and is applied to celestial objects which appear to have a hairy appendage. Modern astronomers do not, indeed, use the word *coma* in this sense, but draw a distinction between the *coma* and the tail. There can be no doubt, however, that the part now called the comet's tail was that from which these objects derived their name. The word *cometa* or *cometes* is not a lately-formed one; but was used by Cicero, Tibullus, and other ancient writers, and it is worthy of notice that all the names applied to comets by the Romans had a reference to *hairiness*—*stellæ comantes, crinitæ, concinnatæ*, they are called by Ovid, Pliny, and Cicero. The last term —signifying stars which show a *curled* or *crisped* hairiness —would not be very applicable to the great comets that have appeared in modern times. The Chinese applied to comets the name *sui*, or "broom."

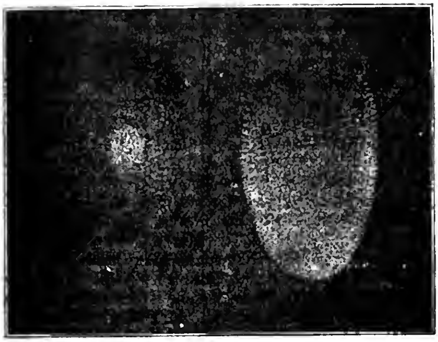

Fig. 1.—Changes of a Comet when first seen.

It might be supposed that the hairy, broom-like, or tail-like appendage, so commonly seen in comets, is really a distinctive feature of these comets. This, however, is far from being the case. A very large number of comets have no visible tails. We refer, of course, principally to telescopic comets; for very few comets which have been conspicuous to the naked eye have wanted this appendage.

The *coma* in the modern astronomical sense is never wanting. This term is applied to a misty, hazy light, surrounding on every side a small bright spot, which is termed the *nucleus* of the comet.

When first seen in the telescope, a comet usually presents a small round disc of hazy light, somewhat brighter near the centre. As the comet approaches the sun, the disc lengthens, and, if the comet is to be a tailed one, traces begin to be seen of a streakiness in the comet's light. Gradually a tail is formed, which is turned always *from* the sun (Fig. 1). The tail grows brighter and longer, and the head becomes developed into a coma surrounding a distinctly marked nucleus. Presently the comet is lost to view through its near approach to the sun. But after awhile it is again seen, sometimes wonderfully changed in aspect through the effects of solar heat. Some comets are brighter and more striking after passing their point of nearest approach to the sun (or *perihelion*) than before; others are quite shorn of their splendour when they re-

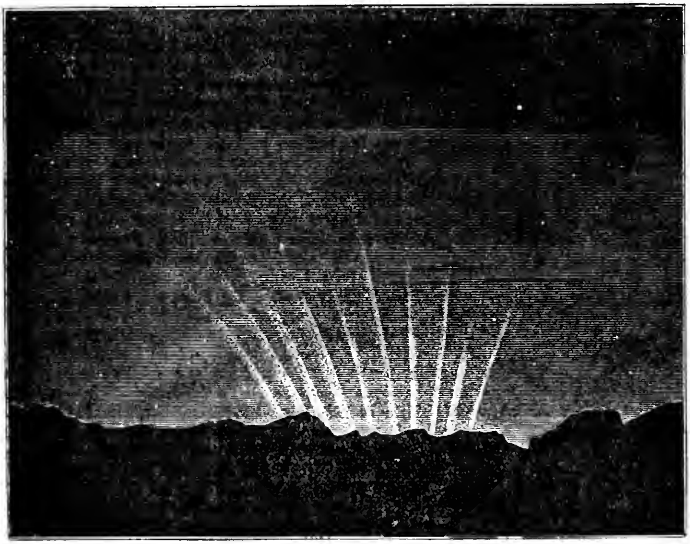

Fig. 2.—The Comet of 1744 (*Cheseaux*).

Fig. 3.—Comet of 1861 (*[illegible]*).

appear. The latter was the case with the comet of 1835-36, as we have already seen. On the other hand, the comet of 1861 burst upon us in its full splendour *after perihelion*-passage.

Some comets have more than one tail. One appeared in 1744 which had no less than six tails, symmetrically disposed (if one can trust the pictures handed down to us) in the figure of a half-opened fan (Fig. 2). Others have presented a yet more peculiar appearance, having, besides a tail in the usual position, a second "unconformable" tail, at right-angles to the first, or inclined to it at some incongruous, out-of-the-way angle—for instance, in one case, one hundred and sixty degrees. Sometimes the peculiarity is presented of a perfectly dark gap separating the tail from the head. More commonly a dark space is seen behind the head, but on each side of this space the light from the head is continued so as to form a bright border on each side of the tail.

away *from* the sun. The same sun which attracts the nucleus seems to repulse the emitted matter with inconceivable energy. Consider for a moment what took place with Newton's comet in 1680-81 (Fig. 3). When this comet was about as far off from the sun as our earth (ninety million miles) it began to throw out a tail. But the comet was going far nearer to the sun than this. Onwards it rushed under the powerful influence of the sun's attraction, until it had crossed the whole space of ninety million miles, making—almost in a straight line—for a point only one hundred and thirty thousand miles from the sun's surface. In four weeks it traversed that vast distance, and then, suddenly (in a few hours) sweeping half round the sun, started on its return journey. But note this: as it approached the sun, the comet had thrown out a tail continually increasing in length, and pointing *back* almost along the orbit; then the comet is lost to sight for a few days, and when it is next seen returning

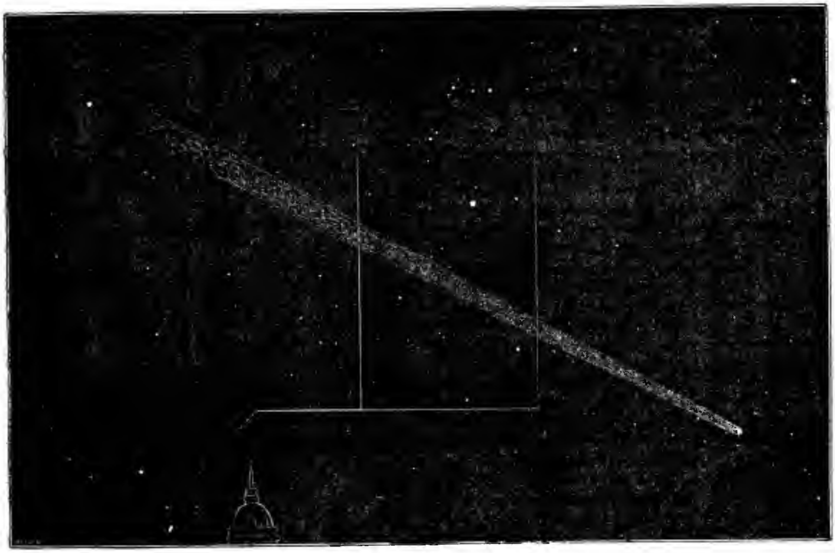

Fig. 4.—Comet of 1843.

As a comet approaches the sun, we have seen that a change takes place in the appearance of the coma and nucleus, and that in some instances a tail is generated. The process actually observed is generally this: in the forward part of the nucleus a turbulent action is seen to be in progress, leading to the propulsion towards the sun of jets or streams of misty-looking matter. Sometimes a regular cap or envelope is seen to be projected in this manner towards the sun, or even a set of envelopes one within the other. The matter thus thrown off is not suffered to pass very far from the nucleus towards the sun, but is swept away, as fast as formed, in the contrary direction. If the funnel of a steam-engine were directed forwards, instead of upwards, then the appearance presented by the emitted steam, as the engine rushed on (against a hurricane, suppose, to make the illustration more perfect) would exemplify the process which seems to be taking place around the front of the nucleus, and far behind it, as the matter formed is continually swept

rapidly from the sun, it has a tail pointing *forwards* (a tail which *must* be a different one, since—as Herschel says—"we cannot conceive a comet's tail to be brandished round like a stick"), and ninety million miles in length. So that, whereas the comet, already moving with a tremendous acquired velocity, had taken four weeks in traversing a distance of ninety millions of miles under the sun's *attraction*, the matter composing the tail had been thrown to the same enormous distance by the sun's *repulsion* in scarcely one-tenth part of the time, possibly (for the tail was formed when first seen) in a few hours!

The comet of 1843 (Fig. 4) was yet more remarkable for the dimensions of its tail and for its close approach to the sun. The tail of this comet stretched half-way across the sky in March, 1843. Its real length was two hundred million miles *at least*, for the end of the tail was lost to view through the excessive faintness of its light. So near did this comet pass to the sun, that many astronomers did not expect ever to see the comet again.

But after all but grazing the sun—sweeping round him at a distance of less than one-tenth of his diameter, the comet escaped and passed back again into space.

When we see the tail of a comet occupying a volume thousands of times greater than that of the sun itself, the question naturally suggests itself, "how does it happen that so vast a body can sweep through the solar system without deranging the motion of every planet?" Conceding even an extreme tenuity to the substance composing so vast a volume, one would still expect its mass to be tremendous. For instance, if we supposed the whole mass of the tail of the comet of 1843 to consist of hydrogen gas (the lightest substance known to us), yet even then the mass of the tail would have largely exceeded that of the sun. Every planet would have been dragged from its orbit by so vast a mass passing so near. We know, on the contrary, that no such effects were produced. The length of our year did not change by a single second, showing that our earth had been neither hastened nor retarded in its steady motion round the sun. Thus we are forced to admit that the actual substance of the comet was inconceivably rare. A jar-full of air would probably have outweighed hundreds of cubic miles of that vast appendage which blazed across our skies, to the terror of the ignorant and superstitious.

The dread of the possible evils which might accrue if the earth encountered a comet will possibly be diminished by the consideration of the extreme tenuity of these objects. But the feeling may still remain, that influences, other than those due to mere weight or mass, might be exerted upon terrestrial races in the course of such an encounter. The subtle breath of some mephitic vapour might penetrate our atmosphere, and, if it did not bring immediate destruction, might leave dire forms of plague and pestilence to work their evil will upon the human race. This fear is not, perhaps, wholly unreasonable, though—as will presently appear—the positive information we now have does *not* favour the supposition that the tail, at any rate, of a comet is likely to exercise such destructive effects. And it is only the tails of comets that we have much chance of meeting. On account of their enormous volumes, it is not so utterly improbable that we should encounter them as that we should meet the comparatively minute nuclei. In fact, there is reason for supposing that the earth actually did pass through the tail of the comet of 1861. At about the hour when it was calculated that the encounter should have taken place, a strange *auroral glare* was seen in the atmosphere, but beyond this, no effect was perceptible.

INTELLIGENCE IN ANIMALS.

Few of the questions raised in Darwin's "Descent of Man" are at once more difficult to deal with satisfactorily, or more important in their bearing on the subject of that volume, than the question how far animals possess mental powers akin to those of man. It is somewhat singular, we may remark in passing, that Darwin and Huxley, whose views in some respects are so similar, and who are regarded by the general public as standing side by side in their advocacy of the theory of the relationship of man to the lower animals, should seem to uphold almost exactly opposite opinions respecting the cerebral qualities of animals—one maintaining that in some cases animals reason, while the other (if we rightly apprehend what Huxley has said about animal automatism) will scarcely allow that animals even possess consciousness.

We propose here to consider some cases in which animals have seemed to reason. The importance of the subject will be recognised if we remember Darwin's admission that, had no organic being except man possessed any mental power, or if man's powers had been of a wholly different nature from those of the lower animals, we should never have been able to convince ourselves that our high faculties had been gradually developed. Darwin expresses his belief that there is no fundamental difference of this kind. "We must also admit," he says, "that there is a much wider interval in mental power between one of the lowest fishes, as a lamprey or a lancelet, and one of the higher apes, than between an ape and a man; yet this immense interval is filled up by numberless gradations." But this has not been so generally admitted, despite the evidence advanced by Darwin, as might have been expected. The feeling is still commonly entertained that a distinction exists between the mental qualities of the cleverest ape and the dullest and stupidest savage, which is utterly unlike any that exists among animals. In this essay we shall have to consider cases in which rats, cats, dogs, &c.,—animals all inferior in mental faculties, though not all in equal degree, to the more intelligent apes—have acted in ways which seem to imply reasoning. We shall treat these cases rather from the point of view of an opponent of Darwin's thesis above quoted than of a supporter, endeavouring in every case to find explanations not involving the exercise of reasoning faculties. But we must admit at the outset, that we find ourselves led to precisely the conclusion which he has indicated.

In the first place, we must recall to our reader's recollection those instances which have been selected by Darwin as so satisfactory, that in his opinion any one not convinced by them would not be convinced by anything that he could add.

Rengger states, says Darwin, "that when he first gave eggs to his monkeys, they smashed them, and thus lost much of their contents; afterwards they gently hit one end against some hard body, and picked off the bits of shell with their fingers. After cutting themselves only once with any sharp tool, they would not touch it again, or would handle it with the greatest care. Lumps of sugar were often given them wrapped up in paper, and Rengger sometimes put a live wasp in the paper, so that in hastily unfolding it they got stung" (the tenderness of some of these students of science towards animals is quite touching). "After this had once happened, they always first held the packet to their ears, to detect any movement within." These were not monkeys of the higher orders, but American monkeys, none of which are so near man in cerebral development as the orang, the chimpanzee, the gibbon, or the gorilla. The next cases relate to the dog, and are important, first, because two independent observers give evidence in the same direction; and secondly, because the action of the dogs can hardly be explained as resulting from the modification of an instinct. "Mr. Colquhoun winged two wild ducks, which fell on the opposite sides of a stream; his retriever tried to bring over both at once, but could not succeed; she then, though never before known to ruffle a feather, deliberately killed one, brought over the other, and returned for the dead bird. Colonel Hutchinson relates that two partridges were shot at once, one being killed, the other wounded; the latter ran away, and was caught by the retriever, who on his return came across the dead bird. 'She stopped, evidently greatly puzzled, and after one or two trials, finding she could not take it up without permitting the escape of the winged bird, she considered a moment, then deliberately murdered it' (the winged bird), 'by giving it a severe crunch, and afterwards brought away both together. This was the only known instance of her having wilfully injured any game.'

"Here," proceeds Darwin, "we have reasoning, though not quite perfect, for the retriever might have brought the wounded bird first, and then returned for the dead one, as in the case of the two wild ducks." If the dog had followed the wiser course, it would not have been quite so clear as in the actual case that he had reasoned, though the pause for consideration after an attempt to take both together, would have gone far to suggest that explanation. But the action of the dog in killing the bird seems quite decisive, because such an act was entirely opposed to the instincts of the breed and to the training which retrievers receive.

To these cases Darwin adds the statement that "the mulateers in South America say, 'I will not give you the mule whose step is easiest,' but *la mas racional*—the one that reasons best": on which Humboldt has remarked, "this popular expression, dictated by long experience, combats the system of animated machines better, perhaps, than all the arguments of speculative philosophy." Here, although Darwin only quotes Humboldt, he manifestly expresses his own view, and we find him opposed in a very definite manner to the theory of Kepler, afterwards supported by Descartes, and recently advocated by Huxley and others, that animals are automata, not possessing consciousness (or at anyrate that this theory is admissible).

The next case to be considered is one which was described a year or two since in *Nature*. It was not one which in reality demonstrated, or even strongly suggested, the exercise of reasoning faculties by animals. We quote it, however, because it illustrates well the mistakes into which want of care may lead the student of our subject. During the cold weather of last January, the writer of the letter in question put bread on the window-sills of his drawing-room for the benefit of the birds. These, finding food there, were constantly fluttering about the windows. "One day a large water-rat was seen on the window-sill, helping himself to the bread. In order to reach the window he had to climb to a height of about 13 ft.; this he did by the help of a shrub trained against the wall. Neither instinct nor experience," proceeds the correspondent of *Nature*, "will easily account for his conduct, since he never found food there before. If neither experience nor instinct, what, save reason, led him? His action seems to have been the result of no small observation and reasoning. He seems to have said to himself: I observe the birds are thronging the window all day; they would not be there for naught: it may be they find there something to eat; if so, perhaps I, too, might find there something I should like. I shall try." The way in which this story is told singularly illustrates the difficulty which we, as speaking animals, find in understanding how a process of reasoning can be carried on without the imagined use of words. Probably few men whose mental powers have been well trained carry on a process of pure ratiocination, without clothing with words the thoughts successively suggested to their minds. It almost seems to a mind thus accustomed to reason with a verbal accompaniment (audible to the mind's ear only) that any mental process not thus accompanied must be to some degree instinctive, and any actions resulting from such a process automatic. But it is certain that even the most intellectual sometimes act in a manner which, if noticed in an animal, would suggest the exercise of reasoning power, not only without putting their thoughts into mental language, but without, in reality, noting what they are doing. However, the point to be specially noticed about the above story is that the narrator overlooks the most obvious, and probably the true, explanation of the rat's behaviour. The rat could not see the food, but most probably he could smell it. If so, his adventuring up the wall to get it was not the result of reasoning, or, at least, not necessarily so, for that was the shortest path to the much-needed food. Possibly the birds themselves may have been an attraction to him. Certainly the case is not one which compels us to believe that water-rats reason.

This objection was so well urged, in company with other points necessary to be considered in such inquiries, by a German writer, Herr H. T. Finck, that we quote his remarks almost in full. "Before we ascribe to a rat such complicated reasoning powers," Herr Finck remarks, "it is necessary to ask if there is no other simpler way of accounting for the phenomena. I think there is. It is well-known that different species of animals vary greatly in the acuteness of their senses. To man, sight is the most important sense, and the same is true of many other animals and most birds. The cat is a representative of another smaller class of animals, whose most perfect organ of sense is the ear; while the dog lives in a field of sensatives, the most important of which are contributed by the sense of smell." This point, as dogs afford many of the most striking illustrations of reasoning, or of what looks like reasoning, in animals, must be carefully remembered. Few are aware, we believe, how imperfect a sense is sight with all dogs, as compared with our own sense of sight. We believe that there could not be cited a single instance tending to show that a dog has been able to see as well as a very short-sighted man would, while in the great majority of cases, it can be shown by a few easily-tried experiments that dogs scarcely see at all in the true sense of the word. Our sense of smell is probably not more completely inferior to the same sense with dogs, than is their sense of sight to ours. To return, however, to Herr Finck. After pointing out that the rat belongs to the class of animals who are guided by the sense of smell, he says, "It is evident, therefore, that the water-rat in question was led to the window-sill by his nose, which in his case was a more trustworthy guide than his eyes would have been. I do not wish to deny, by any means, that animals have reasoning powers. On the contrary, I am convinced that human and brute intellect differ only in degree, not in kind. But what we have to guard against is not to ascribe [he obviously means the reverse, that we are to guard against ascribing] to animals reasoning powers of a higher type than is consistent with the development of their brain, especially when the actions which seem to postulate such powers can be readily accounted for by simply bearing in mind the extraordinary acuteness of one or more of their senses. We are altogether too prone to judge the intellectual life of animals by the human standard—to imagine that the eye is everywhere, as with us, the leading source of knowledge. The neglect of the important *rôle* which the sense of smell plays in animal life has been particularly fruitful of errors in philosophical speculation. It has, among other things, helped to give a longer basis of life to the old theory of instinct, regarded as a mysterious power of nature." In passing, we may remark that at the very beginning of our own life the sense of smell is stronger and more useful than the sense of sight; as though during those first few days, before the eyes acquire power to recognise objects or to do much more than to distinguish light from darkness, we belonged for the time being to that inferior class of animals with whom the predominant sense is that of smell. In that part, also, of their lives, human beings seem so far to resemble the lower animals that their actions appear to be governed by instinct solely. In reality, probably, a sense of smell much keener then than during the subsequent years which alone we can remember, governs the actions in the same way, though not so obviously, as sight governs them in most of the actions of later years.

BIRDS WITH TEETH.

In the year 1861 a feather was found in a slab of lithographic stone from Solenhofen, which Hermann von Meyer assigned to an animal as yet not otherwise known, which he called *Archæopteryx lithographica*. Later in the same year, a large portion of the skeleton of Archæopteryx was discovered in the same formation. There were impressions of feathers radiating fanwise from each of the forelimbs. But Prof. Andreas Wagner, in a report to the Royal Academy of Sciences in Munich, expressed the opinion that the creature was not a bird, but a reptile, whose natural covering presented a deceptive resemblance to feathers. He called it the *Griphosaurus*, which (considering he had not seen the fossil remains) was very obliging on his part. Von Meyer, however, regarded the impressions as representing real feathers, belonging to the same animal as the feather he had already discovered. The fossil was secured for the British Museum in 1862. It is contained in two slabs of Solenhofen limestone; one representing the surface of tidal mud on which the bird lay at the time of its death, the other the layer deposited over the dead body. The lower slab shows the impressions of the tail, wings, and parts of the skeleton. The right shoulder-blade and upper arm (wing), as well as both the forearms, are well preserved. The head, the neck, and the backbone are wanting. Two of the digits of the wing (wing fingers we may call them) are free, and armed with sharp claws or recurved spurs. The right lower limb is well preserved, consisting of the thigh-bone, the tibia or larger lower leg-bone, and the tarso-metatarsal bones, or bones of the upper foot. To the metatarsus, four toes are articulated, one hind-toe and three fore-toes, which are jointed as with birds, and armed with strong recurved claws. "The foot," says Mr. Woodward, from whose description the above has in the main been taken, "agrees well with that of a true perching bird, but from the fanwise and rounded arrangement of the wing-feathers, it would appear to have been a bird of feeble flight."

Without entering further into the peculiarities of this creature, we note that while a few naturalists were doubtful as to its being really a bird, the majority were very confident that it was so. Professor Owen, in particular, pointed out that in one respect in which it differed most from modern birds it resembles the embryonic bird. Its tail-bones diminished gradually to the last, whereas in modern birds, the last vertebra of the tail is almost always the largest. But, said Owen, "All birds in their embryonic state exhibit the caudal vertebra distinct, and in part of the series [of embryonic changes] gradually decreasing in size to the pointed end one." The two-fingered and free condition of the wing-hand, that is of what corresponds to the hand in the bird's fore-limbs (which Owen pleasantly described as the biunguiculate and less confluent condition of the manus), he did not account for in the same way as a feature of an embryonic bird; but in some modern species the forward wing finger supports a claw, and the Screamer has two claws. All who at that time examined the fossil agreed that in all probability the creature had a beak like a bird.

But Mr. John Evans noticed somewhat later (besides a rounded mass which he took for part of the brain-pan, with a cast of the brain) what he regarded as a fossil jaw, on the slab on which lies the fossil body of the bird. It had been supposed to be the beak of Archæopteryx, but "great was my surprise," writes Mr. Evans, "when I detected along its right-hand margin, towards the apex, the distinct impression in the slab of four teeth still attached to it. The teeth themselves remain adhering to the counterpart, and are easily recognised by the lustre of their enamel." The teeth are thus described by Mr. Woodward. "The three which remain in a vertical position with regard to the jaw are about one-tenth of an inch long, and at intervals of about one-fifth of an inch. They consist of a slightly tapering flattened enamelled crown, about a twenty-fifth of an inch in width, and obtusely pointed, set upon what is apparently a more bony base, which widens out suddenly into a semi-elliptical form, so that at the line of attachment to the jaw the base of one tooth comes in contact with that of the next. So sudden and extensive is this widening of the base, that at first it gave me the impression that the teeth were tricuspidate, with the middle cusp far longer than the others. The front tooth of the four, which slopes forward from the rest, and is rather smaller than the others, shows little, if any, similar enlargement of its base. Of the fifth, which lies across the base of the foremost of the four, only a part is visible. There appears to be a well-defined line at the base of the teeth along their junction with the jaw, but I can offer no opinion as to the method of their attachment."

It seemed so unlikely when the above description was written that a jaw armed with teeth could belong to a creature manifestly bird-like, that many supposed the jaw belonged to some fish, though the jaws and teeth of fossil fishes from the same bed were found to be unlike this. Hermann von Meyer, referring to the drawings sent to him by Mr. Woodward, said that he knew of no tooth of the kind in the lithographic stone; nor were the teeth like those of Pterodactyles (the great reptiles with bat-like wings). "An arming of the jaw with teeth would contradict the view of the Archæopteryx being a bird or an embryonic* form of bird. But, after all," he proceeds, "I do not believe that God formed his creatures after the systems devised by our philosophical wisdom. Of the classes of birds and reptiles, as we define them, the Creator knows nothing, and just as little of a prototype or of a constant embryonic condition of the bird which might be recognised in the Archæopteryx. The Archæopteryx is, of its kind, just as perfect as other creatures, and if we are not able to include this fossil animal in our system, our shortsightedness is alone to blame."

Probably the theory that the Archæopteryx had teeth would still be regarded as little better than an assumption, had not other and more complete evidence been obtained, Professor Marsh discovered two fossil birds in the cretaceous shale of Kansas, which had well-developed teeth in both jaws. Of one of these birds—the *Ichthyornis Dispar*—"the teeth were quite numerous," Marsh wrote in *Silliman's Journal* for October, 1872, "and implanted in distinct sockets. They were small, compressed, and pointed, and all of those preserved are similar. Those in the lower jaw number about twenty in each ramus" (that is, on each side), "and all more or less inclined backwards. The series extend over the entire margin of the dentary" (or tooth-bearing) "bone, the front teeth being very near the extremity. The maxillary teeth" (those in the upper jaw, that is) "appear to have been equally numerous, and essentially the same as those in the mandible. The skull was of moderate size, and the eyes were placed well forward. The lower jaws are long and slender. . . . . The jaws were apparently not encased in a horny sheath."

* The word embryonic is here used with reference to the species, not to the individual. It signifies a form which creatures of the species presented before the type of the species had become, as it were, distinct and established. Traces of such past forms of a species are recognisable in the embryonic development of later representatives of the species.

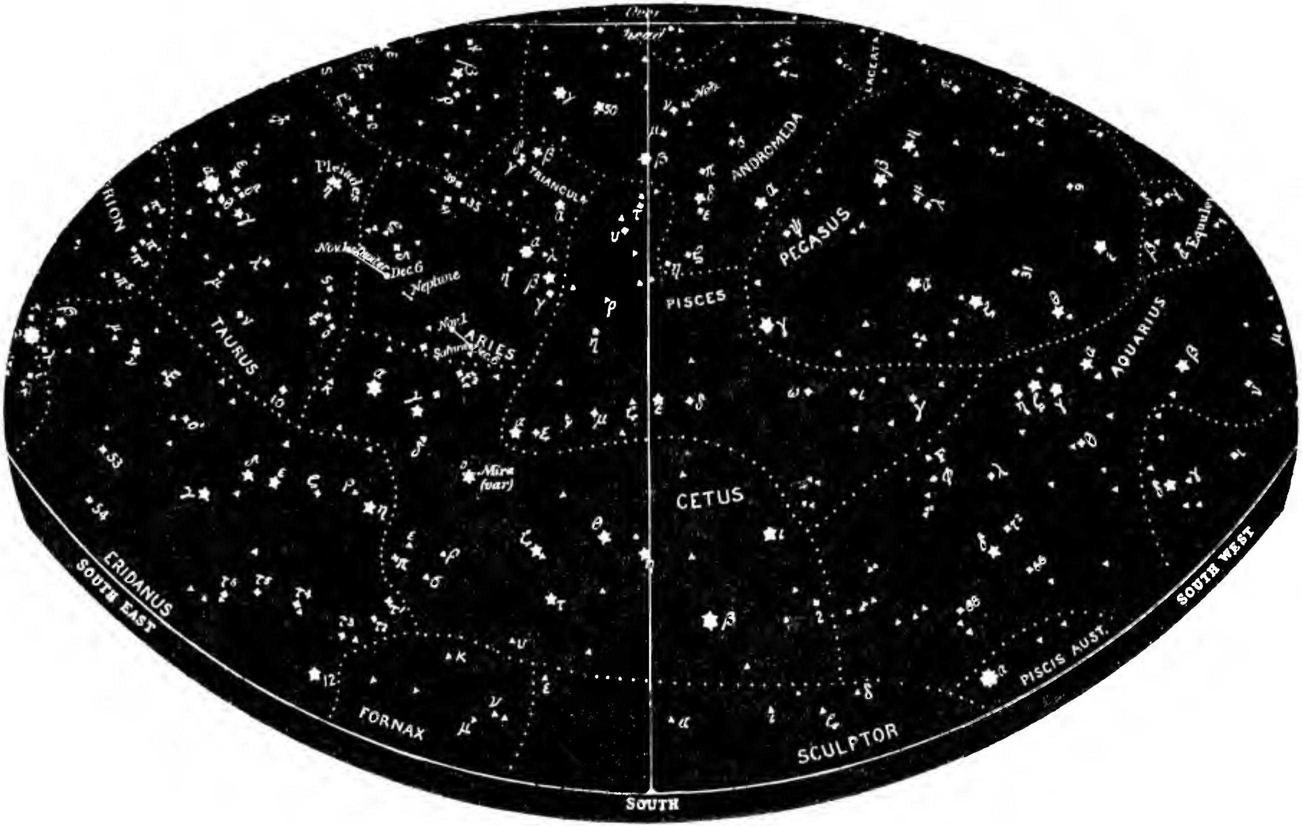
THE SOUTHERN SKIES IN NOVEMBER.



This Map shows the position of the stars in the Southern Skies —

On October 30, at 11½ o'clock.	On November 7, at 11 o'clock.	On November 14, at 10¾ o'clock.	On November 22, at 10 o'clock.	On November 29, at 9½ o'clock.
On November 3, at 11¼ o'clock.	On November 10, at 10½ o'clock.	On November 18, at 10¼ o'clock.	On November 25, at 9¾ o'clock.	On December 3, at 9¼ o'clock.

In this map, as in the map for last week, the movements of some of the planets are illustrated. Saturn and Neptune have already passed opposition, or their place where they are due south at midnight. Jupiter comes to opposition on Sunday Nov. 13th. He is now nearly at his brightest.

*** Stars of the first magnitude are shown with eight points, stars of the second with six, of the third with five, of the fourth with four, of the fifth with three.

Continued from page 30.]
The shoulder-blades and the bones of the wings and legs were all of the true bird-like type. The breast-bone had a prominent keel. The wings were large in proportion to the legs. The wing-bones corresponding to the hand in man, were united as in ordinary birds. The bones of the hinder extremities resembled those in swimming birds. The bird was about as large as a pigeon. The species was carnivorous, and probably aquatic. Professor Marsh called the other form discovered by him *Apatornis celer*.

Later, Professor Marsh announced that having re-examined another fossil bird—a large diving bird nearly six feet high, found in the same cretaceous formation as the *Ichthyornis*, he found that it also had *teeth in both jaws, not in sockets*, like the Ichthyornis, *but in grooves*, as in *Ichthyosaurus*, the great lizard-formed marine reptile.

The skeleton of this toothed bird is pictured in our illustration. Prof. Marsh called it the *Hesperornis Regalis*. Before the discovery of teeth, Prof. Marsh had unhesitatingly classed the Hesperornis as a gigantic diver, though recognising peculiarities of structure. But recently, in a Monograph on the Extinct Toothed Birds of North America, he called attention to its resemblance in certain respects to the Ostrich. He says that if these characters are to be "regarded as evidence of real affinity, the *Hesperornis* would be essentially a gigantic swimming ostrich." Professor Huxley, on the other hand, says that the bird is "in a great many respects astonishingly like an existing diver or grebe—so like it, indeed, that had this skeleton been found in a museum, I suppose—if the head had not been known—it would have been placed in the same general group as the divers and grebes of the present day."

The teeth seem to have been admirably adapted to aid a diving bird (like a grebe) in catching its slippery prey. In the *Odontopteryx toliapicus* of Owen, the bony denticles were inclined at a considerable angle, but with the points forward, yet Professor Owen concluded that even such projections (they could not properly be called teeth) must have greatly assisted the bird in holding captured fish. In the existing bird, the *Merganser serrator*, the tooth-like serrations are inclined with the points backwards. These serrations, however, were not teeth, but merely tooth-like extensions of the horny covering of the beak. The teeth of the *Ichthyornis* and *Hesperornis*, as is shown by the smaller figure (showing a tooth, and, within it, a tooth forming to take its place) were unmistakably teeth. It does not take away from their dental character that they were set in a groove in *Hesperornis* and *Archæopteryx*, instead of in separate sockets, as in higher-toothed races and in *Ichthyornis*.

It should be added that Professor Marsh has examined the specimen of *Archæopteryx* in the British Museum, and fully satisfied himself that it belongs to the class of toothed birds. "The teeth seen on the same slab with this specimen agree so closely with the teeth of *Hesperornis*, that" he "identified them at once as those of birds, and not fishes."

He describes the leading characters of the ancestral bird in the following terms:—"In the generalised form to which we must look for the ancestral type of the class of birds, we should expect to find the following characters: Teeth in grooves; vertebræ biconcave" (that is, the bones of the backbone shaped somewhat as we see them in fish); "breastbone without a keel; tail longer than the body; bones of the hand and wrist, as also those of the foot, free; the bones of the pelvis separate; the sacrum" (or hind bone of the pelvis) "formed of two vertebræ; four or more toes directed forward; feathers rudimentary or imperfect."

If we consider the circumstances under which, according to the theory of evolution, the race of birds came into existence, we can understand that the ancestral creatures whence birds are descended presented many features in which they were not only unlike the birds of our time, but unlike any other race of existing animals. Were they not also, in all probability, very unlike each other? Probably there were much wider differences among the various orders of animals, which included all the ancestry of the modern bird, at the time when first *any* of the characteristics now regarded as avian first existed, than there are now among all the orders of existing birds. This certainly appears from the evidence obtained, not only respecting toothed birds, but also respecting those bird-like animals of which Huxley and others have shown that they were closely akin to reptiles—were, in fact, biped reptiles. We believe that the same holds with every species now existing, even with man—that, for instance, if we could have brought before us in rapid review all those creatures from which the human race of our time has descended (taking only those which belonged to one particular epoch, before man, specialised as we now find him, existed), we should not only find a far wider range of difference among these creatures than among the human races of the present day, but a wider range of difference than even exists between men and apes. There are *à priori* reasons for this view as regards the human race; but, apart from these, the evidence collected by Mivart in his work, "Men and Apes," while not, we think, available to show that there is no kinship between the Simian and Human races, seems only explicable on the assumption that the Simian ancestors of man differed widely *inter se*.

THE FIJI ISLANDS.*

THE ideas generally entertained respecting the Fiji Islands and their inhabitants are not such as to encourage the idea that life to white men would be very pleasant there. Probably most persons, who have not followed the changes which have recently taken place in this important group of islands, suppose that the Fijians are still, as they used to be considered, the most barbarous of all the Polynesians, addicted frightfully to cannibalism, and little changed from those who, as Herbert Spencer puts it, possessed such "extreme loyalty," that if the king willed it, a Fijian cheerfully stood unbound to be knocked on the head. The days are passed, however, when a Fijian king could register by a row of many hundred stones the number of human victims he had eaten. The Conservative Fijian sighs in vain for the good old times when the king's will reigned supreme. A visitor has now only to take with him, as Mr. Horne did, a circular letter of introduction written in Fijian to all the chiefs, to find himself a welcome guest at (instead of upon) their hospitable tables. "In each village some one, generally the schoolmaster, 'teacher,' or native clergyman was found, who could read and explain the letter to the people, who were at all times attentive listeners." The Sunday schools are well attended, and most of the rising generation of Fijians can do something in the way of reading, writing, and ciphering. In fact, with a few guides and an interpreter, a little sugar, tea, coffee, and biscuits, mats for sleeping upon, a rug or so, and a mosquito net, the visitor can enjoy himself immensely in the Fiji Islands, as Mr. Horne's work shows in almost every page.

While the cool weather lasts, Europeans in Fiji can wear with comfort clothing adapted to an English summer; "indeed, at this season, the weather is delightful, finer than the best summer weather in England." In the hot weather, it is true, the heat is oppressive, while storms of thunder and heavy rain are more frequent than pleasant. With reference to the rainfall, by the way, which even for a tropical country is very heavy, Mr. Horne notes a circumstance of considerable interest. "Previous to and during 1861-2 the low hills around Levuka were thickly wooded. Since that time the woods have been cut down, and the number of days on which rain falls has been reduced from 256, the average for 1861-2, to 149, the average for 1865-6 and 1876-7. It would seem that the number of showers diminished simultaneously with the cutting of the trees. The average rainfall has not been much diminished, however, and with an annual rainfall of 118 inches the Fijians may be well satisfied, especially as the rain falls most abundantly during the warm or summer season, when vegetation most requires it. It was absolutely necessary, moreover, to clear the forest region, for the thick woods afforded shelter to the mountaineers, who, on several occasions, appeared in large numbers, and threatened to sack the town and murder the white settlers. "These marauders came from Lasoni, in the centre of Ovalan, just across the mountains from Levuka; stole down upon the town, plundered the goods of the settlers, and then made off into the woods, where it was useless and dangerous to follow them." Unfortunately, since the woods were cleared the rain falls more torrentially than before, and carrying away the loose soil on the surface, where the ground is steep, does great damage to both soil and vegetation.

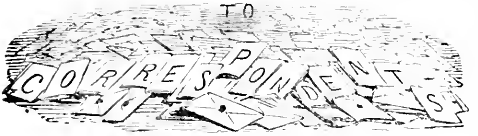
The Fiji Islands number in all 255, having an entire area of about 7,403 square miles, or about 738,350 acres. The largest island of the group, Vili Levu, has an area of 4,112 square miles, while the next in size, Vau na Levu, has an area of 2,432½ square miles. The others are all much smaller. About eighty of the islands are inhabited, the white population being about 2,000 (in 1871), the natives numbering about 140,500. As regards communication with the outside world, Fiji is not badly off. Twenty-four hours after the arrival of the mail from San Francisco at Sydney, a fine steamer of 1,000 to 1,500 tons leaves for Levuka, the voyage occupying seven or eight days. The steamer remains at Levuka nearly a week, and leaves with the mails for England in time for them to be transhipped to one of the Peninsular and Oriental steamers at Sydney. From Melbourne there is direct steam communication with Suva and Levuka once every five weeks. There is also regular steam communication between Levuka and Auckland (New Zealand), and between Levuka and the Friendly Islands. A visit to the Fiji Islands during the cool season would be pleasant for any one who enjoys change of scene; but it is clear from Mr. Horne's book that the naturalist (especially the botanist) would find such a visit at once interesting and profitable.

The natives are hospitable, as also (which is of more importance, perhaps) are the white settlers. The Fijians are daring sailors, and good customers to the boat-builders, who have taken the place of the native canoe-builders. The natives play a number of athletic games, among which may be mentioned throwing the *tinika*, or reed, wrestling, and a game which is something like tennis, a little like cricket, and a great deal like skittles. They throw the tinika (an oval-shaped piece of wood about four inches long and two in diameter at the thickest part) a distance of about 300 yards, or thrice as far as our best cricketers can throw a cricket-ball. The natives are subject to elephantiasis, and consider their children neither strong nor healthy till they have experienced an ulcerous disease, which they call *coko*. A kind of ophthalmia is not uncommon, but it lasts only a few days, both natives and settlers being subject to it. The natives have succumbed in great numbers to epidemics of measles, and many consider that the population has, in consequence, become greatly decreased. But Mr. Horne considers that the many abandoned "patches" may indicate rather a change in the habits of the people than a diminished population.

The animals indigenous to Fiji are bats, flying foxes, and a small rat. The ten species of snakes found there are all harmless. Pigs, introduced from Tonga (where Cook left them), run wild in the forests. There are wild ducks, snipe, sand-pipers, wild pigeons, and beautiful golden orange doves, as well as parrots or parroquets. Whales and porpoises abound in the seas round the group, which swarm with many kinds of fish, edible and otherwise. Sharks abound in the seas, and travel long distances from the sea to the deep pools in the rivers, which must render them less pleasant to bathers than they otherwise would be.

Mr. Horne's book is full of interesting facts, and though it has been specially written in response to an official invitation, it will be found very pleasant reading. There is a copious index—indeed, the index is a little too copious, a passing word in the text being, in many cases, all that is found to bear on a carefully-paged index heading. The facts gathered together here are the fruits of a year of faithful and laborious research.

* "A Year in Fiji: an inquiry into the Botanical, Agricultural, and Economical resources of the Colony." By J. Horne, F.L.S., &c., Director of Woods and Forests, and Botanical Gardens, Mauritius.



Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. He requests that all communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

THE 1 INCH MAP OF THE ORDNANCE SURVEY.

[4]—From time to time we hear expressions of admiration at the beauty and fidelity of those maps of Great Britain and Ireland, based upon that great Trigonometrical Survey, which really began in 1784. In fact, an "Ordnance Map" is with many people a kind of synonym for all that is topographically accurate in the shape of cartography. I venture, however, to express my belief that praise is bestowed upon these maps—be it observed that I am now speaking only of those on the scale of 1 inch to a mile—I say, I believe it will be found that praise is bestowed upon them in the inverse ratio of their employment for purposes where minute accuracy is essential. I have said that the survey began in 1784, because it was in that year that the Triangulation for correcting the Observatories of Greenwich and Paris was commenced by the measurement by General Roy of his famous base of 27,404 feet on Hounslow Heath. I believe, however, that what is now known as the Ordnance Survey had its beginning in 1791, when proceedings were initiated by the remeasurement of the base of which I have just spoken, by Colonel Williams, Captain Mudge, and Mr. Dalby. As an illustration of the manner in which, up to a pretty recent period, the maps on which I am commenting were produced, I may here say that one purchased within a comparatively few years lies before me as I write, and bears upon the upper part of it the legend, "Published 1st February, 1813, by Lieut.-Colonel Mudge, Tower." Now, it is abundantly evident from this, that an old plate must have been worked upon and patched up year after year, alterations being engraved somewhere about the place in which they had occurred; but, as I shall immediately show, they seem to have been put in merely by eye, so erroneous are a large proportion of the minor details when tested with minute precision. To give a single illustration: the mark + stands for a church upon these Maps; but a query as to whether the intersection of the arms of the cross gives the site of the spire (the conspicuous part from which it might well be supposed that all measurements would be made) is always met at the head office at Southampton by the reply that the cross is merely a conventional sign, and does not represent any part of the church in particular! Another stock answer, too, to complainants at head-quarters is that distortion arises from shrinkage in drying the maps: such shrinkage being unequal, and dependent upon the manner in which the maps are hung up to dry after printing. Whence it would appear that after between 79 and 80 years' practice and experience, the combined science of the entire staff at Southampton is unequal to provide for the equable shrinking of a sheet of damp paper. I have been led into these remarks by a recent piece of personal experience, in the shape of the attempted identification of all the chief objects visible from a height, by the aid of a 1-in. Ordnance Map and a 6-in. transit theodolite. One observation will suffice to illustrate the ground of my complaint. It is that of a large and conspicuous church-tower, 8½ miles from the place of observation; the angle between which and the meridian differed 51′, as measured by the instrument and on the map; 51′, 8½ miles off, representing, it is almost needless to add, about 706·7 feet or 235½ yards. The fact seems to be that, while the greater triangles have been surveyed with all the refinements of Geodetical science, the filling in of the details has been done "anyhow." I have, I verily believe, seen quite as accurate plans made by pacing, and with an ordinary prismatic compass. Such of the 25-in. maps as I have examined really do seem to afford remarkable examples of painstaking correctness; and I am informed that those on the 6-in. scale are equally praiseworthy. Moreover, I learn that a new series of 1-in. maps, reduced from this 6-in. survey, are in the course of publication. If this be so, we may live in hope that we shall some day be in possession of a series of portable maps, vieing in accuracy with those issued by the German and other Continental Governments. Meanwhile, let no one go into a shop to purchase one of the present 1-in. Ordnance Maps under the impression that he will receive a rigidly correct chart of the region professed to be represented: because he will not.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

IS THE SUN HOT?

[5]—Will you permit me to remark that "Anti-Guebre's" letter (No. 1., p. 15) is in some respects a repetition of an article of mine entitled "The Astronomy of the Future," which appeared in *Fraser's Magazine*, Nov., 1876, since published in a volume, "Pith," in which I endeavoured to maintain that, in spite of the revelations of the spectroscope, the theory that the sun is incandescent is wholly untenable and improbable. My reasons for thinking so are given at length in the paper mentioned; but perhaps it may be as well to repeat here that if we start with the supposition that the sun is a gigantic galvanic battery, there can be no more reason for believing it to be red-hot, than there is for assuming that the battery we use in our laboratory is a sort of furnace.

Light and heat are surely phenomenal products, caused by magnetic and electrical forces, in a state of intense activity, acting upon atmospheric conditions; so that we are at perfect liberty to maintain that Mercury need not be any warmer or more illuminated than is our earth or Jupiter. The sun may possess the power of producing the phenomena of incandescence, without itself being incandescent.

The inflammatory action apparent on the face of the sun may be merely the chemical conversion of substance into force; and if we could see the working of a dilute acid on the surface of the metallic plates in a galvanic battery, we should probably discover on a minute scale a corresponding commotion to that which is so conspicuous on the sun.

As stars differ from each other in their material composition, it is only natural that the revelations they make of themselves in the spectroscope should be also constitutionally different.—Yours, &c.,

NEWTON CROSLAND.

[6]—You wish for more reasons in favour of the sun's being a cold body. Why is it that, although we have reflected sunlight from the moon, we do not see that light on its way to that body? Surely there would be a broad flood of effulgence along the heavens.

TYRO.

INFLUENCE OF SEX ON MIND.

[7]—Permit me to take exception to the title of the article "Are Women Inferior to Men?" To hold that woman's mind is, like her body, naturally weaker than man's, does not imply absolute inferiority. Overwhelming evidence to prove woman intellectually weaker than man can be classed under five heads:—1. *Anatomical.*—Head-forms, shape of skull, size of brain. 2. *Physiological.*—Woman is always, more or less, an invalid. Hence, if supposed equal to man in intelligence, she is heavily handicapped by her physical organisation. Sex must influence mind. 3. *Historical.*—If the sexes are equal in mind, why has man's intellectual work so far surpassed that of woman? Why was not the alleged sexual mental equality asserted and proved long ago? 4. *Daily Experience* that women cannot argue, and never see more than one side of any question. 5. Woman's *Superior Instinct;* a decisive proof that she has *less reason* than man.

The subject is highly interesting and important, as determining woman's proper sphere and education. If permitted, I would gladly place my views concisely before your readers.

Nov. 5. Yours, &c., J. MCGRIGOR ALLAN.

[Certainly.—ED.]

THE NOVEMBER METEORS.

[8]—In your first number you invite correspondence, and I therefore make no apology for writing and suggesting that, as your publication is intended for beginners in science, it might be an advantage

if in your next number, it were pointed out at what hour, and in what direction, intending observers should look out for the November meteors—that is, as proposed in the current number, use "plain untechnical language", and may I further suggest that (making use of your own two typical words), if you write about small-faced or long-headed men, you would *combine with them* the technical word—e.g., "the race was dolichocephalic, i.e., long-headed." By this means your readers will understand the technical terms, without referring to their lexicons, when they come across them in more advanced books.

London, Nov. 9, 1881. A. T. C.

[The meteors of November 13-14 will hardly be seen this year. If seen at all, it will be after midnight, and they may equally well be looked for in all parts of the sky.—Ed.]

THE EARTH'S INCLINATION.

[9]—It may seem a ridiculous question to ask you to answer, but I can find no satisfaction in scientific primers. Will you kindly tell me, simply and clearly, the reason of this:—The earth's axis is at an inclination of 23° (?) to the sun. Very good. Now suppose the northern hemisphere be nearer that body, if the earth should spin around itself and the sun, why, when it gets on the opposite side, will the northern hemisphere be turned from it? Does the bottom of the body move out [? move nearer], while the top recedes in its annual revolution? TYRO.

SPEED OF AMERICAN ICE-YACHTS.

[10]—With reference to your reply to my query at p. 16, I must confess that while I see the reasoning I had supposed conclusive is not so in reality, yet I fail to understand how there can be any driving force on a vessel driven by the wind when her velocity is equal to that of the wind. It seems to me the observed fact that an ice-yacht travels faster than the wind can only be explained by supposing that the wind comes occasionally in blasts much stronger than the average force of the wind. A fierce blast might give an ice-yacht a velocity much greater than the average velocity of the wind, and owing to the slight frictional resistance, she might retain that velocity with very little loss until the next blast came.

UPSILON.

[11]—An explanation of the great velocity attained by ice-yachts is given in the August number of *Scribner's Magazine*. It runs as follows:—An ice-yacht makes "the greatest speed on that course in which she meets with the least air friction, receives the strongest push of the wind in a forward direction, and yet does not lose the wind too much by her own speed. This course is running free, with the wind on the quarter, or about one hundred and thirty-five degrees off her course. Suppose the boat heads north-west, while the wind blows from the west. Now, her speed diagonally across the wind causes her to receive the wind on the beam, as if it blew from the north-west. She practically has a wind on the beam; this offers but little air friction against her forward motion. The running-friction is so slight that the boat keeps her way, the direction of the sail-push is sufficiently forward to be advantageous, and, lastly, her diagonal course, partly with and partly across the wind, saves her from losing too much of the wind's force by her own speed. Suppose that a twenty-knot breeze blows from B to C, and that she heads towards D, while the wind, represented by the arrow A, blows in a given time to C, it carries the boat with it in nearly the same time; but as she heads diagonally across the wind, she is obliged to run the long distance from B to D, while the wind blows only from B to C; she therefore beats the wind. Her speed is limited only by the loss or change of the wind through the effects of her own velocity. The greatest velocity of an ice-yacht is not recorded, because her finest runs occur either at unexpected moments, or when she sails over unmeasured distances. But the time over short and long courses has often been taken. The distance from New Hamburg to Poughkeepsie is over seven miles. The *Sn[illegible]* ran this course in seven minutes. This is the quickest time on record; but many winters the trip has been made in from nine to ten minutes. This speed is attained with a stiff breeze on the beam or on the quarter, and when the ice is tolerably smooth and clear of impassable cracks. But an ice-yacht very seldom runs a straight course for even a mile. Various obstructions have to be avoided; the wind changes direction very often, and also comes and goes in fitful puffs over the hills. The consequence is that she makes a very crooked course at very uneven speed; she goes more than seven miles, and sails at her full speed during much less than seven minutes. Probably she flies at times from eighty to one hundred miles an hour. The speed of an ice-yacht, in working to windward, which is her poorest course, is from ten to fifteen miles an hour, against an eight or ten-knot breeze."

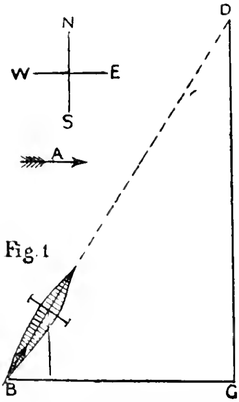


Fig. 1

YACHTSMAN.

[Thanks to "Yachtsman" for his interesting extract. I do not think the explanation, however, is strictly satisfactory. What we want to have explained is just what the explanation takes for granted, namely, *why* the ship runs the longer distance BD, while the wind has gone over the shorter distance BC. Any account which simply says that she does, or that she is obliged to, can hardly be regarded as an explanation. When we consider, too, that with every change of her velocity there is a change in the direction in which the sail-push acts, of which the above so-called explanation takes no account, it must be admitted that it is open, as an explanation, to objection. The explanation referred to by "Upsilon," which I gave in the *Newcastle Weekly Chronicle*, ran somewhat on this wise:—

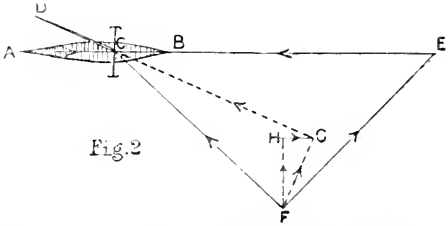

Fig. 2

Let AB be the centre line of the yacht (bow at B), CD her sail. Let CE represent the yacht's velocity at any moment, the effect of which is, of course, equivalent to the existence of a wind blowing in direction EC, and having its velocity represented by EC. Let the actual wind be in direction FE (which would be, if the yacht were at rest, a wind on her quarter), and represented in velocity by FE. Then, by the principle known as the "triangle of forces," we know that the effective wind comes in direction FC, and with a velocity represented by FC. Now, we must resolve this into the two velocities FG, perpendicular to the sail, and GC parallel to it; of course the resolved part GC corresponds to a wind which could have no effect whatever, and therefore may be neglected. What remains is a wind blowing with velocity FG square to the sail. This wind we resolve in turn unto two, one HG, parallel to the yacht's course, the other FH, perpendicular to it. The last has no effect in urging on the yacht, only inproducing lee way. The effective driving wind with velocity HG remains, and unless the accelerating force of this wind is counterbalanced by frictional resistance, it will increase the yacht's velocity, which already exceeds that of the wind.—Ed.]

ARE MEN'S HEADS SMALLER THAN OF YORE?

[12]—In a letter to your contemporary *Nature*, Mr. W. B. Kesteven states that in the hat trade the opinion is prevalent that within the last thirty or forty years the size of men's heads has diminished. "The following statement," he says, "has been given to me by a hatter, whose name has attained a pre-eminence lasting more than a generation." "Five-and-thirty years ago, when I was a young man, we used to purchase hats for retail trade in the following ratio:—

Sizes	21—21½—22—22½—23—23½ inches
Relative number	0— 1 — 2— 4 — 3— 1

At the present time," he adds, "I am selling hats in this ratio —

Sizes	21—21½—22—22½—23—23½ inches
Relative number	3— 4 — 3— 1 — 1— 0"

A manufacturer writes:—"I should say that heads generally are two sizes less than at the time you refer to. A head of more than twenty-four inches' circumference is now quite a rarity, whilst we

make thousands of hats for heads with a circumference of about twenty-one inches." "I have received similar statements," Mr. Kesteven says, "from other members of the trade, both wholesale and retail. The statement comes to me not only from men of experience in the trade, but from men of intelligence and observation exercised beyond the limits of the shop or the factory. It is, I am informed, extensively believed among hatters; it may, nevertheless, be merely a general impression. The diminution, it is said, is observed mostly among grooms and men of that class in the social scale. If this be really the case, the change should be noticeable also among soldiers. The diminution is possibly more apparent than real, and may be traceable to alteration in the style of hair-cutting, or of wearing the hat. It has been suggested to me that men of the present generation have from birth smaller heads, dependent upon an alteration in the dimensions of the female pelvis, in consequence of modern fashion in dress. Of this opinion, however, I obtain no confirmation from eminent obstetricians of whom I have made inquiries. The statement, then, as it stands, is wanting in explanation, and calls for further investigation." Mr. Kesteven quotes the reply sent him by Professor Flower to his question as to the statement made by the hatters, "that men's heads were smaller than they were twenty years ago":—

"Before drawing any important conclusion from such a statement, it would be necessary to know much about the authority upon which it is made. Who, for instance, are the hatters that make it? Do all hatters concur in the same statement? Is it a mere general impression, or is it founded upon actual arithmetical data? Does it refer to any particular class of men, and does it refer to the same class of men? If it should be true, may it not arise from some change of fashion, if only founded upon the size of the hat, and not of the head) other even than the one you suggest of hair being worn shorter—such as hats being worn more on the top of the head than formerly (in old-fashioned prints one sees the hat well down over the ears, which is certainly not the case now), or, perhaps, hats of the kind specified being now worn by a different (perhaps lower) class of the community, or by younger people? All these questions must be considered, and, perhaps, other sources of error eliminated which may not occur at first, before the statement can be accepted. If the evidence of the statement appears to bear investigation, it would be well worth while following it up, as, if true, it would be one of the most remarkable facts with which I am acquainted, that in the space of twenty years a material diminution in the average size of the heads of the same population had taken place—a fact so contrary to all theory and to all experience."

Professor Flower's opinion seems to me very much to the point. I may note, in addition, that the different material of which hats were made thirty years ago may have something to do with the supposed change. Those who remember the heavy beavers of that period will hardly doubt, I think, that they must have been worn more loosely-fitting than the lighter hats of the present time.

Can any readers of KNOWLEDGE throw light on this subject? Considering that the hope of the future lies much in our growing men with larger heads than now, it would be a serious matter were the hatters right.

Are grooms and men of that kind drawn now from the same classes as of old? May not the best of those classes now seek better employment? Or may not emigration have had something to do with the supposed change?—Yours, &c.,

CEREBRUM.

[The question raised by Mr. Kesteven seems to us of considerable interest, though it is utterly unlikely that within so short a time, any change, such as hatters suppose, can really have taken place in the size of men's heads—even if, which is almost as unlikely, any change in the direction suggested is going on at all. We may mention one circumstance, which, however, would hardly affect grooms. Wigs were certainly more commonly worn thirty years ago than now, and wigs in those days were wigs indeed. The average size of hats must have been quite appreciably greater in those times on that account alone, we should imagine. It is, however, really true that hats of 23½ inches are no longer kept in stock? We should have supposed, from our own observation, that in any good hat-shop a hat of 24 inches could generally be obtained. This leads us to consider another point. Possibly hatters measured heads differently in former times than at present. If they measured round the head then, instead of taking, as now, the two diameters of the cranial oval, they would certainly have had a higher average for the circuit of the head. Any one who has examined the head-shapes in American hat-shops will know that nine heads out of ten are quite irregularly shaped. We have seen some having an outline more like a long oblong than the oval which a well-shaped head should have. But taking the case of a regular oval (or egg-shape), or even a truly elliptic head, the true circumference would be somewhat greater than that inferred from the hatter's reckoning. Take, for instance, a head section having diameters 6 and 7: then, if I remember rightly, the hatter would call the circumference 3 times 6½ inches + 1 inch (*i.e.*, an inch more than three times the mean between the two diameters), or 20½ inches. Now the actual circumference would be in the case of an ellipse—

$$7\pi\left[1 - \tfrac{1}{4}\cdot\frac{13}{49} - \frac{1}{64}\,\frac{(13)^2}{(49)^2}\,\&c.\right]$$

$$=\frac{3\cdot1416}{21952}\times 113303$$

or 20·58 inches; that is, nearly a tenth of an inch longer. In the case of an oval shape the difference would be about a tenth and a half, while, in the case of an irregular head, it would be fully a quarter of an inch. Where the section of the head is long (dolichocephalic), the difference between the estimated and the measured circumference would be much greater.—ED.]

THE FIFTEEN PUZZLE.

[13]—I am told that in a magazine article which appeared some time since, you have attempted to show that there are positions in the Fifteen Puzzle from which the won position can never be obtained. As I believe that the won position can be obtained from any position whatever, including that in which the numbers 13, 15, 14 appear in that order on the last line, I should like to know how the reverse has, in your opinion, been demonstrated.—BOSS.

[I thought the Fifteen Puzzle was dead, and hoped I had had some share in killing the time-absorbing monster. (It is an excellent puzzle, by-the-way, except when the puzzled ones try to do impossible things with it.) I have no doubt "Boss" has succeeded in obtaining, from the losing position he names, or others of the same class, what he regards as a won position. For instance, he may have obtained the arrangement—

	1	2	3
4	5	6	7
8	9	10	11
12	13	14	15

or some other, which seems as satisfactory to him as the true won position. But he cannot have obtained this last. The proof would occupy too much space to be given here. But "Boss" may try this. Taking any positions at random, let him take the fifteen numbers one after another as they occur, and for each let him count how many come after it which ought to precede it (running along the lines in the way in which we read the lines of a book, or as the numbers run in the won position). Let him add together all the numbers he thus obtains, and call the result the "total displacement." This number will be either odd or even. The vacant square will be either on an odd line (the first or third) or on an even line (the second or fourth), or, for convenience of expression, say the vacant square will be either odd or even. Now, he will find that if the "total displacement" and vacant square are both odd or both even, so they will remain after any change he may make by sliding a block, after two such changes, after three, in fine, after any number of legitimate sliding changes. If the "total displacement" is odd and the vacant square even, or *vice versâ*, so will they be after any number of legitimate sliding changes. ("Boss" will readily see the *raison d'être* of this, after examining a few cases.) No amount of changes, then, will cause the "total displacement" and the vacant square to be both even or both odd, unless they were so at the outset. As they have to be both even in the won position (for which the total displacement is 0, an even number, and the vacant square on the fourth, an even line, whereas, when the last line runs 13, 15, 14, the total displacement is odd and the vacant square even) no amount of changing will bring the losing position, mentioned by "Boss," to the true won position.

In the article referred to I showed that what, as I have above said, will be found on trial in any given cases, must be universally true. I also showed, in a part of the article which most readers found rather tough reading (there were several misprints, too, the article having been written when I was in Australia), that from any position any other of the same class, either losing or winning, can be attained. As there are more than ten millions of each kind, it is not wonderful that the proof of this general proposition was not altogether simple.

It is singular to think that though probably not fewer than twenty millions of persons tried the Boss Puzzle, probably not a

hundredth of the multitudinous positions of which the pencil-ledicats were occupied among all the positions (set up, attained, or passed through) in the thousands of millions of trials those millions made.

If "Boss" is not content, let him try the easier task of bringing eight blocks from the position shown in Fig. 2 to that shown in Fig. 3.

1	2	3
4	5	6
8	7	

Fig. 2.

1	2	3
4	5	6
7	8	

Fig. 3.

This is a less complicated task than that of the original "Boss" puzzle, for instead of more than 10,000,000, there are only 181,440 losing positions in a nine-square puzzle. Or he might try to change from

1	2	3
5	4	

to

1	2	3
4	5	

There are only 360 losing positions in a six-square puzzle. Or finally from

1	
3	2

to

1	2
3	

, where he has only twelve losing positions to trouble him. He will see at once that the last task is an impossible one; but he may rest assured it is not more completely so than the others, and it wastes much less time.—Ed.]

Queries.

[1] Ultima Thule.—One often finds the expression *Ultima Thule* used as if indicating the remotest known regions of the earth. Where in classical authors is this expression used, and in what sense?—Alpha Sigma.

[2] A Fifteen Puzzle.—Most of your readers are no doubt familiar with the puzzle how to send out fifteen school-girls walking, three and three, so that during seven successive walks no two of them shall be more than once in the same set of three. Is there any mathematical treatment of this puzzle corresponding to the mathematical treatment of permutations and combinations? It seems to me that there should be. For instance, one might begin by showing that nine persons could walk out three and three (with the same restriction) for four successive days, and then apply the method of demonstrative induction to show that if $3\,(2n-1)$ persons can be arranged to walk out in the required manner on $(3n-2)$ different days, then also $3\,(2n+1)$ persons may be arranged in the required way on $(3n+1)$ different days. It will be obvious that the number of persons must be of the form $3\,(2n\pm1)$; that is, three times some odd number. The successive numbers to be dealt with are, therefore, 3, 9, 15, 21, &c., and the number of days in which the three can go out in the required way are respectively 1, 4, 7, 10, &c.—Rusticus.

[3] Flight of Birds.—Is it the case or not, that the flight of birds is greatly aided by the presence of warm, and, therefore, light air in the air passages of the bones?—Aerial.

[4] The Earth's Inclination.—In diagrams explaining the season's differences, the figure of the earth is shown to rotate on an oblique axis. Were it to rotate on an upright axis, would not perpetual summer reign at the poles, with greater heat at the equator?—Moonstruck.

[5] Hot Winds, Cause of?—The difficulty is as to the force from front or back which will overbalance the tendency to *rise* over the hot area. Take the case of a Mediterranean sirocco, why is there not rather an *in*rush to the hot sandy plains?—L. S.

[6] Lying To.—Wanted, diagram of forces when a ship lies to, 1° under sale, 2° under steam.—L.S.

[7]—Flying Bridge.—Wanted, diagram of forces, arrangement of rubber, position of ropes, when the vessel has passed the middle of the river.—L. S.

[8] Volume of Sphere.—Is there any simple way of showing that the volume of a sphere is two-thirds that of the enclosing cylinder?—Archimedean.

[9] Sun-dial.—Can any of the readers of Knowledge describe any method of constructing a sun-dial by which the error arising from the shadow not being sharp may be got rid of?—Solar Time.

[10] The Zoetrope.—In the zoetrope we get a series of pictures of a moving body, showing it in a certain number of positions from among the infinite number that it passes through in accomplishing the movement illustrated. Can any one explain how it is that the impression conveyed to the mind by this incomplete series of views is that of continuous motion? It seems to me that we ought to recognise a certain jerkiness in the apparent movement. But in well-arranged zoetropic illustrations no jerkiness can be noticed.—Zulu.

A Cargo of Human Bones.—New York, Sept. 11. A special from London says:—A great sensation was caused at Bristol by the discovery of a cargo of three hundred tons of human bones being discharged there to the order of a local firm engaged in manufacturing manure. The bones were shipped from Rodosto, at Constantinople, and are supposed to be the remains principally of the defenders of Plevna. There are complete limbs among the horrible cargo, and in some cases the hair still adheres to the skulls. Peter Cooper says it is a common thing among the British to buy human bones. "In fact, they will take all they can get at any time and from any part of the world. They use them for manuring their lands. I have often heard it said that England was manured with bones taken from the battle-field of Waterloo. There is no finer to be had."—*New York Herald.*

Science in the Police Court.*—At Bow-street last week, Mr. Waddy, Q.C., attended before Sir James Ingham, with Mr. Besley and Mr. Bernard Coleridge, to apply for a summons under the Vivisection Act, against an eminent professor of science. Special reference was made to the subsections providing for a licence to be granted to any one practising vivisection, and for the administration of some anæsthetic of sufficient power to prevent the animal feeling any pain during the experiment. If pain was likely to continue after the effect of the anæsthetic had ceased, or any serious injury was inflicted on the animal after the experiment, it was to be killed before it had recovered from the effects of the anæsthetic. When it was desired to extend the experiments for a lengthened period, it was necessary to procure a certificate authorising the extension of the experiments, and the summons was asked on the ground that this provision in the Act had not been complied with. In support of the application the learned counsel read extracts from a report in the *Lancet* on cerebral localisation, the subject having been brought under the notice of the recent International Medical Congress. One of the speakers was Professor Goltz, who had experimented upon two dogs by exposing the surface of the animals' brains, and washing away large portions of the substance by subjecting it to the action of a powerful stream of water. With reference to this experiment, Professor Ferrier has expressed his views upon the subject and gave details of some experiments he had made upon two monkeys. These animals had been operated upon some months previously, definite motor paralysis being procured in one, and in the other absolute and perfect deafness. The animals subjected to these experiments were produced by each of the professors, Professor Goltz asserting that he had removed the greater part of both hemispheres, including all the supposed motor and sensory areas. That the operative procedures to which the animals had been subjected had been extensive was quite obvious upon examination of the skulls, large gaps in the continuity of the upper and external walls of which were felt. Saving some clumsiness in its movements, one of the dogs showed but little signs of injury. It appeared possessed of considerable intelligence, and certainly did not suggest to the onlookers that it was a dog demented. In startling contrast were the two monkeys exhibited by Professor Ferrier. One of these had been operated upon in the middle of January, the left motor area having been destroyed. There had resulted from the operation right-sided hemiplegia, with conjugate deviation of eyes and head. Facial paralysis was at first well marked, but ceased after a fortnight. From the first there had been paralysis of the right leg, though the animal was able to lift it up. Its arms it had never been able to use. Lately rigidity of the muscles of the paralysed limbs had been coming on. The other monkey, as a consequence of paralysis of its auditory centres, was apparently entirely unaffected by loud noises, as by the firing of percussion-caps in close proximity to its head. From the *Times*.

* The report would be somewhat clearer if it were not taken throughout for granted that the readers must necessarily be medical students. Why should not paralysis of the right side be written, instead of right-sided hemiplegia? wryneck and squinting for "conjugate deviation of eyes and head?" The "motor and sensory areas" are, of course, those parts of the brain which are supposed to regulate respectively the movements and the sensation.

UNHEALTHY HOUSES.*

In an interesting lecture at the London Institution, Prof. F. de Chaumont mentions the following causes of disease:—

(1) Want of renewal of air in our rooms.

(2) The pollution of the house air by admixture with sewer emanations.

(3) The contamination of our water supply.

He says that could arrangements be effectually carried out in our dwellings for removing these causes of disease, certain much-dreaded maladies might disappear altogether. "But we must further remember," he proceeds, "that it is not death alone we have to dread, terrible as its effects often are in a household. For every case, we have to bear in mind, argues a considerable number of cases of illness, which, even if recovered from, may leave consequences behind them sufficient to affect the health of a lifetime, and to diminish the power of the sufferer for the work he has to do. The duration of illness alone is often a serious break in the life of a professional man, artisan, or labourer—a break which in some cases may mean the difference between comfort and penury, or between a successful career and a struggle for existence." "I think I shall be understating the case," he says, "when I say that each case of death argues about a dozen cases of illness, although the number is somewhat less in the severer diseases, such as enteric fever, which is fatal in one out of six cases, and diphtheria, which kills one out of three." Taking even these, however, Prof. de Chaumont shows that in London alone from 50,000 to 60,000 weeks of productive labour are totally lost to the community from illness due almost entirely to the unhealthiness of our houses.

The lecture was delivered for the purpose of bringing before the public the subject of sanitary assurance, and to advocate the cause of the Sanitary Assurance Association, founded in November, 1880. The objects of the Association are as follow:—

"The practical application of Sanitary Science generally, and especially the encouragement and development of proper systems of house-drainage, water supply, and ventilation.

"The examination, inspection of, and reporting on houses and buildings, or plans of houses and buildings, either erected, in course of erection, or to be erected, as regards their sanitary arrangements; the supervision by the officers of the Association of any work done, or to be done, by or on behalf of the members of or subscribers to the Association in connection with the sanitary condition of such houses or buildings; and the granting of certificates relative thereto.

"The publishing of reports on matters connected with the progress of sanitary science in the United Kingdom and abroad, and the distribution at the end of each year of any surplus funds, or part of any surplus funds, to such institutions as are devoted to the advancement of sanitary science."

If there is one application of science in which all should be interested, it is the endeavour to diminish disease and suffering. Were there no nobler reason, sheer selfishness might well cause all men who claim to be reasoning beings to join, each to the best of his abilities, in helping the cause of sanitary reform. But this is in truth a case where the good of each is the good of all.

That the objects of the Association may be the better effected, it has been formed of two classes—(1) Members who are responsible to a certain amount for the necessary expenses of the Association, and who have a voice in the management of its affairs; (2) Subscribers who incur no liability, and who will take no part in the management of the Association.

The Association not being formed for executing works, leaves the members and subscribers to employ any person they may select to carry out the recommendations of its officers.

Members and subscribers alike contribute an entrance-fee of half a guinea and an annual subscription of half a guinea, or a life-subscription of five guineas, and on payment in accordance with the graduated scale, they are entitled to have one house in London placed on the Assurance Register. The fees for houses outside the metropolitan district will be increased according to distance. The secretary of the Association is Joseph Hadley, Esq., 5, Argyll-place, Regent-street, W.

PLAIN WORDS IN SCIENCE.†

In making use of language to express our thoughts, we ought to be sure—(1) That the words used really express the idea which it is wished to convey; (2) that they are the shortest; and (3) that they are the most familiar words which are available. Words must be as objective as possible, *i.e.*, they should bring the subject with the utmost vividness before the mind's eye; and, therefore, those words to which the eye, and the ear, and the mind had been accustomed for the longest time (vernacular terms used from infancy) were the best; and, other things being equal, the shortest words were the best. If the advantages of expressing themselves simply were so obvious, why, it would be asked, do men continue to use the polysyllabic gibberish which passes current as the language of science, but which proves that they have not yet come to a right comprehension of the scientific use of language? By using a language "not understanded of the people" for the expressing of scientific facts, they undoubtedly seriously curtailed the area from which they drew their scientific recruits; and he took it that one explanation of the scientific fervour which pervaded the whole of Germany was to be found in the fact that scientific terms were in that country very largely derived from the German vernacular, and that he who only knows the German language was not necessarily confronted in a German scientific book with words which compelled him to close the volume almost as soon as opened with a sigh of helplessness and hopelessness. It must be admitted that our long words had not hitherto been of much use as a means of international communication. For international communication they must make themselves familiar with each other's languages. That was certain. And it was manifestly of importance that each nation should try to keep its language pure, in order that it might be the more easily learned. The practice of concubinage with the dead languages merely had the effect of producing a mongrel language (as unproductive as are all other mules), of huge bulk and monstrous form, which has to be learnt as an additional study. It seems to be the pitiable ambition of some writers to seize upon a trifling fact, and to give it the longest name they can invent with the aid of a lexicon. Some, possibly, are under the impression that their dictionary-made expressions may gain for them a reputation for classical learning. They cannot afford, as did John Hunter, to rely for their reputation upon the facts which they discover, who, when he was twitted with his want of knowledge of Greek and Latin, wrote thus characteristically to a friend: "Jesse Foote accuses me of not understanding the dead languages; but I could teach him that on the dead body which he never knew in any language dead or living." The defence has lately been put forward for scientific jargon that every trade or profession must have its own technical terms. He confessed he could not see the necessity. The tailor, as far as he knew, derived no advantage from calling his smoothing-iron a "goose"; and seamanship is not advanced because a sailor's "companion" is one thing at sea and another thing on shore. It seemed to him that technical terms ought, as far as possible, to be discouraged, because the coining of new words when they are not wanted, and the giving of strange and conventional meanings to common words, must increase the difficulty of acquiring any art or handicraft. Among unworthy motives which had induced them to have long words, must be reckoned the desire to appear more learned than they were. There was in human nature a tendency which was expressed by the words, *Omne ignotum pro magnifico*—a tendency to put an undue value upon the unknown. It was this natural tendency which led the hero of Warren's famous novel, "Ten Thousand a Year," to make the fatal experiment of applying to his hair the pomade called "Cyanochaitanthropopoion," and it was the same tendency which led the public to buy anything, no matter how common or how worthless, to which the vendor had given a name which was utterly incomprehensible to them. By pandering to this tendency he doubted not that medical terms had been in reality an unspeakable, though delusive, comfort to the public; and that the lady who was told by the physician "that there was still in her husband's lung a perceptible amount of 'whispering pectoriloquy,' although the 'ægophony' had happily completely disappeared," derived from the information the same kind of consolation as did the old woman who, listening to a deep and learned sermon by her rector, found solace in "that blessed word Mesopotamia."—*Times.*

* "Sanitary Assurance," a Lecture by Prof. de Chaumont. (J. & A. Churchill, London.)

† From an Address by Dr. George Vivian Poore, F.R.C.P., Prof. of Medical Jurisprudence, University College.

TRUSTING TO LUCK.

It is worthy of notice how little those who trust most to chance understand of the laws of chance. This is shown in hundreds of different ways, but by none, perhaps, more than by the strange selections made by the venturesome among the various methods in which they may risk their money: their preference for this or that form of risk, rather than for some other, is scarcely ever based on any real advantage which one form has over the other. Ask a gambler, for instance, to pay £1 for a ticket in a lottery where there are a thousand equal chances and but one prize of £1,000, and he

will gladly pay the money. He would most probably not refuse even if there were two thousand equal chances, and the prize were still but £1,000, though the real value of the ticket would be but 10s. If, however, you asked him to pay £1 for the chance of getting £1,000 if a tossed coin comes up head eight times running, he will reject (probably with ridicule) the idea of accepting it. Yet in reality the offer is a far better one than the other. He ought to pay very nearly £2 for the chance offered him for £1 (the exact value of the chance is £1. 19s. 0¼d.). Or the "eight times running" might be changed to "nine times running" if the £1,000 prize were increased to £1,024, and the second offer would then be as fair as the other. But the same gambler who thinks he is quite likely, owing to his luck, to draw the right ticket out of a thousand, would utterly despair of tossing head nine times running.

"Increased knowledge confers an increased feeling of duty, and increased power to perform it."—*Maudsley.*

The Cedars of Lebanon.—The Vienna *Politische Correspondenz* says:—The once famous cedar forest of Lebanon, formerly so extensive, has dwindled down to the dimensions of a mere thicket, numbering about 400 trees. To save it from complete destruction and preserve it at least in its present extent, Rustem Pasha, the Governor-General of the Lebanon, has issued a special ordinance, containing a series of stringent regulations calculated to check, if not quite put a stop to, the vandalism and carelessness of most travellers. It is expressly forbidden to put up tents or other kinds of shelter within the district of the trees, or to light fires or to cook any provisions in their vicinity. No one is allowed to break off a bough or even a twig from the trees. It is forbidden to bring any beasts of burden, be they horses, mules, asses, or any other kind of animal, within the district. Should oxen, sheep, goat, or other pasturage cattle be found within the prescribed limits, they will be irredeemably confiscated.

Professional Astronomers and Popular Astronomy.—We are inclined to doubt whether the official chiefs of great observatories are, as a rule, the persons best fitted to write treatises on popular astronomy. It is not that they are unwilling to deal with astronomy in a popular manner. On the contrary, they are apt to adopt too familiar and condescending a tone, as if writing for children. But in reality, their astronomical labours, whether in the observatory or in the calculating-room, are not adapted to give them that knowledge of the general science of astronomy, without which no man can present astronomical truths at once simply and effectively. Their work bears the same relation to the real living astronomy of men like the Herschels that land-surveying bears to geology as dealt with by a Hutton, a Playfair, or a Lyell. They find more interest, as a rule, in the correction of a star's place by the tenth of a second of arc than in the inquiry into the star's attributes as a sun. A perturbation affecting the moon's position by the hundredth part of her diameter is more important to them than telescopic evidence of the most tremendous changes in the moon's surface would be. In fine, their way of viewing the heavenly bodies somewhat resembles the way in which a certain Senior Wrangler is said to have viewed Snowdon, who, when asked if he had climbed that mountain, replied that he had not, because a neighbouring hill was equally suitable for trigonometrical purposes. The astronomy thus taught differs as widely from the astronomy of the Herschels as a series of anatomical plates differs from the Venus of Milo or the Theseus and Ilyssus of the Parthenon.

The Induction Balance applied to Surgery.—It was stated in the *Times* of Aug. 5 that the place of the bullet in President Garfield's body had been localised by the use of the induction balance. The *post-mortem* examination seems to have shown that the diagnosis was incorrect. The *Times* Correspondent at the Paris Electrical Exhibition makes the following remarks on the subject, which are interesting as including a concise and sufficiently simple account of the method in question. "I am convinced," he says, "that if the experiments were conscientiously carried out there could be no error. A remarkable confirmation of the utility of the apparatus as a means of diagnosis has just come to my notice, but I will first give a short account of the action of the instrument. A current of electricity is passed through two coils of insulated wire, which are kept apart. The current is rapidly made and broken by clockwork. Above each coil is a second similar coil of insulated wire, and every time that a current is made or broken in the first pair of coils a second current is induced in the secondary coils. These secondary coils are connected together and to a telephone, and the currents induced in either coil tend to produce a noise in the telephone. But these coils are so connected as to induce currents in opposite directions in the telephone, so that under ordinary circumstances they destroy each other, and no noise is heard in the telephone. If, however, a piece of metal be placed inside one of the coils, the character of the induction is changed in that coil, and the balance is destroyed, so that a noise is heard in the telephone. The amount of noise depends upon the form, mass, and conductivity of the metal placed inside. By choosing pieces of metal all of the same size, but differing in their composition, it is possible to compare the conducting powers of the metals. A long scale of metal, wedge-shaped, is moved along above the coil which does not contain the metal to be tested, until the thickness of the wedge over one coil is sufficient to balance the metal inside the other coil. The reading of the scale on the wedge then gives a measure of the conductivity. Some most astonishing results have been thus obtained. It is found that pure copper electrically deposited has a conducting power far greater than the copper of commerce, the difference being far greater than was generally supposed. I will now describe the experiment which has just been completed. Mr. Elisha Gray, of America, whose name is so well known in connection with the telephone and the harmonic telegraph, was a disbeliever in the utility of the induction balance as a surgical appliance. He said to Professor Hughes, 'Thirty years ago, when working at some metal-work, a filing of iron entered my finger; the more I tried to extract it the deeper it went in. I believe it is still there, and if your instrument is of any value, you ought to be able to tell me in which finger it is.' The presence of bone or flesh in the coil of the balance would produce no effect; a metal or other conductor is necessary. Professor Hughes tested Mr. Gray's fingers; none of them gave any sound until he came to the forefinger of the right hand, when the balance of the coils was quite destroyed, and a noise was given out. This was the very finger in which the filing was buried thirty years ago. I need hardly say that Mr. Gray was completely convinced."

Weather Forecasts.—That the daily forecasts issued from the Meteorological Office are often wrong I need not say. Why they are so is simply because general disturbances in the atmosphere only are taken into consideration, local disturbances being ignored. And so long as the forecasts are based solely upon the distribution of barometrical pressure this cannot be otherwise. When there is no distinctly-developed area of high or low pressure lying over the country or approaching our shores, the forecasts must be made at random, for the observer has nothing whatever to guide him in his prediction. He may say "wind light and variable," or "calm," or "weather unsettled"; but such forecasts are liable to falsification in many districts through the operation of local influences. A little hurricane may start up in one spot, rain may pour in another, and a thunderstorm may burst over a third, all unexpectedly, and the observers in the Meteorological Office could not possibly have been expected to warn the afflicted districts. I think, then, the importance of local meteorology cannot be exaggerated. The distribution of rainfall over the British Isles sufficiently shows the potency of physical conditions, but a more striking example is found in the fact that within a radius of twelve miles around Somersham Railway Station (Huntingdonshire) hailstorms are so frequent and destructive that all the insurance companies charge double the ordinary rates per acre on crops growing within that district. Violent winds, too, are often due to local causes. An instance of this came under my notice some years ago in the Isle of Man, when a violent gale blew over Ramsey from the westward, the air a couple of miles to the north being almost still all the time. The storm rushed along the base of North Barrule, lashing the bay into foam, and apparently becoming dissipated out at sea. The afternoon on which this occurred was bright and almost cloudless, and the storm maintained its fury for several hours. Such local disturbances may be quite as destructive as more general ones, and forecasts, to be of any practical use, ought certainly to take cognisance of the causes which produce them. To render forecasts as reliable as our present knowledge can make them, I would suggest that a local observer be appointed in each district to act in concert with the Meteorological Office, and to base the forecasts upon the information and charts supplied by that office, supplemented by his own knowledge of local conditions and influences. Every district has its system of natural weather signs dependent upon its physical features, and experienced farmers, and others who have given attention to them, can predict the weather with far greater certainty than the functionaries in London. There was a time when natural signs were our only aid to a foreknowledge of the weather, but since the invention of telegraphy and the consequent discovery of cyclonic movements in the atmosphere, the cat has been discarded and the barometer put in her place. Why not use both? Theoretical meteorology, so to call it, determines the general distribution of wind and weather over the country; local meteorology, the particular kind of weather in a district. The one is the complement of the other; and in order to obtain the best result they should be used accordingly, the one supplying what the other lacks.—*J. A. Westwood Oliver in the "Times."*

Our Chess Column.

WE propose to consider the chess openings in the following general order:—

First we shall examine the best methods of attack and defence following from
1. $\frac{\text{P. to K.4.}}{\text{P. to K.4.}}$ 2. $\frac{\text{Kt. to K.B.3.}}{\quad}$ or the *King's Knight's Opening.*

Next we shall examine those following from
1. $\frac{\text{P. to K.4.}}{\text{P. to K.4.}}$ 2. $\frac{\text{B. to Q B.4.}}{\quad}$ or the *King's Bishop's Opening.*

We shall then take the King's Gambit, examining first the various forms of the opening which follow from
1. $\frac{\text{P. to K.4}}{\text{P. to K.4}}$ 2. $\frac{\text{P. to K.B.4}}{\text{P. takes P.}}$ 3. $\frac{\text{Kt. to K.B.3}}{\quad}$
the King's Knight's Gambit. Then those following when White plays $\frac{\text{3. B. to Q.B.4}}{\quad}$ the *King's Bishop's Gambit.*

We shall then consider other openings following from 1. $\frac{\text{P. to K.4}}{\text{P. to K.4}}$ as 2. $\frac{\text{Kt.Q.B.3}}{\quad}$ the Vienna opening; 2. $\frac{\text{P.Q.B.3}}{\quad}$ the *Q's Bishop's Pawn Opening;* 2. $\frac{\text{P. to Q.4}}{\quad}$ the *Centre Gambit*, and so forth.

Next we shall examine the chief openings resulting from
1. $\frac{\text{P. to Q.4}}{\text{P. to Q.4}}$ 2. $\frac{\text{P. to Q.B.4}}{\quad}$ the *Queen's Gambit.*

And lastly, we shall examine the various openings called *Irregular*, which include all openings beginning otherwise than 1. $\frac{\text{P. to K.4}}{\text{P. to Q.4}}$ or 1. $\frac{\text{P. to Q.4}}{\text{P. to Q.4}}$ We may note in passing that some of these so-called irregular openings deserve in reality to be regarded as more regular, because steadier and surer, than many of the openings classed as regular.

We do not propose to give a deep analysis of any of these openings, because our wish is to be of use to the many, not to cater for those who are already first-class players. We wish, in fact, to give just so much of what is called book-knowledge of chess as may enable amateur chess-players to start each game on sound chess principles. We wish also to show how, when they meet opponents of superior book-knowledge, they may avoid those openings in which book-knowledge alone can save them from disastrous defeat.

We shall occasionally deviate from this course to discuss the various points illustrating general principles of play, as such points may be suggested by communications received from our correspondents.

King's Knight's Opening. (Two Knights' Defence.)

There are only three sound replies to the move 2. $\frac{\text{Kt. to K.B.3}}{\quad}$; viz., first, 2. $\frac{\quad}{\text{Q.Kt. to Q.B.3.}}$; secondly, 2. $\frac{\quad}{\text{P. to Q.3}}$; and thirdly, 2. $\frac{\quad}{\text{Kt. to K.B.3.}}$ of which the third is rather a counter-attack than a defence. There is a fourth way of meeting the move, by 2. $\frac{\quad}{\text{P. to K.B.4.}}$ (called Greco's counter-gambit), which, though not strictly speaking sound, is often used with great effect by an experienced player against one unfamiliar with the opening. We shall have therefore to consider it, though briefly, further on.

We take first the line of play which we should advise the learner nearly always to follow till he has become tolerably familiar with its various sequels, viz.:—
1. $\frac{\text{P. to K.4}}{\text{P. to K.4}}$ 2. $\frac{\text{Kt. to K.B.3}}{\text{Kt. to Q B.3}}$
The continuation is now either 3. $\frac{\text{B. to Q.B.4.}}{\quad}$ leading to a number of the most interesting openings known in chess or 3. $\frac{\text{P. to Q 4.}}{\quad}$ the Scotch Gambit, or 3. $\frac{\text{B. to Q.Kt 5.}}{\quad}$ the strong Ruy Lopez attack, or 3. $\frac{\text{P. to Q.B.3.}}{\quad}$ a quiet continuation. If the move 3. $\frac{\text{B. to Q.B.4.}}{\quad}$ is met by the same move on Black's side (Black is for convenience regarded always, in these analyses as second player), we have an opening which may be resolved into the *Giuoco Piano*, or Steady Game, by 4. $\frac{\text{P. to Q.B.3.}}{\quad}$ or 4. P. to Q.3, or into the brilliant Evans Gambit by 4. $\frac{\text{P. to Q Kt 4.}}{\quad}$

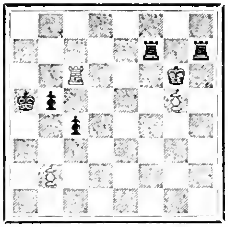
Against a player well acquainted with the openings, the safest reply to 3. $\frac{\text{B. to Q.B 4}}{\quad}$ is, perhaps, 3. $\frac{\quad}{\text{Kt. to K.B.3}}$, which constitutes the Two Knights' Defence; for this move saves the second player from the Evans Gambit, to meet which requires thorough knowledge of a great number of varied lines of play, while declining the proffered Queen's Knight's pawn subjects the second player to a cramped defensive game. We do not ourselves advise 3. $\frac{\quad}{\text{Kt. to K.B. 3}}$ for general adoption, for the games to which it leads are seldom so interesting as those following from 4. $\frac{\quad}{\text{B. to Q.B.4.}}$ But, properly played, it is a safe defence. And as the variations following from it are not nearly so numerous as those from 4. $\frac{\quad}{\text{B. to Q.B.4,}}$ it will be well to dispose of it before entering on the latter.

We shall begin the inquiry into the Two Knights' Defence next week.

In the meantime we give for consideration two positions.

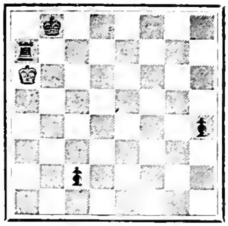
No. 1, which occurred a few nights ago in a game in which we had given the odds of a Queen to a lady.

No. 1. Actual End-Game.
Black. (Lady).



White. (Chess Editor.)
White to play and draw.

No. 2. By Mr. F. Healey.
Black.



White.
White to play and draw.

Black's last move was R. to K.R. 2, imprisoning the King, while leaving the two Black Rooks free to move *ad lib.* along Black's second row. This move, however, enabled White to draw the game. The young player will readily see how.

This, of course, as occurring in ordinary play is not to be regarded as a Chess study. It simply illustrates one of the dangers which a weak player, who, after a game at odds, finds himself with a winning superiority of force, should carefully avoid. Position No. 2, by the celebrated problem-maker, Healey (which appeared in the *Westminster Papers*, as nearly as we can recollect, in 1871) illustrates the same danger very prettily.

[1.] Chess Query.—In an old number of the *Illustrated London News* I find the following problem given by the Chess Editor (then Mr. Staunton, I believe), as a puzzle, by the Anonymous Modenese. White K. at Q.Kt sq.; Q. at K.B. 4; R. at K.Kt.5; B. at Q Kt 2; Ps. at K.B 5, Q Kt.3, and Q.R 2. Black K. at K.R sq., Q. at Q.4; R. at Q.sq.; Kt. at Q.R.5; Ps. at K.R.2 and K.Kt.2. White to play and Mate in four moves. Can any one give me the correct position? There seems to me to be no solution with the position as given. Queen's Knight.

Knowledge.—Although we offer our readers more in the way of original matter (apart from correspondence, which is not to be estimated by mere bulk) than any other journal of similar price and character, we wish to do better still. We hope so to extend the circulation of Knowledge that we may be justified in enlarging each number, in giving more illustrations, and in extending the number of our original contributors. To attain this end we need the co-operation of our readers. Those among them who approve our scope and plan can do more to improve Knowledge than either editor or publishers. If every reader were to obtain but one new subscriber, our circulation would be doubled, and our power to improve the matter placed before our readers would be increased in like proportion. If our readers will remember this, they will follow the best course for making Knowledge what we wish and hope that it may before long become.

Our Whist Column.

By "Five of Clubs."

Introduction.

Whist, properly played, is the finest of all card games, perhaps not even excepting chess—the finest of all sedentary games. But Whist, as it is often played, without any knowledge or appreciation of the real nature of the game, seems to have nothing making it better worth playing than Pope Joan or Casino, and to be decidedly inferior to Euchre. There is an intermediate kind of whist, the game played by persons who have a keen perception of the strategy of the game, but no knowledge of its language, which may be full of interest or full of annoyance, as the cards may happen to lie. To watch a proficient in this kind of whist, playing a good hand, and ably supported by a steady-going partner who understands his ways, one would say Whist was the most delightful of all games; but to see him playing an average hand, and to note his wrath when his partner, considering his own hand, fails to play precisely as he wishes, one would say Whist was a rather severe form of punishment.

The present series of papers on Whist, and the problems, games, &c., which will accompany and follow it, are intended to indicate the nature of the only game of Whist which is worth playing—Whist as a game between two forces, two pairs of partners, each pair having between them twenty-six cards. The game thus played, that is with constant reference by each player to the fact that he has a partner, may be regarded as a really scientific game. It is often called the book game, theoretical play, and by other names, implying that a fine player need care very little about it. But it is, in truth, the only common-sense, practically-sound form of the game, and no one can be regarded as a really good, still less as a fine, player who does not play it. It has, moreover, the additional advantage of being readily learned by those who have not the capacity for really great play; and when it has been learned, such players, though never brilliant, become good and safe partners. Moreover, by learning the rules of scientific Whist, which seem at first an extra trouble to the memory, the learner finds that his power of remembering the fall of the cards is greatly increased. It is, indeed, the purposeless nature of ordinary unscientific Whist play which makes it so difficult for the bad player to remember what cards have been played, and by whom. So soon as he has adopted just principles of play, each hand is played according to a plan, the development of which is full of interest, so that the stages are easily remembered. Each card is played with a purpose, and whether the purpose succeeds or fails, the result is noted and remembered, whereas when there is no purpose, the memory has no such aid.

The first great principle of the scientific game of Whist is to give your partner (always at the beginning, and almost always throughout the play of the hand), all the information in your power within the rules of the game. (There arise cases occasionally towards the end of a hand where it becomes clear that the partner can do nothing, and nothing can be lost by misleading him; then, and then only, false cards, deceiving him, but deceiving the adversaries also, may be usefully played.) To this the objection is repeatedly made—especially by brilliant one-handed players—"a player has but one partner while he has two adversaries, and by playing so as to give information to one friend, he gives information to two enemies, or the harm exceeds the good two-fold." The true answer to this objection does not seem to me to have been recognised by Pole, Cavendish, Clay, and other great masters of the game, who have yet, of course, known perfectly well from practice that it is advantageous to give to your partner all the information in your power. Cavendish says the objection would have considerable force if you were compelled to expose the whole of your hand, but you possess the power of selecting what facts shall be announced and what concealed. Pole says the objection "involves a confusion in reasoning: for if the opponents are equally good players, they will adopt the same system, and the positions must be equal; and if they are not good players, they will be incapable of profiting by the indications you give, and the whole advantage will rest with you: adding that "even good players seldom pay so much heed to their opponents' as to their partners' indications." Pole and Drayson agree in saying that by not giving your partner information, you run the risk of having to fight three opponents single-handed. Clay does not specifically consider the objection.

The true answer seems to me to be different from any of these. The reply of "Cavendish" implies that there is a limit to the principle that it is more important to inform your partner than to deceive your adversaries. Pole's reply takes the system for granted, by assuming that good opponents will follow it; and certainly he does not reason soundly in suggesting that even good opponents pay less attention to their opponents' than to their partner's indications. It is also an exaggeration to speak of a partner as becoming a third opponent if not duly informed as to your cards; he may take one or two of your winning cards, but cannot play as an opponent throughout the hand, as they seem to imply. (The mischief is bad enough, without exaggeration.) The real reason why information to your partner is so important as to outweigh the knowledge given to the adversary, is that it is only by giving him information that your cards can be combined with his in the strategy of the hand. You tell him points about your hand which he can utilise, let the opponents do what they will, although, of course, you may also give him information which he cannot utilise, whether because the adversaries have also learned it, or not. Cases of the latter kind count neither one way nor the other; if you had not suggested such and such a plan, he would not have tried it, and when you have told him he has not succeeded, so that you are none the worse; all the cases of the former kind are so much clear gain.

Take a familiar instance. I lead ace, and follow with queen of my best suit. My partner *knows* that I have the knave and a small card left. Suppose he has the king in his own hand and a small one left after the first round. Now according to the state of the score and of his own hand, it may be better to let the trick fall to my queen, or to take it with his king, leaving me still the command of the suit with my knave. By my play, showing that I have the knave, I have left it open to him to do whichsoever of these two things may be best for both of us, and this choice he has, let the opponents act as they please. But suppose that, instead of following the recognised line of play for such cards, I lead the second round with my small card. My partner plays his king, and, let us suppose, wins the trick. He cannot now play as he would (as it might be absolutely essential to success that he should) if he knew that I had the command of the suit. On the contrary, so far as he can understand me at all, he thinks I have three small cards of the suit left, and that the queen lies with one of the adversaries. His consequent play in this case spoils our common game, whereas in the other case his play advances our common game. In either case it is *his* play, not the opponents', which affects our combined game for good or for ill.

In fine, instead of the maxim, "It is more useful to inform your partner than to deceive your adversary," I would substitute this—"Your single partner can do more good than both your adversaries can do harm by utilising information you may give by your play." (Good here includes the avoidance of harm: we might supplement the rule by saying that your partner is likely to do much more mischief through ignorance of your hand, than could be counterpoised by any good which the adversaries might chance to do you.)

It is the recognition by good players of this first rule, as resulting from the general principle that partners should play in harmony and with a common purpose, which has led to the system of modern whist strategy. There are commonly more ways than one in which, if the partner's cards were seen, the qualities of the combined hands might be used; but there is only one system by which, in the actual method of play, your partner can work in harmony with you. That system being adopted, the principles guiding us in the opening of a hand, and determining the play of first, second, third, and fourth player, are deduced at once. Our books of whist seem, indeed (and it has always seemed to me a fault in them), to require that the learner should know multitudinous rules for leading, and for playing second, third, and fourth; but in reality all these rules depend on one general principle. I do not say that the player ought at once to know, from his knowledge of this principle, his proper course as leader, second, third, or fourth player. He has not time to go through all the considerations involved in applying it to particular cases. He must be content, therefore, to retain a number of rules for such cases in his memory. But his memory will be greatly helped, and the number of rules will be greatly diminished, when he recognises the general principle on which modern whist-play proceeds.

In my next I shall show what this general principle is, why it has been selected in preference to others, which, at first view, seem to have great, if not equal advantages. Afterwards we shall consider how this principle suggests the various leads, the play of second, third, and fourth hand, &c., endeavouring so to treat the matter that the memory may be as much as possible helped to retain the resulting rules, by recognising the string on which these seemingly scattered beads of Whist wisdom are in reality strung.

I may in the next number present a game actually played, mentioning the inferences which a player of the systematic game would make at once. Those who follow our explanation of the system will presently see that these inferences are not, as they might suppose, recondite, but perfectly obvious, even after a very moderate study of the modern system of Whist play.

SOLIDS, LIQUIDS, AND GASES.

By W. Mattieu Williams.

PART I.

THE growth of accurate knowledge is continually narrowing, and often obliterating the broad lines of distinction that have been drawn between different classes of things. I well remember when our best naturalists regarded their "species" of plants and animals as fundamental and inviolable institutions, separated by well-defined boundaries that could not be crossed. Darwin has upset all this, and now we cannot even draw a clear, sharp line between the animal and vegetable kingdoms. The chemist is even crossing the boundary between these and the mineral kingdom, by refuting the once positive dictum that organic substances (*i.e.*, the compounds ordinarily formed in the course of vegetable or animal growth) could not be produced directly from dead matter by any chemical device. Many of such organic compounds have now been made in the laboratory from mineral materials.

We all know broadly what are the differences between solids, liquids, and gases, and, until lately, they have been very positively described as the three distinct states or modes of existence of matter. Mr. Crookes suggests a fourth. I will not discuss this at present, but merely consider the three old-established claimants to distinctive existence.

A solid is usually defined as a body made up of particles which hold together rigidly or immovably, in contradistinction to a fluid, of which the particles move freely over each other. "Fluid" is the general term including both gases and liquids, both being alike as regards the mobility of their particles. At present, let us confine our attention to liquids and solids.

The theoretical or perfect fluid which is imagined by the mathematician as the basis of certain abstract reasonings has no actual existence. He assumes (and the assumption is legitimate and desirable, provided its imaginary character is always remembered) that the supposed particles move upon each other with perfect freedom, without any friction or other impediment; but, as a matter of fact, all liquids exert some amount of resistance to their own flowing; they are more or less *viscous*, have more or less of that sluggishness in their obedience to the law of finding their own level which we see so plainly displayed by treacle or castor oil.

This viscosity, added to the friction of the liquid against the solid on which it rests, or in which it is enclosed, may become, even in the case of water, a formidable obstacle to its flow. Thus, if we make a hole in the side of a tank at a depth of 16 feet below the surface, the water will spout from that hole at the rate of 32 feet per second, but if we connect with this hole a long horizontal pipe of the same internal diameter as the hole, and then observe the flow from the outlet of the pipe, we shall find its velocity measurably diminished, and we shall be greatly deceived if we make arrangements for carrying swift-flowing water thus to any great distances.

Three or four years ago an attempt was made to supersede the water-carts of London by laying down on each side of the road a horizontal pipe, perforated with a row of holes opening towards the horse-way. The water was to be turned on, and from these holes it was to jet out to the middle of the road from each side, and thus water it all. I watched the experiment made near the Bank of England. Instead of spouting across the road from all these holes, as it would have done from any *one* of them, it merely dribbled, the reason being that in order to supply them all, the water must run through the whole of the long pipe with considerable velocity, and the viscosity and friction to be overcome in doing this nearly exhausted the whole force of water-head pressure. Many other similar blunders have been made by those who have sought to convey water power to a distance by means of pipes of such diameter as should demand a rapid flow through a long pipe.

The resistance which water offers to the stroke of the swimmer or the pull of the rower is partly due to its viscosity, and partly to the uplifting or displacement of some of the water. If it were perfectly fluid, our movements within it, and those of fishes, &c., would be curiously different, and, in fact, the whole face of this globe would be strangely altered in many respects. I will not now follow up this idea, but leave it as a suggestion for the reader to work out for himself, by considering what would remain undone upon the earth if water flowed perfectly, without any internal resistance.

The degrees of approach to perfect fluidity vary greatly with different liquids.

Is there any such a thing as an absolute solid, or a body that has no degree of fluidity, the particles or parts of which will admit of no change of their relative positions, no movement upon each other without fracture of the mass? This would constitute perfect *rigidity*, or the opposite to *fluidity*.

Take a piece of copper or soft iron-wire, about one-eighth of an inch in diameter, or thereabouts, and bend it backwards and forwards a few times as rapidly as possible, but without breaking it; then, without loss of time, feel the portion that has been bent. It is hot—painfully so—if the experiment is smartly made. How may this be explained?

It is evident that in the act of bending there must have been a displacement of the relative positions of the particles of the metal, and the force demanded for the bending indicated their resistance to this movement upon each other; or, in other words, that there was friction between them, or something equivalent to such internal friction, and thus the mechanical force exerted in the bending was converted into heat-force.

Here, then, was fluidity, according to [illegible] tion: not perfect fluidity, but [illegible] the above defini- [illegible] fluidity attended with

resistance to flow, or what we have agreed to call viscosity. But water also offers such resistance to flow or viscosity, therefore the difference between iron or copper-wire and liquid water as regards their fluidity is only a difference of degree, and not of kind: the demarcation between solids and liquids is not a broad, clearly defined line, but a band of blending shade, the depths of tint representing varying degrees of viscosity.

THE PHILOSOPHY OF ANIMAL COLOURS.

By Dr. Andrew Wilson, F.R.S.E.

PART II.

But, descending to still lower grades of life, we may discover examples of this "mimicry," not only of surroundings, but also of lifeless or inorganic objects, and of, it may be, plant structures as well, on the part of animals. The so-called "stick insects," or "walking twigs," as they are often called—the *Phasmidæ* of the naturalist—present us with the most perfect reproductions of bits of dried twigs. A figure of one of these insects is before me as I write. It is represented climbing on the delicate branch of a shrub, and but for the expectation of what one is looking for, there would be considerable difficulty in determining which is insect and which plant. The bodies of these "twig insects"—which belong, by the way, to the *Orthoptera*, or that order which harbours the familiar crickets and grasshoppers—are represented by mere lines. The wings have disappeared, and it has been remarked that in their gait these insects exhibit a peculiar habit of using their legs in a singularly awkward fashion, and thus apparently aid the illusion of the spectator that he is regarding a dried twig, moved erratically by the wind.

More extraordinary still are the "Leaf insects;" near allies, indeed, of the walking-sticks. Here "mimicry" of the plant proceeds so far as to fully justify the eminent naturalist's remarks, that it is strange to find the animal assuming a mimetic disguise and apeing the actor's art. The wings in the "leaf insects" exactly imitate leaves. The venation, or arrangement of the veins in the leaf, is clearly seen, and in one form (*Phyllium*) even the chest and legs of the animal assume leaf-like characters. When such an insect rests amid foliage, the value of such a close resemblance to its plant surroundings as a means of protection can be readily understood. In some "leaf insects"—all of which are tropical species—the wings resemble leaves that are dried and withered. In others, the minute fungi that attack leaves are imitated. Mr. A. R. Wallace tells us that one of the "walking-sticks" obtained by him in Borneo, "was covered over with foliaceous excrescences of a clear olive green colour, so as exactly to resemble a stick grown over by a creeping moss or Jungermannia. The Dyak who brought it me assured me it was grown over with moss, though alive, and it was only after a most minute examination that I could convince myself it was not so."

Lastly, there may be noticed in connection with these curious traits of animal life, the fact that certain animals, themselves harmless and inoffensive, may assume the exact appearance of offensive neighbours. In this respect, certain butterflies are *facile principe*. Certain South American butterflies, known collectively under their family name of *Heliconidæ*, exhibit a brilliant colouration, but like[illegible]ise possess a very strong odour; and, it may be presumed from [illegible] sequel, a highly disagreeable taste as well. They are highly [illegible]onspicuous insects, and the under sides of their wings are as brilliantly coloured as the upper surfaces; so that, even in repose, and when resting with the wings apposed over the back, they are readily enough seen. Their colours are prominent, not to say gaudy. Yellows, reds, and whites, commingle with blacks, blues, and other tints in a striking fashion. They are, further, by no means rapid flyers, and, putting the foregoing circumstances of their gaudy colour and their slow movements together, no group of animals would seem more liable to the attacks of bird enemies than these Helicon butterflies. Yet the reverse is the case. So far from being decimated, their race flourishes apace, and this result is clearly due to the strong odour and nauseous taste they possess. The mere touch of a Helicon is in itself a pungent matter, which reminds one of nothing so much as the persistence of the musk-rat's secretion, or the still more awful effluvium of the American skunk. Their neighbour butterflies may fall victims by the score to the rapacity of their feathered enemies, but the Helicons are spared from even the semblance of attack.

So far there seems nothing unusual or striking in a group of butterfles being protected, through strong odour and worse taste, from their natural enemies, the birds. But now comes the most curious phase of this history. Another and distinct family of butterflies, known as the *Leptalidæ*, allied to the common white cabbage butterfly, and removed from the Helicons, also possesses representatives in South America. There are no points of agreement between the Leptalides and the Helicons, save, indeed, that both are butterflies. Furthermore, the Leptalides are entirely destitute of the nauseous odour and of the strong taste of the Helicons, and in respect of their more agreeable presence, should become a prominent article—as do other butterflies—in the bill of fare of the birds. Yet, strangely enough, the Leptalides escape persecution; and the reason is not far to seek or difficult to find. When they are carefully examined, certain species of the Leptalides are seen to be exact *facsimiles*, in colour and appearance, of the stinking Helicons! Naturalists at first classed both as Helicons, until a closer examination showed the difference between these butterflies, and likewise proved that the Leptalides had thus "mimicked" in the plainest possible manner the colours of their strong-smelling neighbours. Nor are the colours alone imitated. The very shape of the Helicon's wings is reproduced in those of the Leptalides, and the "feelers" likewise mimic those of the former group. Again, special forms of Leptalides "mimic" special forms of Helicons. The flight has become of similar character in both species, and the habits have been also slavishly copied.

Such instances as these certainly present "food for thought" to the reflective mind. It is the business of philosophy to account for facts by placing the facts in scientific juxtaposition—philosophy, in this light, is the thread upon which the pearls of knowledge are strung. What, then, it may be asked, is the philosophy which can explain the curious resemblances seen in the animal world, ranging from, say, a mere likeness in tint to the surroundings (as in the flounder or woodcock), through more intensified likenesses, to the exact "mimicry" and to the slavish copy of colour and form, as in the butterflies?

A first and highly important feature in the consideration of the case is found in the fact that there is a gradation in the degree of "mimicry." From the mere sand or ground tinting of the flounder to the exact colouring of the butterflies is, of course, a wide step, but it is one which is bridged over by intermediate examples and stages. Then, secondly, we discover a purpose or use in the disguises: that purpose, apart from any considerations of its origin, being the protection of the animal from its enemies, and the con-

sequent good and increase of its race. Thirdly, it appears possible to account for these curious transformations and disguises, by finding an *initial* step. It is the old story of *le premier pas qui coûte*, applied to natural history research: and this first step is found in the solid axiom, that every living species is liable to *variation* and change. Next succeeds the consideration that such varieties as are produced have to "struggle for existence." Suppose a number of white varieties produced in a cold, snowy region, along with varieties of more conspicuous colours. It is evident that, whilst the white varieties would escape from their enemies, the darker-coloured individuals would succumb. Thus the white race comes to the front, and holds its own, and its perpetuation and increase becomes a matter of surety. Summing up the argument, we find that two factors are at work in bringing about these wonderful colour likenesses in the animal world. The one is variation, producing the colour-varieties: the other is the circumstances of life, which weed out the weak and give the battle to the strong, which latter are those whose colours best suit their surroundings. This is the philosophy which natural history to-day lays down for our acceptance. Nay more, it is a philosophy which explains far more important facts of life than mere mimicry. It is "evolution and development" reduced to their plainest and fundamental terms—in a word, Darwinism in a nutshell, as illustrated by the variation and change that all life knows, and by the warring of that life bringing the best of its units to the front of the battle.

BRAIN TROUBLES.

Impaired Memory.

The first mind trouble we propose to consider is the apparent temporary impairment of the memory. The gradual progressive decay of the power of memory with advancing years is, of course, a change which all may expect who attain great length of years; though, as Cicero long since pointed out, and as has been repeatedly exemplified by modern instances, the change is to some degree under control, and those matters in which an aged person takes special interest may be well remembered, when others about which he cares little are easily forgotten. "I never heard," says Cicero, "of any old man that had forgotten where he had hid his treasure; things which they regard, old men remember—the securities they have out, and who are indebted to them, as well as to whom they are indebted." And so forth. The points to be noticed here are, first, that memory is seen to be in large degree a question of attention as well as of retention; and, secondly, that decay of memory implies a change in the mind analogous to that which makes the old incapable of great bodily efforts. So that when the memory of a person who is not old becomes impaired, we may infer that unless there is actual disease, the symptom indicates overwork of the mind, precisely as bodily weariness indicates that the body has been overwrought. We may, perhaps, be led to inquire here whether a distinction should be drawn between loss of memory, as shown by a weakening of the power of committing to mind new matter (of whatever kind) which we may wish to remember, and the passing away from the mind of matter which had been already committed to it, and retained so long and so recently that its being forgotten can be explained only as due to some marked and recent change in the state of the mind. Suppose, for instance, that after carefully noting a number of facts, which under ordinary conditions we should remember thenceforward for weeks, we find that they have left no sufficient impression on the mind: here we obviously have evidence that the power of attention on which, in the first instance, memory depends, is for the time being enfeebled. Can we, however, infer that it is weakened in the same way and in the same degree as we should judge it to be if we found that numbers, dates, names, or words which we had had occasion to refer to daily for years, were suddenly clean forgotten? Making use, as we conveniently may (though we must not place too much stress on the method), of the analogy between bodily and mental relations, we may compare a change of the former kind to a diminution of the power of acquiring some new feat; a change of the latter kind, to the sudden loss of a feat already acquired and long practised. It can hardly be doubted that an athlete who should find himself unable to perform some new gymnastic trick, which he had supposed well within his powers, would not be so much struck by the circumstance, as he would be if he should suddenly find himself unable to achieve a feat in which he had hitherto found no difficulty.

Let us inquire, however, whether known cases of loss of memory of either kind afford any means of answering the question which has thus arisen. Of course, those cases in which the trouble has been only temporary, though far more numerous than those in which loss of memory has been symptomatic of actual disease, stand far less chance of being kept on record, so that we may have to consider cases of the latter kind to discover the relative importance of the two forms in which loss of memory may be noticed. The reader must not judge from cases thus cited that either class of symptoms is necessarily, or even probably, indicative of serious brain mischief.

We will begin, however, with a case in which the trouble was only temporary, and, moreover, its cause obviously indicated.

Sir Henry Holland gives the following suggestive account of a transient loss of memory due to fatigue. It will be seen that the failure of memory belongs to the second class above referred to, that, viz., in which what had been long and well known is suddenly forgotten. "I descended," he says, "on the same day, two very deep mines in the Harz Mountains, remaining some hours underground in each. While in the second mine, and exhausted both from fatigue and inanition, I felt the utter impossibility of talking longer with the German Inspector who accompanied me. Every German word and phrase deserted my recollection, and it was not until I had taken food and wine, and been some time at rest, that I regained them." This case would seem to show that transient loss of memory, even of this kind, need not be regarded as necessarily an alarming symptom.

The following case points in the same direction even more decisively. "A gentleman," says Dr. Winslow, "well known for his intense passion for field sports (living, it may be said, upon the saddle during the greater part of the year), frequently complained of transient attacks of loss of memory after a hard day's run with the hounds. His remedy for this affection was half-a-pint to a pint of port wine *at a draught!* The effect of this heroic dose of vinous stimulant upon the depressed energy of the brain was evidenced by the memory immediately recovering its vigorous activity." It would, however, be unwise to infer that this sportsman, in thus prescribing for these attacks, showed himself the "physician" of the proverb relating to fools and physicians. The remedy was a dangerous one. His was specially a case where prevention was better than cure. The transient attacks of loss of memory showed that the hard day's run with the hounds overtaxed his strength. He would have done wisely to have limited his exertions

in the field (not giving up hunting, but restraining his zeal on those occasions when the day's run promised to be harder than usual).

The effect of wine used regularly, not in pint draughts, is in many cases undoubtedly good where the memory is apt to fail. We have an illustration of this in the following case, belonging to the first of the two classes above considered. A gentleman whose mental and physical powers had been severely taxed, lost all power of recollecting recent events. "Whilst engaged in active conversation, he was able, by a strong effort of the will, to retain possession of the ideas suggested by others to his mind; but if there were the slightest interruption, even to the extent of a minute, in the conversation, he lost all recollection of what he had been previously saying. This gentleman had been living for some weeks below par, with the view of enabling him to perform an amount of urgent mental work, requiring for its execution the lengthened concentration of a clear and vigorous intellect. He had been in the habit of drinking a fair portion of wine, but had unwisely abandoned the use of stimulants, fancying that by so doing he would be better fitted for clear-headed mental occupation." Under Dr. Forbes Winslow's advice, the patient "lived generously, took iron tonics, quinine, and valerianate of zinc, and resumed his daily quantity of wine. This treatment eventually restored his memory to a state of health." Dr. Forbes Winslow adds that he has known other instances of temporary loss of memory cured within a short time by the free use of tonics and stimulants. "In these cases," he says, "the brain is generally in a starved and impoverished condition, arising from a deficient supply of blood; it is in a state of enervation and inanition." On the other hand, the excessive use of stimulants produces unmistakably mischievous effects. Temporary attacks of loss of memory have been caused by intemperance. "By an old Spanish law," Dr. Winslow mentions, "no person was admitted into the witness-box to give evidence in a disputed case who was proved to indulge in habits of intemperance, as an excessive use of stimulants was considered to weaken and destroy the memory."

(*To be continued.*)

INTELLIGENCE IN ANIMALS.

PART II.

The next case cited also relates to the apparent exercise of reasoning faculties by rats, and is interesting, because probably their action was guided by the sense of hearing, rather than by that of smell. "Some years ago," says the narrator, "a plumber told me that he had, on several occasions, been called in to examine into the cause of leakage of water-pipes under the flooring of houses, and had found that the rats had gnawed a hole in the leaden pipe to obtain water, and that great numbers of them had made it a common drinking place, as evidenced by the quantity of dung lying about. The plumber brought me a piece of leaden pipe, about three quarters of an inch in diameter, and one eighth of an inch in thickness, penetrated in two places, taken by himself from a house on Haverstock-hill. There are the marks of the incisors on the lead as clear as an engraving; and a few hairs and two or three of the rat's whiskers have been pinched into the metal in the act of gnawing it. This crucial proof of brute intelligence for a rat will not drink foul water—interested me so much that I ventured to send an account of it to Dr. Charles Darwin, asking his opinion on the means by which the rats ascertained the presence of water in the pipe. To this he replied: 'I cannot doubt about animals reasoning in a practical fashion. The case of the rats is very curious. Do they not hear the water trickling?'" This explanation would go far, it would seem, to do away with the idea that the rats in this case had reasoned, seeing that if they recognised the presence of water by the sense of hearing, their action in biting their way through to what they wanted would correspond precisely with what we have been taught (erroneously, in all probability, but that is a detail) to regard as instinctive. The narrator, however, did not read Dr. Darwin's reply in this sense. "It may be conceded," he says, "that this explanation is the most probable, and if it be the true one, we have an example of an animal using his senses to obtain the data for a process of reasoning leading to conclusions about which he is so certain that he will go to the trouble of cutting through a considerable thickness of lead. Obviously man could do *no more* under the same conditions." If the rats had shown in their boring operations some special aptitude for securing most conveniently, with the least possible overflow, the water they required, this would be a just inference. But as we know no more than that, having found, probably by the sense of hearing, that water was present in the pipe, they bored their way through to reach it, we have in reality no more proof of reasoning power than is afforded by the familiar action of mice in biting their way through the wooden or card casings of boxes of edibles they like, of whose presence within such boxes the sense of smell has convinced them.

This objection is well put by Mr. Henslow in a letter discussing this particular case, and Dr. Darwin's comments thereon, only, as it seems to us, he carries the objection rather farther than it will fairly go, extending it to cases to which we think it can hardly be applied. "It has always seemed to me," he says, "that brute reasoning is always *practical*, but never *abstract*" (but he tries to show that there is very little reasoning at all in the matter). "They do wonderful things, suggested by the objective fact before them; but, I think, never go beyond it. Thus, a dog left in a room alone, rang the bell to fetch the servant. Had not the dog been taught to ring the bell (which, on inquiry, proved to have been the case), it would have been abstract reasoning; but it was only practical. The Arctic fox—too wary to be shot, like the first, who took a bait tied to a string, which was attached to the trigger of a gun—would dive under the snow and so pull the bait down below the line of fire. This is purely practical reasoning: but had the fox pulled the string first out of the line of fire, *in order* to discharge the gun, and *then* to get the bait, that would have been abstract reasoning, which he could not attain to." This, however, is assuming more than can be proved: the fox in the case referred to did not act in the way which would have implied abstract reasoning; we do not know that no fox has ever done so, still less that, failing a simpler way of attaining his object, no fox could so reason. Albeit, we believe there are very few cases in which a line of reason involving so many steps as that suggested by Mr. Henslow has been followed by an animal. Mr. Henslow makes a good point in noting how like the practical reasoning of animals is the reasoning of young folk. "A boy the other day," he says, "found the straps of his skates frozen. The fact only suggested *cutting* them. Not one of his schoolfellows reflected upon the abstract fact that the ice would melt if he sat upon his foot a few minutes. Hence brutes and boys are exactly alike in that nothing occurs to either beyond what the immediate fact before them may suggest. The one kind I call purely *practical* reasoning, which both have; the

other abstract, which brutes *never* acquire; but the boy *will* as his intelligence develops."

Certainly the next case cited in the correspondence suggests practical rather than abstract reasoning. "In Central Park, one very hot day, my attention, writes Mr. James J. Furniss, of New York, "was drawn to the conduct of an elephant which had been placed in an inclosure in the open air. On the ground was a large heap of newly-mown grass, which the sagacious animal was taking up by the trunkfull, and laying carefully upon his sun-heated back. He continued the operation until his back was *completely thatched*, when he remained quiet, apparently enjoying the result of his ingenuity. It seems to me that *instinct* should have prompted the elephant to eat the grass, and that it was reason which caused him to use it for the purpose of diminishing the effect of the sun's rays." Undoubtedly, had hunger been the prevailing sensation at the time, instinct would have caused the elephant to eat the grass. But, as he was probably much troubled by the heat, it was not more wonderful that he should throw grass on to his back, than it would have been if, had there been any shadow, he should have withdrawn under it. Doubtless, however, the true explanation is that the elephant reasoned in a practical way. The effect of the grass as a protection from the heat was obvious to his senses, so he continued to add more and more grass to his covering until he felt comfortable. If the use of the grass for food occurred to him at all, it would have appeared obvious enough that even if all the grass were used for shelter, it would be none the less suitable for food when hunger began to be troublesome.

ARE WOMEN INFERIOR TO MEN?

M. DELAUNAY next proceeds to compare the brain capacity of men and women. Huschke estimates the mean capacity of the cranium for Europeans to be 1,446 cubic centimètres (about $88\frac{1}{4}$ cubic inches) for men, and 1,226 (about $74\frac{4}{5}$ cubic inches) for women, or the masculine brain exceeds the feminine, on the average, nearly 18 per cent. in capacity. However, before we too hastily assume that this implies inferiority, we may as well consider the relative dimensions of men and women in other respects. We have to take into account rather the relative than the actual dimensions of the brain. Now, the average height of men in European countries exceeds that of women by about one-seventeenth part, that is, men are taller than women in about the ratio of 18 to 17. Men, therefore, exceed women in bulk in about the ratio of 18 times 18 times 18 to 17 times 17 times 17 (for the volumes of bodies vary, not as their linear dimensions, but as the cubes of these dimensions), or rather more than the ratio of 118 to 100. Hence, so far as Huschke's estimate can be trusted, the cerebral capacity of women is relatively greater than that of men.

We learn from Broca, though one would like to be assured that the statistical evidence is trustworthy, that the brain of man is heavier than that of women as 111 to 100. This, like Huschke's evidence, but in even greater degree, would be unfavourable to M. Delaunay's position. But Broca also notes that the female cranium is longer and less high than the male. The broader-headed among men will probably regard this as evidence of inferiority, while the dolichocephalic, or long-headed, will regard it as proof positive that at any rate women have equal, or probably superior, brain fitness, so far as shape is concerned.

"The graphic curves of feminine brains of various races," says M. le Bon, "shows that even in the most intelligent societies, as the Parisians of to-day, there is a notable proportion of the female population whose brains approach more to the volume of those of certain gorillas than the least-developed crania of the masculine sex." This sounds unflattering, but in reality it means very little. For the worst developed crania which are here compared include, both among male and female specimens, abnormal cases, from which it is not easy to infer the true relations of brains of that class. Moreover, the men of worst-developed brains are more apt to get eliminated from society, so that the very worst specimens of masculine crania being removed, the comparison between the bad male and the bad female heads is affected unfavourably for the latter.

The frontal lobes, "the seat of the highest intellectual faculties, are less developed in woman than in man, while, on the other hand, the occipital lobes, which especially preside over the life of sentiment, are more voluminous in the woman than in the man." In its totality, according to Professor Wagner, "the brain of the woman is always in a state more or less embryonic." This must, of necessity, relate to averages, not to individual brains. If the brains of those women who have been distinguished for genius were compared with the brains of ordinary men, there would not be found any evidence of a state more or less embryonic. This, of course, would by no means dispose of the argument, but it indicates a circumstance to which in all statistical inquiries attention should be carefully drawn, the effect namely of selection, conscious or unconscious, in affecting the result. Is it certain that the female crania which have been at the disposal of anatomists for examination have come from the same classes (or in the same degree from those classes) as the male crania? Are there not reasons for thinking that, on the whole (and in considering averages this would be a sufficient objection), the women whose crania have been examined belonged to lower classes than the men?

We note these points, not that we would confidently deny the asserted superiority of male crania, on the whole, in capacity and shape. Such superiority may exist, but may indicate no original difference of capacity. Broun Sequard has shown how the brain grows with use; and it is certain that existent systems of education give, on the whole, far less exercise to feminine than to masculine brains. In America, where women are more fairly treated, the customary tests of capacity show by no means that degree of masculine superiority which might be inferred from M. Delaunay's reasoning. On the contrary, the feminine brain holds its own so well against the masculine as to suggest the thought that had equal chances been given for as many centuries as years, the superiority might be quite the other way. Nor has this been the case only during the earlier stages of education; but often up to the final examinations.

In passing, we may note that at present it can hardly be said that the frontal lobes of the brain have been proved to preside definitely over the intellectual, while the occipital lobes preside over the life of sentiment. The animals whose brains have been experimented on do not exhibit so clearly the respective action of intellectual and sentimental ideas, that the different functions of parts of the brain can be thus localised. *Post-mortem* examinations are confessedly unsatisfactory. The relation assumed by M. Delaunay without any doubt or scruple most probably exists, but it has not yet been demonstrated.

To the objection that the intellectual inferiority of women, assuming it to exist, is due to the fact that for centuries she has not received the same education as man, M. Delaunay replies that it is unsound. "In past centuries

the mass of the people were sunk in ignorance; neither the one sex nor the other received any education." He therefore maintains, with Professor Bischoff, of Munich, "that women have not had to the exercise and evolution of their brains any other hindrances than those proceeding from their constitution and their capacity for development." On this point he uses Cyril's argument:

> "They hunt old trails," said Cyril, "very well;
> But when did woman ever yet invent?"

"Female musicians receive," he says, "the same education as males, and yet it is well known that, though there have been some excellent female performers, there is no instance of a great female composer. It is the same with painters and with the culinary art; among the thousands of women who have exercised the latter, there have been few, if any, *cordons bleus*. If we prepare a list of the men and another of women most distinguished in poetry, painting, sculpture, science, and philosophy, each containing a dozen names, the two lists would not bear any comparison." He cites the opinions of manufacturers and commercial men who employ individuals of both sexes. "They all agree that women are more assiduous, but less intelligent, than men. In printers' establishments, for example, women work with minute care, mechanically, without knowing very well what they are doing. Thus they make good compositors in the case of reprints, a work not demanding much intelligence, but set up manuscripts badly, not understanding them so well as men." To which it may be replied that as yet the capacity of women for such work has not been fairly tested. Miss Emily Faithfull asserts, however, that well-trained female compositors show as much readiness to deal with manuscripts as the best male compositors.

M. Delaunay touches, indeed, on the moral qualities of men and women, referring to the many authors who have maintained that women are more prone to every kind of wickedness than men, though he admits they commit proportionately fewer crimes. Poisoning is more favoured by women—that is, the poisoning of others—than by male criminals. "Moralists have noted that woman is more playful, more changeable, more capricious than man. She is also more destructive and less circumspect. The number of women run over in the streets is greater than that of men." *Quorsum hæc tam putida tendunt?* What has all this to do with M. Delaunay's subject? The argument which Mr. Delaunay uses to clinch his case, supplies the best answer to this part of his reasoning. "All known legislators take for granted the intellectual inferiority of the feminine sex as compared with the masculine. Everywhere woman is regarded as a minor, incapable of taking care of herself, and requiring a guide and tutor." The laws, in fact, having been made by man, assert his superiority, and so far as they can, ensure it. Woman is carefully placed in an inferior position, and then assured that she is an inferior being.

COMETS' TAILS.

By the Editor.

FROM what we have already seen, it will be manifest that the formation of comets' tails is a process of a very marvellous nature, as apparently involving forces other than those with which we are acquainted. The tail, ninety millions of miles in length, which was seen stretching from the head of Newton's comet nearly along the path which the retreating comet had to traverse (the comet thus passing away with its tail in front, instead of behind, as when it approached the sun), must, it would seem, have been formed by some force far more active than the force of gravity. The distance traversed by the comet in the last four weeks of its approach to the sun under gravity was no greater than that over which the matter of the tail, seen after the comet had circled around the sun, had been carried in a few hours. Yet we have no other evidence of any repulsive force at all being exerted by the sun—at least, no evidence which can be regarded as demonstrative—and still less have we any evidence of a repulsive force exceeding in energy the sun's attracting power.

Fig. 1.—Donati's Comet, September 24, 1858.

This difficulty, and the circumstance that a comet's tail lies in the direction opposite to the sun, or in the position which the shadow of the head would occupy, has led many, unfamiliar with the laws of optics, to suppose that the comet's tail may be simply the track of the luminous rays which have passed through the comet's head. They seem to think that the head may act in some way to send a beam of condensed light along the region opposite to the sun. It should hardly be necessary, however, to explain that no such beam of light could ever be seen where we see the comet's tail. The cases supposed to correspond with the formation in this way of the tail-like appendage are, in reality, of an entirely different kind. Thus, when we see a long beam extending from a bright light, we find that first the light has been caused to pass in that direction only (as when light is admitted into an otherwise darkened room through a hole); and secondly, there is matter along

the course of the light to be illuminated. The beam is simply that long array of material particles which the light illuminates while leaving the particles in neighbouring space in darkness. So understood, such a beam is seen to be utterly unlike a comet's tail; for, in the first place, we know of no matter behind the head to be illuminated; and, in the second, we know that light is falling on the regions all around the apparent array of illuminated particles, so that these surrounding regions should be as brightly lit up, which is not the case.

If any further doubt could remain as to this theory, it would be removed by first, the circumstance that the tail of a comet is generally curved; and, secondly, the existence of several tails extending from the head of one and the same comet.

Professor Tyndall started a theory based on physical experiments, and otherwise in better accordance with scientific possibilities. Having found that certain gases, even in an exceedingly attenuated form, form a luminous cloud under the action of the electric light, he suggested that a comet's tail may be a luminous cloud of this sort, formed in the æther of space by those rays of sunlight which have passed through the comet's head. The rays which, without passing through the head, fall on the æther of space, would not call into existence this visible cloud, because their heating action would destroy what their chemical or actinic action *by itself* would produce. And as fast as, by the comet's motion, the cloud formed behind the head came under full solar action, it would be destroyed. So the tail would always be behind the head.

It appeared to Professor Tyndall that the curvature of a comet's tail, or the existence of more tails than one, as in Donati's Comet (Figs. 1 and 2), was not inconsistent with this interpretation. For he noticed that, according to the gas dealt with, the luminous cloud would take a longer or shorter time in becoming visible. And he suggested that when the cloud formed slowly, the tail would be curved, the part near the head being behind the position which the head had recently passed through, while the part near the end of the tail would be behind the regions through which the comet had passed much earlier. Such luminous trails as were formed more quickly would account, he considered, for the straighter tails. He overlooked, I think, the circumstance, that the shape of the luminous cloud-trail would not in reality depend at all upon the length of time which the cloud might take in becoming visible. Light would pass with the same velocity through the different kinds of tenuous gas, and whether the cloud became visible at once along the space thus passed through, or did not become visible for several seconds, or minutes, or even hours, it would become visible at the farther end of its course only just so long after it had become visible at the nearer end, as light had taken in traversing the length of cloud so formed. This interval of time would be the same for the quickly-appearing as for the slowly-appearing luminous cloud, and there would, therefore, be no difference between their forms. It would be necessary to account in this way for the curvature of the larger tail in the figure, as compared with the straightness of the smaller tails, that the curved tail should have been more slowly extended from the head; whereas the theory gives the same rate of extension for both, namely, the rate at which light travels.

Fig. 2.—Donati's Comet, September 26, 1858.

We seem almost forced, by the phenomena of such a comet as Donati's, to the theory of the actual repulsion of matter from the head of the comet into the tails—matter repelled most swiftly forming the straighter tails, while matter repelled more slowly, and seemingly in greater abundance, forms the great curved tail.

We shall proceed to consider in our next paper the evidence which seems to show that, strange though this theory of material repulsion may be, it is in point of fact the only admissible theory. If this shall be established, we shall have to admit the existence of a repulsive force, whose action on the grosser material of planetary bodies is insensible.

"All knowledge, and wisdom which is the seed of knowledge, is an impression of pleasure in itself."—*Bacon*.

The Population of the Globe.—According to MM. Bohm & Wagner's *Bevölkerung der Erde*, Europe has now a population of 315,929,000 inhabitants, Asia 834,707,000, Africa 205,679,000, America 95,405,000, Australia and Polynesia 434,000, the Polar regions 82,000, giving a total of 1,455,923,000, being an increase of 16,778,000, according to the latest known censuses. At the end of 1877 Germany had a population of 43,943,000, Austria and Hungary (1879) of 38,000,000, France (1876) of 36,900,000, Turkey in Europe of 8,860,000, Russia of 87,900,000. In Asia, China possesses 434,900,000 inhabitants, Hong Kong 130,144, Japan 34,300,000, according to the census of 1878. The British possessions in India number 240,200,000 people (an estimate made before the census of this year), the French possessions 280,000, Cochin China 1,600,000, the East Indian Islands 34,800,000, the islands of the South Sea 878,000. The area of Africa is estimated at 29,383,000 square kilomètres, divided as follows:—Forests and cultivated land 6,300,000, savannahs 6,235,000, steppes 4,200,000, deserts 10,600,000. The inhabitants of British North America number 3,800,000, of the United States 50,000,000, of Mexico 9,185,000, and of Brazil 11,100,000. The Polar regions extend round the Arctic Circle with an area of 3,859,000 square kilomètres, and the Antarctic regious about 600,000. The population of the former is small, with the exception of Iceland, which has 72,000, and Greenland 10,000.—*Times*.

Reviews.

IN Mr. Paterson's "Studies in Life,"* he presents a series of lectures delivered to the members of a Young Men's Christian Association. His subject is full of interest, and his book is interesting, and, on the whole, well written; but it would have been much more interesting, and, as a literary work, it would have been far better, if he had forgotten that he was addressing a religious body, or (which comes to much the same thing) if he had remembered that he was speaking about science. Mr. Paterson seems to think that he must state nothing which he cannot prove to be in exact "accordance with what we read in the Book, and what we might expect from the narrative we have there." It is true that, after starting on this principle, which for a student of science is an illogical one, he is careful to discover an accordance on a plan of his own, and then to say that it is not because such and such theories oppose the Bible, but because they are inconsistent with facts, that he rejects them; but he only makes his position more illogical still by this most transparent device. The science writers of a hundred years ago were wiser in their generation. They said (we quote from the "Encyclopaedia Britannica," 1778): "This opinion, however plausible, we are not permitted to adopt, being taught a different lesson by Revelation . . . . we cannot doubt of the authority of Moses." If Mr. Paterson were content to do this, his position would be as logical as theirs. But, after expressing in effect the same opinion, he proceeds to argue the matter out, as though he were in doubt of his position. All the space thus occupied is simply wasted; and the reasoning can hardly fail to be as offensive to those who accept the authority of the Bible unquestioningly, as it is to those who cannot see what place Bible references can possibly have in scientific treatises. Mr. Paterson should know, every real student of science should remember, that science is of no creed as it is of no country. A writer of science has no more occasion to show that the science he teaches accords with his or any one else's interpretation of any religious book, than the tailor has to show that the clothes he makes are on a pattern accordant with Christian, with Mussulman, or with Buddhist doctrines.

Hence we must limit our praise of Mr. Paterson's work to the remark that if one-fourth were removed and the price proportionately reduced, it would be a work which students of biology would find worth getting and reading. With the fourth referred to would go much false science. We venture, too, to say that the interests of religion are, to say the least, not advanced by such passages as we refer to. It cannot conduce, for example, to the reverential spirit Mr. Paterson inculcates, to read a paragraph, beginning with the statement that Darwin's theory is essentially atheistic, going on to refer to what Mr. Paterson knows "in his inmost soul by the revelation of the Holy Ghost"; and closing with the statement that, even if the Bible does not forbid, hybridity sets up an impassable barrier.

In "Health Studies" † and "The Human Body," ‡ Mr. Paterson appears to better advantage, though he loses even here no opportunity of making science and religion simultaneously ridiculous.

Yet all three works are full of interesting and, for the most part, instructive matter; and but for the serious defect we have pointed out, they might all three be strongly recommended. Albeit, there is another fault—to wit, an affectation of simplicity, a very different thing from real simplicity. No one could write more simply than Faraday, yet his simplest words never wanted dignity, and never offended his reader's sense of self respect: when we find our author speaking of the features of the face as Mouthgate, Nosegate, and so forth, and gravely telling us that the nose is useful, "even though it may also be ornamental," and the like, we cannot accord the same praise to him.

* "Studies in Life," by H. Sinclair Paterson, M.D. (London: Hodder & Stoughton.)

† "Health Studies," by the same author.

‡ "The Human Body," by the same author.

"The Fiji Islands."—We omitted to notify in the footnote to our review of Mr. Horne's work on "The Fiji Islands," that it is published by Mr. Edward Stanford, Charing Cross.

THE GREAT PYRAMID MEASURES, AND THE DIAMETERS AND DISTANCES OF THE SUN, EARTH, AND MOON.

By Joseph Baxendell, F.R.A.S.

[It must not be understood that we accept our esteemed contributor's views. They illustrate well the whole theory of pyramid coincidences, but these coincidences disprove, in our opinion, what Mr. Baxendell considers that they prove.—Ed.]

A FEW months ago the results of a partial discussion of the Great Pyramid measures, given by Professor C. Piazzi Smyth, in the fourth edition of his work entitled "Our Inheritance in the Great Pyramid," led me to believe that the data which had formed the basis of the design for the Pyramid were the diameters and distances of the sun, earth, and moon, combined with the ratio (π) of the circumference of a circle to its diameter—a quantity which forms an important feature in the relations of the Pyramid measures; and, also, that in order to reduce the results of the astronomical data to magnitudes suitable for the design and construction of the Pyramid, a scale of one pyramid inch to a length, one-thousandth part greater than the present English mile, or 63,360 pyramid inches, had been used by the architect; but as I found that the values of the diameters and distances given in various astronomical works, especially those for the diameter and distance of the sun, would not yield results agreeing *exactly* with the Pyramid measures, although they were generally remarkably close approximations, I was induced to undertake a more extended discussion and analysis of the measures, with a view to ascertain, if possible, the exact values which had been employed by the architect in his reductions, and it thus became necessary to attempt a solution of the following problem. Given approximate values of the diameters and distances of the sun, earth, and moon to find the values which in simple combinations will give, with *strict exactness*, the various Pyramid measures and numbers, the scale for the reductions being one Pyramid inch for a Pyramid mile of 63,360 Pyramid inches. For some time I had considerable difficulty in forming the requisite number of suitable equations for the complete solution of this problem, but ultimately succeeded, and obtained the following values:—

	Pyramid miles.	English miles.
Diameter of the Sun	855,938	856,793
Equatorial diameter of the Earth	7,917·7	7,925·6
Diameter of the Moon	2,157·2	2,159·3
Mean distance of the Sun.........	91,758,800	91,850,558
Mean distance of the Moon	238,483	238,721

Let S = distance of the sun; M = distance of the moon; s = diameter of the sun; e = equatorial diameter of the earth; m = diameter of the moon. Then the following equations, in which pyramid miles and inches are adopted, will show the relations between these numbers and the pyramid measures:—

1. $\frac{se}{m} = 1{,}000{,}000\pi$.

It is probably owing to the remarkable relation in the magnitudes of the three bodies shown by this equation that the quantity π forms so prominent a feature in the relations of the Pyramid measures.

2. $\sqrt{s\pi^2} = 9{,}131{\cdot}05$ = length of one side of the base of the Pyramid.
3. $\sqrt{s2\pi} = 5{,}813{\cdot}01$ = height of the Pyramid.
4. $\frac{s\pi^2\pi\sqrt{\pi}}{25{,}000} = 1{,}881{\cdot}59$ = length of Grand Gallery.
5. $\frac{2\sqrt{s\pi}\sqrt{\pi}}{25} = 412{\cdot}13$ = length of King's Chamber.

6. $\frac{\sqrt{s\pi}\sqrt{\pi}}{1{,}000}$ = 5·151,646 = the number which has been called the key number to the dimensions of the King's Chamber, and of the Pyramid generally.

7. $S = \frac{25{,}000{,}000e}{m}$

8. $M = \frac{em\pi}{3^2 5^2}$

9. $M = \frac{se^3}{9ms}$

10. $\frac{2S}{5{\cdot}151{,}646M}$ = 149·37 = height of ante-chamber.

11. $\frac{3\sqrt{SMs\pi^3}}{250e}$ = 36,524·22 = perimeter of base of the Pyramid.

12. $\frac{3\sqrt{SMs\pi^3}}{500e\pi}$ = 5,813·01 = height of the Pyramid.

13. $\frac{es\pi^4}{75\sqrt{SM}}$ = 1,881·59 = length of Grand Gallery.

14. $\frac{80e\sqrt{s\pi^2}}{3\sqrt{SM}}$ = 412·13 = length of the King's Chamber.

Among the equations I obtained during the investigation were several which gave a smaller value for the diameter of the sun; and as I am not aware that any sensible difference has ever been observed between the polar and equatorial diameters, this result seemed adverse to the theory of a connection between the Pyramid measures and the diameters of the three bodies, until it occurred to me that probably one diameter referred to the photosphere, and the other to the comparatively dark and solid or liquid body of the sun. This latter diameter is 853,718 Pyramid miles, or 2,220 miles less than that of the photosphere, and the following equations, in which it is represented by the Greek letter σ, will show its connection with the Pyramid measures:—

15. $\frac{\sigma^2\pi}{e^2}$ = 36,524·20 = perimeter of base.

16. $\frac{\sigma^2}{2e^2}$ = 5,813·01 = height of Pyramid.

17. $\frac{\sigma^2}{100e^2}$ = 116·26 = length of ante-chamber.

18. $\frac{\sigma^2\sqrt{\pi}}{50e^2}$ = 412·13.

19. $\frac{\sigma^4\pi\sqrt{\pi}}{400{,}000e^4}$ = 1,881·59.

20. $\frac{\sigma^2\sqrt[4]{\pi^3}}{e^2 2\sqrt{10^5}}$ = 1,881·59.

21. $\frac{\sigma^2\sqrt{\pi}}{4{,}000e^2}$ = 5·1,516.

The length of the earth's polar axis is assumed by pyramidists to be 500,000,000 pyramid inches, or 7891·41 pyramid miles of 63,360 pyramid inches to the mile, or 7,899·30 English miles, while the value derived by Col. Clarke, from an elaborate discussion of measurements of arcs of meridian, is 7,899·11 English miles—the difference being therefore, less than two-tenths of a mile. I was, therefore, much surprised to find that the Pyramid measures would not yield a less diameter for the earth than 7,892·54 pyramid miles, or more than a mile greater than the generally-accepted length of the polar diameter. The question therefore arose—Can this latter length be in error to the extent indicated, or is the value I have obtained connected in any way with some marked feature of the Pyramid? It seemed to be highly improbable, if not impossible, that the results of the calculations of Bessel, Airy, and Clarke could be in error to the extent of more than a small fraction of a mile, and assuming, therefore, that the figure of the earth is truly spheroidal with major axis = 7,717·7, and minor axis = 7,891·41 Pyramidal miles, I calculated the geo-centric latitude in which a diameter will be 7,892·54 miles, and found it to be 78° 25′ 33″; and, deducting this from 90°, we have 11° 34′ 27″. A glance at this result at once suggested that it was the polar distance of the Pyramid pole-star, *a* Draconis, multiplied by the quantity π, and on dividing 11° 34′ 27″ by π I obtained 3° 41′, which is a very close approximation to the calculated polar distance of *a* Draconis at the time of the building of the Pyramid. Now a section of the earth through the parallel of latitude marked out in so singular a manner has a diameter of 1,583·54 Pyramid miles, or exactly one-fifth of the earth's equatorial diameter, and an area of 1,969,462 miles, or one twenty-fifth that of a section through the equator, which is 49,236,600 miles. The occurrence of the Pyramid numbers 5 and 25 in connection with the diameter thus indicated in so striking a manner gives a peculiar importance to it, and accordingly I have found that expressions in which it is a factor can be formed which give *exactly* the various Pyramid measures. Thus, representing this diameter by the Greek letter η (eta), we have

22. $\eta = \frac{S\sqrt{\pi}}{1{,}000 \times 5{\cdot}151{,}646}$ = 7,892·54.

23. $\eta = \frac{Se^2}{\sigma^2}$

24. $\frac{S\sqrt{\pi}}{1{,}000\eta}$ = 5·151,646.

25. $\frac{S}{\eta}$ = 11,626·02 = 100 times length of ante-chamber.

26. $\frac{S^2\pi\sqrt{\pi}}{1{,}000\eta^2 5{,}151{,}646}$ = 36,524·22.

27. $\frac{\sqrt{2e\eta}}{100}$ = 111·795 = height of granite wainscot in ante-chamber.

28. $\frac{450\sigma^2\eta}{5{\cdot}151{,}646e^3m\pi}$ = 119·37.

29. $\frac{S^2\pi\sqrt{\pi}}{400{,}000\eta^2}$ = 1,881·59.

30. $\frac{S\pi 5{\cdot}151{,}646}{100\eta}$ = 1,881·59.

31. $\frac{S\pi}{4\pi}$ = 9,131·05.

32. $\frac{S}{2\eta}$ = 5,813·01.

It may be remarked that the diameter η is exactly one seven-thousandth part greater than the polar diameter, and that the parallels of latitude in which it occurs may be regarded as the limits of the habitable portion of the globe.

The results of my investigation having proved that a measure corresponding to our English mile, and containing 63,360 Pyramid inches, was used by the architect of the Pyramid, it became a matter of interest to ascertain, if possible, how it originated, and ultimately I arrived at the following formula:—

33. $10\sqrt{\frac{Se}{m}}$ = 17,724·5 miles, which is the circumference of a circle whose area is 25,000,000 miles, or equal to the area of a section of the earth through the parallel of latitude in which the length of a diameter is equal to the mean of all the earth's diameters (7,904·545 P. miles). This area expressed in Pyramid inches, is equal to a square, the side of which has a length of 316,800,000 inches, and this, divided by 5,000 = 63,360 inches.

My experience in the development of the theory which has yielded the results given in this paper has convinced me that there is no feature of the Great Pyramid, or relation of its various parts, which cannot be expressed in terms of the astronomical data I have used, and in some cases, as I have already shown, two, three, or more equations can be formed, each containing one or more factors not in the others, but giving precisely the same result. It is evident, therefore, that the builder possessed a far greater amount of mathematical and astronomical knowledge than it has hitherto been supposed could possibly have been acquired by the ordinary course of observation and scientific investigation in the early age of the world when the Pyramid was built; and the fact that the values of the diameters and distances used by him are within the limits of the probable errors of the means of the best astronomical determinations of recent times proves that, so far at least as these values are concerned, modern science has made no real advance upon the science known to the builder of the Great Pyramid 4,000 years ago.

NEW MODE OF GROWING PLANTS.

By E. C.

To Dr. C. W. Siemens, the celebrated electrician, we are indebted for a series of experiments lately tried by him on the effect of the dynamo-electric light in promoting the vegetation and growth of plants. The idea that the electric current might be utilised in this way first occurred to him by observing that the blistering effect on the skin from this light was very similar to that produced by a hot sun. Without the aid of the sun's rays, *chlorophyll* is not formed, and this is an all-important element in vegetable life, as it produces the green colour of the leaves, and supplies the plants with carbon and starch for forming woolly tissues, by causing the decomposition of the carbonic acid vapour absorbed from the atmosphere by the leaf. The electric light, being, in fact, a sun on a small scale, has been formed to produce *chlorophyll* and other necessary chemical changes in a similar way to solar rays.

The apparatus employed for the series of experiments was a small upright Siemens machine, worked by a gas engine. The two carbons in the regulator lamp were respectively 10 and 12 millimetres in diameter, and the light it produced was equal to 1,400 candles. The first plan that was tried was by placing the lamp about 7 ft. above a melon pit and a reflector was arranged to concentrate all the light on the sash. Pots of rapidly-growing plants were, in succession, brought under this influence, some exposed only to the electric light, some to the sun alone, and some to the sun and electric light alternately. The latter made the most rapid progress, and were the best in colour. In the next experiment, the lamp was put inside a greenhouse, and as near the roof as possible. Various plants were placed in pots on the floor, at a variety of distances, and the light was kept burning all night for one week. The plants nearest to the influence of the lamp made the most rapid progress, and the foliage and plants were of a far brighter hue than if they had only had sunlight during the day. As regards forcing fruit, the electric light seems very efficacious. In ten days time some strawberry plants, which had been kept alternately under the influence of the sun and light, had large, full-flavoured fruit, while plants which had only been exposed to the rays of the sun for a similar period, had merely green berries on them. There is no doubt that the use of artificial sunlight in horticulture will be of immense advantage; but whether it can be used by market gardeners and people supplying the London markets, entirely depends on the price at which it can be produced. The machine used by Dr. Siemens, of 1,400 candle-light, costs about fivepence an hour to work, exclusive of a man, but including the cost of carbons. Dr. Siemens is of opinion, that a light equal to 6,000 candles would prove to be economical in working. This would have to be fixed 20 ft. above the ground. For forcing early fruits and flowers for the London markets, this discovery, if not too expensive, will be invaluable, as the rays may be concentrated on a brick wall, and by this means fruit may be rapidly ripened. At a lecture at the Royal Institution, given by Dr. Siemens, the action of the dynamo-electric light was tried on some tulips, and it had the effect of causing the small buds to expand to full-blown flowers in about twenty minutes. The electric machine will apparently soon be applied to purposes of general utility, as it enables work on a heavy scale to be carried out, and it is already employed for telegraph work, superseding the voltaic battery. Should Dr. Siemens succeed in producing it in a cheap form, it would be largely adopted, without doubt, in horticulture, as the advantages of being early in the market are well known. It seems almost an undisputed fact, that plants subjected to the influence of the dynamo-electric light arrive at perfection in rather less than half the time they would have taken if left only to the rays of the sun.

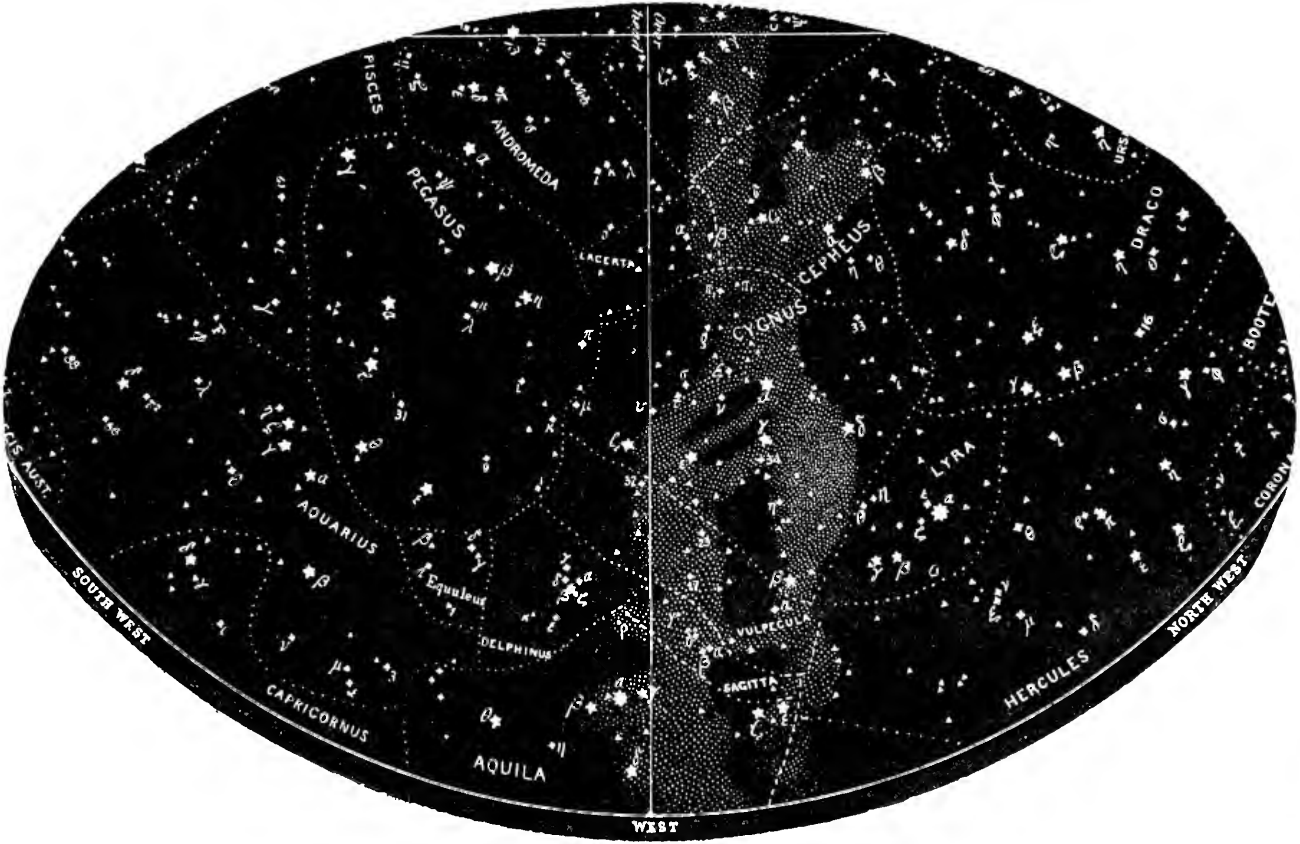
A PLANET OUTSIDE NEPTUNE.

Rather more than half-a-century ago, astronomers were beginning to suspect that outside the path of the planet Uranus another planet must travel, whose attraction caused Uranus to deviate somewhat from the motions which theory assigned to him. We know how this idea eventually led to the discovery of Neptune. From the observed disturbance of Uranus, the place of the disturbing body was determined by Leverrier and Adams independently, and when the telescope was turned to the region of the heavens where this as yet unknown planet should be, *there*, quite close to the calculated spot, was his disc seen. It seems not unlikely that before many years pass another planet further away than Neptune will be discovered. When Professor Newcomb, of Washington, published his "Tables of Neptune" in 1866, he said, "It is almost vain to hope for the detection of an extra-Neptunian planet from the motions of Neptune before the close of the present century." But since Newcomb's "Tables of Uranus" were published in 1873 the planet (Uranus) has been found to pass increasingly more in advance of its calculated place. Mr. D. P. Todd, Assistant in the Nautical Almanac Office at Washington, has found that by a graphical method (the problem not being yet in such a condition that processes of calculation can be applied), that the position of a disturbing body outside the orbit of Neptune can be approximately inferred. He places this body at a distance from the sun exceeding the earth's fifty-two times, so that its revolution around the sun would require 375 years. Its present position along (or near) the ecliptic would be within ten degrees either way of longitute 170°, so that it might be looked for ten degrees along the ecliptic, on either side of the star Tau Leonis. Assuming the distance correctly taken (as in the case of Neptune, the real planet may be at a much greater or at a much less distance than the hypothetical one, without greatly affecting the result as to the disturbing body's apparent position), the mass would be such that, assuming the density similar to that of the four giant planets, the apparent diameter would be about 2″1 (say about the 900th part of the moon's), and it would appear as a telescopic star of about the thirteenth magnitude. He puts the point where the planet's path crosses the ecliptic in longitude 103°, and the inclination to the ecliptic as 1°21′. By the kindness of Rear-Admiral Rodgers, superintendent of the Washington Observatory, Mr. Todd was allowed to begin the search for the trans-Neptunian with the magnificent 26-inch telescope. A power of 400 was employed, which would make the diameter equal to nearly half the moon's, and should therefore show the disc very obviously. On thirty clear moonless nights Mr. Todd searched along the neighbourhood of the ecliptic from longitude 126° 8′ to longitude 186° 1′, without leaving any unsearched space between these longitudes. He says, "if a trans-Neptunian planet is ever discovered, having a diameter as great as 2″, I shall be very much surprised if it is found that it must have eluded my search." But he suggests that at and about the time of the next opposition (which, if his assumed position is correct, would occur within ten or twelve days on either side of March 20), a new search should be made, with a telescope of sufficient power. If a careful and sufficient search near the indicated longitude should prove unavailing, it would be necessary to extend the observation to a limited zone, all round the heavens. It is not likely that the inclination of any trans-Neptunian planet to the ecliptic would be more than 2°, so that an ecliptical zone 4° wide would probably suffice for survey.

Reports of Societies.—We have been requested to insert reports of the meetings of various societies. But the papers read before scientific societies are, as a rule, unsuited to our columns, and we prefer (for the present at any rate) to give our space, which is limited, to matter not requiring translation before it can be understood by the general reader. We shall be very glad to find space for clear and simple accounts by the authors of papers communicated to societies, of the matter which they properly enough present in technical terms to fellow workers. And when papers are of sufficient interest, we shall present our readers with translation specially drawn up for these pages. But reports of scientific societies as usually prepared, that is condensed versions of statements too technical even without condensation to be generally understood, would be simply a waste of space in a journal expressly intended to be of interest to the general public. Moreover, a large amount of matter communicated to learned societies has no interest (even when explained) to other than experts. Our wish is not that all such matter as is thought suitable for communication to scientific societies should appear in these columns (by a sort of editorial pitchforking), but that whatever is worth knowing outside those societies may be sifted out and placed, when duly translated, before our readers. The former course would be the easier and the cheaper; the latter seems the more honest, as alone in accordance with our programme.

Indiarubber Gathering in Columbia.—An interesting account is given of this process in a report just issued by the United States Consul at Carthagena. When the hunter has found a rubber tree, he first clears away a space from the roots, and then moves on in search of others, returning to commence operations as soon as he has marked all the trees in vicinity. He first of all digs a hole in the ground hard by, and then cuts in the tree a V-shaped incision, with a machete, as high as he can reach. The milk is caught as it exudes and flows into the hole. As soon as the flow from the cuts has ceased, the tree is chopped down, and the trunk raised from the ground by means of an improvised trestle. After placing large leaves to catch the sap, gashes are cut throughout the entire length, and the milk carefully collected. When it first exudes, the sap is of the whiteness and consistence of cream, but it turns black on exposure to the air. When the hole is filled with rubber it is coagulated by adding hard soap, or the root of the mechvacan, which have a most rapid action, and prevent the escape of the water that is always present in the fresh sap. When coagulated sufficiently, the rubber is carried on the backs of the hunters by bark thongs to the banks of the river and floated down on rafts. The annual destruction of rubber trees in Columbia is very great, and the industry must soon disappear altogether, unless the Government puts in force a law that already exists, which compels the hunters to tap the trees without cutting them down. If this law were strictly carried out there would be a good opening for commercial enterprise, for rubber trees will grow from eight to ten inches in diameter in three or four years from seed. The trees require but little attention, and begin to yield returns sooner than any other. Those that yield the greatest amount of rubber flourish on the banks of the Sinu and Aslato rivers. The value of the whole indiarubber imported into the States annually is about $10,000,000.

THE WESTERN SKIES IN NOVEMBER.

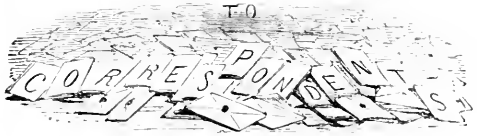


This Map shows the position of the stars in the Western Skies:—

On November 3, at 11¼ o'clock. | On November 10, at 10¾ o'clock. | On November 18, at 10¼ o'clock. | On November 25, at 9¾ o'clock. | On December 3, at 9¼ o'clock.
On November 7, at 11 o'clock. | On November 14, at 10½ o'clock. | On November 22, at 10 o'clock. | On November 29, at 9½ o'clock. | On December 7, at 9 o'clock.

The stars in the western skies are passing downwards towards the horizon, moving aslant, from left to right; but those shown on the right or northern side of the map will not set, but pass over towards the north, there to pass below the pole.

*** Stars of the first magnitude are shown with eight points, those of the second with six, of the third with five, of the fourth with four, of the fifth with three.



Letters to the Editor.

[*The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. He requests that all communications should be as short as possible, consistently with full and clear statements of the writer's meaning.*]

All communications should be addressed to the Editor of KNOWLEDGE, *74, Great Queen-street, W.C.*

All Cheques and Post-Office Orders to be made payable to Messrs. Wyman & Sons.

∴ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

ERROR IN COMPUTING PERIPHERY OF ELLIPSE.

[14]—Will you pardon me for pointing out a slight error on page 37 of KNOWLEDGE?

In the reduction of the expression

$$7\pi\left[1-\frac{1}{4}.\ \frac{13}{49}-\frac{1}{64}.\ \frac{(13)^2}{(49)^2}\ \&c.\right]$$

You give the result as 20·58 in., instead of which it should be 20·508 in. I give the details as follows:—

$$7\pi\left[1-\frac{1}{4}.\ \frac{13}{49}-\frac{1}{64}.\ \frac{(13)^2}{(49^2)}\right]$$

$$=7\pi\left[\frac{64.\ (49)^2-16.\ 49.\ 13-(13)^2}{64.\ (49)^2}\right]$$

$$=7\pi\left[\frac{153664-10192-169}{153664}\right]$$

$$=21.\ 99912.\ \frac{143303}{153664}$$

$$=20{\cdot}508.$$

The solution by logarithms gives a similar result.

Yours faithfully,

WILLIAM J. HARDING.

P.S.—May I suggest that the above expression may be given as an example worked out by logarithms to show their great convenience?—W. J. H.

[Mr. Harding is quite right. Turning to my computation, I find logarithm of result given correctly as 1·3119321, which is the logarithm of 20·50841. I took out the number, however, incorrectly. The difference between the circumference of an ellipse having axes 7 and 6, and the circumference of a circle having diameter 6½, is only a tenth of what I deduced, and is in fact less than the hundredth of an inch. Had I taken axes less nearly equal, there would have been a greater difference; but it is only when the very irregular heads are considered that the difference arising in this way can be worth taking into account.—ED.]

COMETS.

[15]—I have read with interest the article on comets. I am always on the look out for astronomical news, and turned to the article in question in the hope that some light might be shed on the physical nature and purpose of these mysterious tourists in space. I have long been expecting some definite theory to be broached to account for them; some facts have been collected, but comets are still, apparently, without the pale of celestial civilisation and order. The connection between them and meteor streams is established. Are we, then, to regard meteor streams as the condensed material of comets left behind, and separated from the main body in the course of its revolution round the sun? If so, how is the fact accounted for that spectroscopic examinations shows that comets are mainly composed of the vapour of carbon, while the meteorites that have been examined generally contain a large proportion of iron, nickel, &c.? Is it possible that a flight of meteors at a great distance might present the appearance of a comet? Are comets to be regarded as a primary condition of matter, to be afterwards condensed into meteors, and these in turn to assist in the formation of new planets, and the gradual increase of old ones? I believe the theory, first put forth by the editor of KNOWLEDGE, that the rings of Saturn* are composed of a multitude of minute satellites, is generally accepted. Would it be in accordance with that theory to go a step further, and consider the rings to be dense meteor streams? and if so, might they have been introduced to Saturn's system by a comet or comets? Any information on these points will, doubtless, be acceptable to others besides

ONE WHO WANTS TO KNOW.

P.S.—The crape ring of Saturn was well seen here (Hastings) on the evening of Nov. 6, power 250, 4¼ in. refractor.

FIGURES OF THE CONIC SECTIONS.

[16]—When I am studying geometry, as in Euclid, I am able to describe circles of any size and in any position with compasses. But in studying the geometry of the conic sections, I am not able to make such illustrations as I want. I cannot draw the parabola or the hyperbola freehand; nor, indeed, can I draw a satisfactory ellipse in this way. But, even if I could, I want something more. I want to be able to draw with exactitude a parabola, hyperbola, or ellipse, as occasion may require, in any position and of any size or shape (parabolas, of course, are all of the same shape, but hyperbolas and ellipses are not). I observed a few weeks since in a back number of the *English Mechanic* what seems to me a very simple and satisfactory way of drawing parabolic and hyperbolic arcs, as follows:—

For the *parabola*, set two straight lines AB, BC, (Fig 1) at right angles to each other, and divide each into the same number of equal parts in the points 1 2 3 4 5, join A1, A2, A3, A4, A5, and through

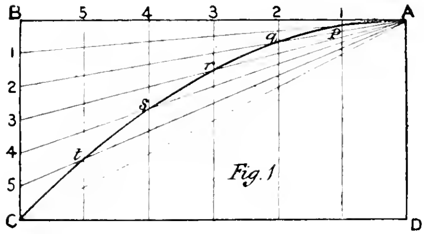


Fig. 1

the points of division along AB draw parallels to BC. Then the points p, q, r, s, t, in which the parallels through 1, 2, 3, 4, 5 meet A1, A2, A3, A4, A5, lie on a parabolic arc through AC, which can be swept out as in the figure.

For the *hyperbola*, set two straight lines AB, AC (Fig. 2) at right angles, and from a point O outside BAC draw through any points 1, 2, 3, 4 on AB, straight lines cutting AC in 1, 2, 3, 4. Through

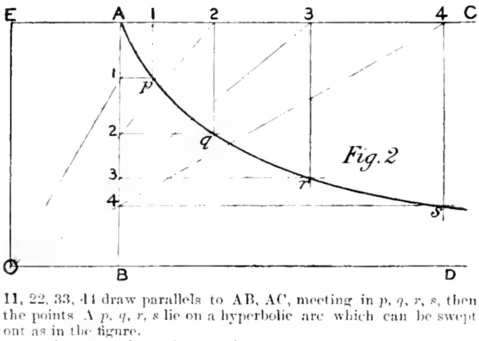

Fig. 2

11, 22, 33, 44 draw parallels to AB, AC, meeting in p, q, r, s, then the points A p, q, r, s lie on a hyperbolic arc which can be swept out as in the figure.

This is well, so far as it goes; but it does not meet my difficulty.

* [The theory was first advanced by the Bonds, in America, and independently by Clark Maxwell, of Glasgow.—ED.]

We get in this way a parabolic and a hyperbolic arc (the ellipse cannot be represented at all in this way by the simple use of parallel straight lines), but we have no means of drawing a parabola or hyperbola of given size, having a given focus and directrix, or in the case of the hyperbola, having a given centre and given asymptotes. I am aware that there are mechanical means, some of which seem simple enough, for drawing all the conic sections, but they do not suit my purpose. I want to be able at any time, with the instruments found in an ordinary box of instruments, to draw a parabola, hyperbola, or ellipse of determinate size, position, and shape. Can you help me to meet this difficulty?

GEOMETRICUS.

[I will take an early opportunity to describe some simple methods of drawing the conic sections in the way required by Geometricus. The methods described in his letter are correct; but in practice it is well to have methods which give a series of enveloping lines, guiding the hand in sweeping out the curves after such points as p, q, r, s, and t have been obtained; or the curve may be struck out in that way without obtaining determinate points as above. To illustrate my meaning, let Geometricus join C 3 in Fig. 1, which line will be trisected where crossed by p 5 and s 4. Join these points of trisection with the points 2 and 1 (on A B) respectively; then the two straight lines thus drawn and C 3 will touch the parabolic arc at C, s, and q respectively. With A B there will be four tangents. If A 3 and C 3 (3 on A B) be divided into six equal parts, and the successive points of division along C 3, be joined with the successive points of division along 3 A, there will be obtained seven tangents touching the arc A C at A, p, q, r, s, t, and C. Tangents for the curve A, q, s, Fig. 2, may be obtained in another way, which I will describe, as also methods for drawing ellipses, either by obtaining any number of points along the curve, or by getting a series of tangents enclosing it. In the meantime, I note that A is the vertex, AD the axis of the parabolic arc AC in Fig. 1; neither its focus nor its directrix is given directly by that method, but by taking BC bearing a definite ratio to AB, the position of the point which is at the extremity of the latus rectum (or focal chord perpendicular to the axis) can be determined at once, and thence the position of the focus and directrix. In Fig. 2, A q, is part of one branch of a rectangle hyperbola, of which O is the centre, and OD, OE are asymptotes. The point A is not a determinate point on the curve unless the rectangle OA is also a square, in which case A is the vertex of the branch. By making OA a rhomboid, a hyperbolic arc having its asymptotes inclined at any angle, can be obtained; and if the rhomboid is also a rhombus, the vertex of the arc so described will be at that angle of the rhombus which lies farthest from O.—ED.]

CAN ICE-YACHTS SAIL FASTER THAN THE WIND?

[17]—"Upsilon" (letter 3, p. 16) is one of the many and intelligent men who have been perplexed by this apparently simple question. I think the following considerations appeal to the judgment, perhaps, more forcibly than those you append to "Upsilon's" letter:—

If a ship is sailing before the wind, a pressure is manifestly exerted on its sails, and in consequence, the velocity increases until the ship has the same velocity as the impelling fluid (the air). This is the theoretical limit, for then the pressure ceases.

But if, on the other hand, a ship is sailing with the wind abeam, no matter how great the velocity, the moving air exerts a pressure on the sails. The component of this pressure resolved in the direction of the ship's motion tends to increase that motion, and since the wind pressure is constant in action and direction, the ship may be considered to be moving under a uniformly accelerating force. Hence, if there be no drifting to leeward (of course, a theoretical consideration), there is no theoretical limit to the velocity which the ship may attain. In the case of ice-yachts, the drifting and friction are at a practical minimum, and the speed they attain may be very much greater than that of the wind.

CRUSADER.

[The reply we gave last week takes the line which "Crusader" suggests. He will see, however, that the accelerating force is not uniform, but diminishes as the velocity of the ship increases. It would be a pretty problem to determine, with certain necessary assumptions as to sails, frictional resistance, &c., the maximum velocity attainable with a given wind. ED.]

IS THE SUN HOT? (*Abstract.*)

[18]—The sun is regarded as the fountain head of all terrestrial energy. The gravitation of the central mass of the sun causes tremendous compression, giving birth to the forces that are transmitted to us. Now the forces that we are most sensible to are heat and light, but there is another force that we are not so sensible to, i.e., chemical force. Did "Anti-Guebre," when he drew near to his fire, ask himself the following question: Where did the heat originate? The answer is: The sun. For the sun transmitted his energy (by the medium of the æther) to the earth, the force was utilised by plants, plants in course of time changed into coal.

Now, as regards the "mountain proposition." It is a well-known fact that the "rays" of the sun pass *through* the atmosphere without materially altering its temperature, and are absorbed by the earth, which gives out *again* the heat which it has absorbed to the surrounding atmosphere. Now, on a mountain or in a balloon, we are further from the actual source of heat, and the air, being thin and rarefied, does not absorb heat like the denser and nearer-to-the-earth atmosphere.

The explanation of the mountains, &c., will also apply to the cirrus clouds.—Yours, &c. SUN.

[19]—With regard to Mr. Newton Crosland's letter (No. 5, p. 35) on this subject, which is after all mere supposition, surely it is more natural to suppose that a body which produces all the phenomena of heat is in itself hot—at all events, till we find more evidence to the contrary than N. C. can furnish. He says the inflammatory action may be merely the chemical conversion of substance into force. I should like to know what is combustion but this? Your correspondent "Tyro" seems under the impression that light is visible; perhaps when he hears it is not, he will be able to account for the non-appearance of the broad flood of effulgence.—Yours, &c., C. J. SHAW.

[20]—I may, perhaps, be permitted to say a word in opposition to "Anti-Guebre's" views.

Before discussing any point, I shall at once state that I take the "conception of a medium filling space, and fitted mechanically for the transmission of vibrations of light and heat"—in other words, the *luminiferous æther*, as the foundation of my remarks. "Anti-Guebre" leaves the subject of radiation and absorption untouched, and here I think we have the explanation of his observations.

The conception of the æther filling space may now fairly be said to be inductively proved. Prof. Tyndall's experiment, in which he allows heat waves from a radiant body to pass through a glass tube, taking the temperature by the thermo-electric pile, shows, beyond a doubt, that *air* is incapable of absorbing heat.

He says "oxygen, hydrogen, nitrogen, and the mixture, atmospheric air, prove to be practical vacua to the rays of heat." Waves of heat, then, travel from the sun to us without having been absorbed; but directly they impinge upon the earth, and upon absorbing and radiating bodies, they produce heat, and cause a brisk radiation. Taking the accepted scientific definition of heat as "a brisk agitation of the parts of an object," we can easily understand that when the atoms of the æther "swing" with the atoms of the bodies upon which they impinge, a quicker movement takes place, and consequently heat is generated. Absorption, then, is a source of heat, and heat so generated is radiated into the air and turned to account. The power of the atmospheric aqueous vapour to absorb heat *radiated from the earth* is immense, and it is calculated that 10 to 15 per cent. of heat from the earth is absorbed within 10 or 20 feet of the earth's surface. It has been observed that where the air is dry, and remarkably free from aqueous vapour, as in Australia, the temperature of the night is 50° to 60° below that of the day, because there is no check to radiation. Anti-Guebre's, and all observations fall in with these explanations, and prove them. The further we go from the earth's radiation, the colder we get. It is a remarkable fact, proved by experiment, that aqueous vapour has the power to absorb rays of heat coming from the *earth*, but is incompetent to absorb rays from the *sun*.

By this remarkable adjustment the earth is rendered habitable.

G. F. P. DYER.

1, Queen-square, Bath.

WASTE OF SOLAR HEAT.

[21]—The letter in your present issue touches on a point in which it has long appeared to me that scientific language is erroneous. We talk of "Heat" coming from the Sun; and under that impression, "Anti-Guebre's" complaint of the "loss of Heat" has some plausibility. But it appears to me that the energy radiated by the Sun is only one factor of the result called Heat.

Energy	+ or	×	Something	=	Heat
Energy	+ or	×	Something else	=	Light.
Energy	+ or	×	Something else	=	Electricity,

and Heaven knows how many other yet unknown powers. There-

fore, it is by no means certain that this energy should be wasted, although it fails to (i.e., is not designed to) form heat on this little globe.—Cogito.

A CLEVER SEA-GULL.

[22]—During a recent passage over the North Sea, a flock of sea-gulls followed the steamer for many miles. At last I noticed that one of them, a remarkably fine bird, had, by some chance, got an angler's line attached to its wing. The poor thing flew about the rigging, its companions, meanwhile, uttering loud cries. After great cawing, the bird flew quickly towards the ship, dashed round one of the ropes several times, and ultimately flew off, leaving the line twisted round the rope. Was this what Mr. Herbert Spencer would call "reason in inferior animals?"

Hoping to see your journal succeed, as it deserves to do,

I remain, yours,

Geo. B. Fraser.

Helensburg, November 5, 1881.

A LUNAR ILLUSION.

[23]—With reference to geometrical illusions, I am sure that many persons must have noticed the following, and yet my attention has never been drawn thereto either in conversation or in print:—The crescent moon being Diana's bow, we shall give the name "sagitta" to the line drawn from the middle of the invisible bow-string connecting the two horns of the moon to the middle of the convex side of the crescent, or the illuminated limb of the moon; and we shall still apply the name, even when the moon is no longer a crescent. The sagitta is necessarily aimed directly at the sun; and yet, to the eye, it always seems to point above, often very considerably above, the sun. The reason is that we are accustomed in drawing, and looking at, pictures on flat surfaces, to consider and treat points or forms as they are projected on the "plane of vision"; but they are really presented to us as projected on a spherical surface, whose centre is the eye. The difference is trifling when the angular field of view is small, and from habit we neglect it, and we are led to do this even when the difference is very important, and we know it to be so. Take the simplest case of the illusion mentioned. The sun is on the horizon, and the moon is 90° distant, not perceptibly different from half-moon; we shall suppose her altitude to be 25°. The moon is at the highest point of the great circle of the sphere of vision passing through the sun, the moon, and the point of the horizon opposite to the sun. As the sagitta points directly to the sun, it lies on that great circle; but as it is at the highest part of that great circle, it is horizontal. Now, when we produce the horizontal sagitta sunwards by the eye, we cannot help picturing to ourselves a line which remains always parallel to the horizon, and our mental production of the sagitta, instead of hitting the setting sun, passes 25° above it.

The illusion is connected with the fact that, in turning to look from the moon to the sun, the observer rotates his head, or perhaps his whole body, round a vertical axis, and not about an axis perpendicular to the plane containing his eye, the moon, and the sun. By turning himself properly in the latter manner, the observer can, by the eye, correctly produce the sagitta so as to hit the sun; it will be better, though not necessary, to screen off the horizon. We have neglected refraction, the effect of which is small comparatively, but in the case considered, the difference of refraction goes to diminish the illusion, and not to help it.

M.

[Five or six years ago I put the question raised by "M" before the readers of the *English Mechanic*. It is connected with a question of some interest to artists, viz., the true rules of perspective for pictures including a very large visual area.—Ed.]

LATIN QUOTATIONS.—OPTICAL ILLUSION.

[24]—I welcome with much pleasure the appearance of your new scientific journal, and feel sure that it will meet with the support it deserves. It is not everyone who cares to pay sixpence for *Nature*, and the cheaper ones are sadly wanting in the tone and character which I think should pervade everything connected with science. I should like, however, to make one deprecatory remark. I think that the too frequent use of Latin quotations should be avoided in a paper addressed principally to those who have not had an university education. Many who take a lively interest in science have not had time to study the dead languages,* and to them (unless accompanied by a translation) these quotations are simply repellent.

I enclose an instance of an optical illusion just observed. It will be noticed that Mr. Smith's address appears to decline to the left. Yours truly,

Nov. 9, 1881. C. J. Watson.

Mr. J. J. SMITH,

Blank Green,

SMITHBOROUGH,

Near BLANKTOWN

* [There are quotations so familiar that they can scarcely be regarded as belonging to a dead language. Such was the one I used, *Nescit vox missa reverti*, which means that "what has been said cannot be unsaid."—Ed.]

OPTICAL ILLUSIONS.

[25]—The No. 1 illusion I made an independent discovery of many years ago, as also, no doubt, have many more who have been much used to drawing geometric and mechanical patterns. Since the advent of Knowledge, however, I have thought a little more over it. The explanation of this figure is, I believe, to be found in the peculiar movements of the muscles of the eyeballs. The principal movements of the eyeball are vertical and horizontal. Vertical lines are followed by means of one pair of muscles, which move the eyeball through a vertical plane. Horizontal lines are followed by corresponding muscles. Oblique lines are followed by the eye through the combined action of both these pairs of muscles. It is true that there is also an oblique pair of muscles, but from their position, I do not think they assist the eye to follow an oblique line, being more suited to rotate the eye upon the axis of its lenses. Referring now to diagram No. 1, the eye follows the line EG by a simple movement, but in following the line AB, both pairs of muscles are employed. This movement being more complex, is not so certainly continued when the guide of the line is lost by the interposition of the space EH. The eye is led away, as it were, also by the commencement at the point B of the line BG, which breaks the continuity of the oblique movement. It seems to me further complicated by the movement of

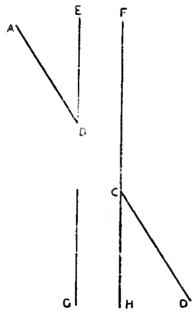

Fig. *a*.

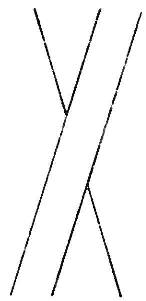

Fig. *b*.

two eyes, which work more easily together in the vertical and horizontal movements than in the oblique. This may be noticed when closing one eye, the illusion being then not so complete.

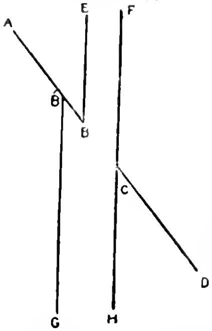
In confirmation of my remarks, I send you two diagrams. If the line EG be broken at B, the illusion is almost destroyed, the line having lost its power of attracting the eye to a simpler movement (Fig. *a*).

Again, if the same diagram be set before the eye symmetrically disposed to the vertical position, so as to present to the eye similarly situated oblique lines, the illusion will vanish, as then the oblique movements of the eyes are required to follow both the parallel line *and* the one which is opposed to them. This, then, brings the diagram to the form of an ordinary Roman X (Fig. *b*) in which there is no difficulty in following the single line. If this same diagram be set before the eye with the parallel lines either vertically or horizontally disposed, the illusion will reappear. Hoping Knowledge will be as successful as it deserves, I remain, yours, &c.

W. D. Richmond.

[26]—In his interesting article on "Illusions" in your first number, Mr. Foster writes

"The lines A, B, C, D of Fig. 5 appear to be curved so as to be nearer at the middle than at either end; while the lines E, F, G, H, in the same figure, appear to be so curved as to be farther apart in the middle than at either end."



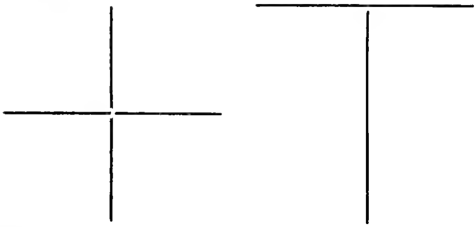
The impression on my mind on looking at the figure is *exactly the reverse* of this. Is the letterpress at fault,* or does the difference depend upon my mental reception of the phenomena?

Referring to Fig. 1, might I be allowed to suggest as an explanation of the illusion, that the mind unconsciously grasps the impression of the vertical distance between EG and FH to the exclusion or depreciation of the greater distance between B and C. I find that if I construct the figure as below, making the distance of B'G from FH equal to the diagonal distance BC, the illusion disappears.—Yours faithfully.

Wm. H. Allen.

---

[27]—A correspondent sends the following:—



How much longer is the perpendicular than the horizontal cross-bar?

A NEW THEORY OF THE TIDES.

[28]—Your correspondent, "A Fellow of the Royal Astronomical Society," in your first Number, was very hard upon paradoxers. Would he be very much shocked to hear—if you will permit me to utter the contumacious opinion—that one of the most blundering paradoxes with which I am acquainted is the Newtonian doctrine of the tides? Let us examine this question carefully and briefly. Every one knows that the tide rises or falls simultaneously on opposite sides of the earth. Newton endeavoured to explain this phenomenon by the hypothesis that the moon attracted the water on the side nearest to itself, and at the same time drew the earth away from the water on the opposite side. This theory has been accepted with universal approval, but can anything be more erroneous, not to say absurd? We are coolly asked to believe that when the sun and moon are in conjunction on one side of the earth, drawing up the tide, one of the most mobile of substances, the water, on the other side, is left bulging out into space, where there is no rival attraction to hold it, and that it is capable of resisting three attractions—that of the sun, of the moon, and of its own earth—all at once!

If this is the best explanation that can be given of the tides, no wonder that Aristotle proclaimed the difficulty to be "the grave of human curiosity."

I maintain that it is a monstrous scientific fallacy.

Those who pull down ought to be compelled to reconstruct; those who denounce one system are bound to offer some substitute which may be considered preferable. Therefore, I must not shrink from this imperative task. With your permission I will here give a quotation from my paper on "The Astronomy of the Future" in "Pith":—

"What we say is, that the magnetic attraction of the moon, as a magic wand or beam, penetrates the earth from one side to the other—sword-like it sheathes itself in the diameter of our globe. At the spots where this spiritual and invisible falchion makes its entrance and exit, the waters rise to meet it in obedience to its mighty beckoning and summons; and as the moon is for ever shifting its position, so the waters are *for ever* chasing over the surface of the globe the two mundane extremities of the moon's irresistible, triumphant electrical wand! Or we may, as an alternative, assume that this magnetic influence, which is attractive on one side of the earth, becomes repellant on the other."

I now wish to invite your readers' attention to another point connected with the Newtonian System of Astronomy. I fancy that we must discard the theory of "universal gravitation" which has been so belauded, in favour of the theory which I have termed "The Polarity of the Universe." Gravitation, with its clumsy addition of a centrifugal force, is simply an impossible explanation of the movements of the heavenly bodies. Centrifugal force, which is entirely of a mechanical origin, cannot be originated and sustained between two bodies unless they are physically connected and moved from a central power; whereas magnetic polarity, with its attraction and repulsion, is a satisfactory solution of the phenomena of motion in the solar system. As long as a planet presents its poles in a slanting direction towards the sun, the revolution of the planet is an everlasting dynamic certainty, and it is quite possible that the sun may possess a number of poles, one for each planet.

In the first article on "Comets," you say that Newton discovered that their motion was regulated by the law of gravitation. I contend that this discovery was a delusion. We know that some comets move off in curves, which render their return to our system an impossibility; and if there occurs, in Nature, one exception to a law, what becomes of such law? It is null and void. I submit that comets *do* obey the laws of polarity, and that they *do not* obey the law of gravitation.

I believe that we must abandon the teaching of Sir Isaac Newton, and consider him one of the paradoxers and scientific old fogies of the past.—Yours, &c., Newton Crosland.

London, *Nov.* 12.

[I fear Mr. Newton Crosland belongs to the class of confirmed paradoxers, those who having encountered difficulties which they have been unable to surmount, suppose that they have made discoveries concealed from others. As a mere matter of fact, the accepted theory of tides would give (apart from effects of oceanic friction) low water under the moon and opposite that region; yet the Newtonian theory that the moon's attraction would of itself cause a leaping up of the water, both under the moon and opposite, is sound. Gravitation requires no centrifugal force, and, indeed, it is only in treatises by ill-informed writers that the theory of a centrifugal force as such is propounded. What is called centrifugal force is in reality simply the measure of what the centripetal force does, it is only another way of viewing the centripetal force. I believe Mr. Crosland's views will be received when Newton is entirely forgotten—but not till then.—Ed.]

DR. FERRIER AND VIVISECTION.

[29]—A distinguished professor at one of our colleges once said to me: "The manner in which our countrymen receive the conjectures of popular teachers of new doctrines only proves what most of us knew before, that they are the most gullible of all intelligent nations." The remark may be applied not only to the votaries of science, but to the followers of any agitator who from the rostrum calls upon his supporters to uphold or denounce what he considers to be right or wrong. As a nation, we are opposed to cruelty and oppression. We boasted in former days of our Anti-slavery Leagues, and our Society for the Prevention of Cruelty to Animals receives (and justly) a large share of public support. If a man kicks his donkey or starves his dog, he is speedily brought before a justice of the peace, who rarely fails to punish the offender. Last Thursday the humanitarians applied for a summons against Dr. Ferrier, under the Vivisection Act, for performing an experiment which was described as being "frightful and shocking."

The summons was granted, and long ere this many thousands of kind-hearted people of both sexes have given vent to their horror of the professor's experiments on the two unfortunate monkeys, and doubtless have settled in their minds that he is a fit subject to be made an example of, and worthy of punishment.

The vexed question of vivisection has been well ventilated by abler pens than mine. It is not my intention to say a word either for or against the practice, but the impartial reader should pause before he passes sentence in this matter. *Audi alteram partem* should be the motto of every right-thinking Englishman, and important subjects, particularly those relating to medical science, should be carefully analysed before an opinion is expressed, and such a man as Dr. Ferrier ought not to be placed in the category with the human brutes who daily appear in the dock to answer charges of wanton cruelty.

[* The error is in the figures; the upper should have been the lower.—Ed.]

I have long watched with interest the results of Professor Ferrier's labours in the cause of humanity, and a few words upon the nature of his experiments may not be out of place here.

Physiology is, comparatively speaking, a new science. Before the discovery of the circulation of the blood, physicians were little better than charlatans. Many of the early philosophers were mere dreamers; they made little or no advancement in the natural sciences, but their extravagant ideas influenced civilised nations for nearly twenty centuries. Aristotelianism and peripatetic dogmas *hindered* the progress of science. When the great Bacon arose giant-like, amidst the chaos of hypotheses and truthless doctrine, and laid the foundations of the inductive and experimental philosophy, then a new era commenced, and scientific progress followed.

There is no subject in physiology more attractive than the study of the human brain; that wonderful and complex organ has occupied the attention of philosophers in all ages, but little light has been thrown upon its functions until recently. Several physiologists of the seventeenth, eighteenth, and early part of the present century, wasted a deal of their time in fruitless searches after the exact seat of the soul. Some held that the soul was equally diffused through every part of the body. Descartes maintained that it is in the pineal gland of the brain, and Borri asserted that in the brain is formed a certain very subtle, fragrant juice, which is the principal seat or residence of the soul, and that the subtlety and fineness of the soul depended on the temperature of this liquor, rather than on the structure of the brain. Now, all these fanciful theories were very interesting to read, but they did not benefit mankind, and it was not until Flourens commenced his experiments upon the brains of animals that any definite knowledge of the functions of the cerebral organ was arrived at.

A worthy follower in the footsteps of the French physiologist is Dr. David Ferrier. The work of the latter on the "Functions of the Brain" has been justly described as "marking the end of an old era and the beginning of a new one in cerebral physiology." In briefly summing up the results of Dr. Ferrier's experiments on the brains of animals, I wish to direct attention to the localisation of two or three of the cerebral functions as demonstrated by the learned professor. The upper end of the Fissure of Sylvius, called the angular gyrus, is the centre of the sense of sight. When that part of the cerebral substance is destroyed, the sense of vision is gone in the opposite eye, though all the other senses remain, and an animal can hear, and smell, and taste, and touch, and perform every voluntary action as before. "It is a remarkable fact," says Dr. Ferrier—and let it comfort you, oh ye anti-vivisectionists—"that the brain is unsusceptible to every kind of irritation except electricity. You may cut and cauterise the brain without exciting sensation, although it is the organ of feeling. This we have learnt from experiments and the testimony of men who have had their brains injured." In another convolution of the brain, called the temporo-sphenoidal lobe, Dr. Ferrier found the centre of the sense of hearing—from the lower extremity of the lobe proceeds a large tract or process which is called the olfactory tract. When this part of the brain is destroyed, the sense of smell is abolished. All these discoveries explain certain facts which have been observed in connection with disease. Of course, I have only selected a few of the many illustrations of the Professor's experiments, and it only remains for me to point out the vital importance of such discoveries to the medical profession, and, I may add, to all who are suffering, or likely to suffer, from cerebral disease. It is impossible to experiment upon the human subject. There is no alternative but to practise upon the living animal, if an accurate knowledge of the functions of that important organ is to be gained.

Surely, when the facts are known, few will accuse the Doctor of wanton cruelty. All his experiments are made for the benefit of suffering humanity and the advancement of science. To conclude, in the Professor's own words:—"You may rest assured of this, that every addition to our knowledge of the brain will inevitably lead to a better appreciation, and more successful prevention and treatment of a large, and it is to be feared, rapidly-increasing class of distressing diseases of the brain and nervous system, which, even to those best acquainted with them, are still involved in profound obscurity."

W. L.

A. PLANET'S MOVEMENTS.—THE TIDES.

[30]—In looking over the first number of KNOWLEDGE, I find on page 13 the following—for an explanation of which I shall feel thankful.

1. "The planet Mars, it will be noticed, passes during this month what is called a stationary point; he is advancing (moving from right to left) till November 17th, after which he retrogrades. But he does not really come to apparent rest, owing to the wide sweep of the loop he forms between his stationary points. Jupiter, Saturn, and Neptune are all three retrograding." 1. Do the planets move in their orbits uniformly, or turn backwards and forwards, or how? 2. What is the cause for this, and is this retrograde motion performed during each revolution; if so, how often? 3. What am I to understand by "Mars not coming to apparent rest, owing to the wide sweep of the loop he forms between the stationary points?" What does this loop signify; and is there really such an occurrence as Mars or the other planets coming to a rest, &c.?

2. In Guillemin's "Heavens," page 391, in note by R. A. P., I find the following: "If we consider only the dynamical relations, we find that the place of low-water should be under the moon, and at the opposite part of the earth, the place of high-water between these regions." Will you kindly explain how the point of high-water ought not to be directly under the moon, but at a point at right angles to it?

ZETA.

[The movements referred to are only the apparent motions of the planet in the heavens. The planets constantly advance in their own orbits. I will take a later opportunity to answer "Zeta" more fully on both subjects.—ED.]

WHAT IS THE CAUSE OF GRAVITY?

[31]—I was glad to see the appearance of a paper like this, giving the views of the best men of to-day about the more interesting things in nature in plain language. As you invite correspondence, permit me to state that, although a toiler who cannot find much time for reading, I take, nevertheless, a very great interest in the study of nature. It gives me hope and affords me pleasure. And, as you say, it is certainly religious and improves our feelings. As regards myself, I take an especial interest in the law of gravity, not as to how, but as to its cause. I have read that Sir Isaac Newton could not tell. I should feel very grateful if you would give us the various theories that have been given out on this subject, no matter how silly they be, in as short a form as possible. On inquiry, the answer is always "Attraction"—a meaningless word. I have for many years observed every phenomenon resembling the action of gravity, and have come to conclusions as to what its cause is, that on careful comparison harmonise with all the well-known and undoubted fundamental laws of nature. I have read of experiments made and theories submitted that in no way come near the mark, but I may not have reached the right source yet. Experiments to prove gravity are difficult to make because we cannot exclude the earth's gravity from them even for a moment. But, by the help of reason, it can be made, and even clear to a mind that can comprehend other natural phenomena that can only be seen by the mind's eye. But, as soon as the idea has been grasped, numberless things come to view that resemble the earth's gravity on a smaller scale. "Attraction," as a word, is misleading, for to attract there must be a substance having these impossible qualities of pulling down every kind of matter in a vacuum of any substance.

However, to write my view on this would be months of labour and certain ruin. I merely wanted to suggest how interesting a subject this would be to many more.

Yours, &c., F. J. D., "SELBST."

[The subject is, doubtless, most interesting. It is, also, exceedingly difficult. Does "Selbst's" theory accord with the demonstrated fact that the action of gravity is communicated far more rapidly than light travels?—ED.]

PHRENOLOGY.—VECTORS.—INTONING IN SYNAGOGUES.

[32]—I don't know whether you will consider the following questions worth asking or answering in KNOWLEDGE.—

1. Assuming that phrenology is all wrong, *what are the causes* that determine the shape of the head? I am myself a sceptic, in the proper sense of the word: but Lewes' opinion, that the brain acts as a whole, and that its functions are not localised, seems to me, *à priori*, highly improbable. 2. Having lately begun to take great interest in mathematical physics, I read carefully Maxwell's little book on "Matter and Motion." The mode of treatment was almost entirely strange to me; and what I want to know is, whether the new method has any special value: whether any, or what peculiar benefits are gained by the use of vectors in mechanics, as distinguished from the old geometrical and analytical methods. In any case, Maxwell's treatise wants a good deal of expansion and illustration to make it intelligible to a tyro. 3. My last question, I am afraid, hardly falls within your province, unless you take in *omne scibile*; but it is one to which I have hitherto failed to get an answer. In reading the Scriptures in the Jewish synagogue, a certain intonation is employed. Is this expressed or expressible in the ordinary musical notation, or in any musical notation whatever, and if so, where could it be found?

G. P.

Queries.

[11]—Logarithms.—Will you kindly state the best cheap "Table of Logarithms and Antilogarithms," &c., suitable for a general science student, but more especially for one preparing for examination in "mine surveying," in connection with the City and Guilds of London? He would observe that he has seen a book of tables advertised at 2/-, and written by W. C. Unwin, and if you think that will be quite suitable, "yes" opposite the initials will be deemed a sufficient answer. The writer was intending to purchase the above book, but on reading your remarks on logarithms in No. 1 of Knowledge, determined to seek your advice.

James Grundy.

We use ourselves Chambers's "Tables" for ordinary work, and Hutton's when certain subsidiary tables are required. We have not used the work named above, but probably some of our readers can give Mr. Grundy the information he requires.—Ed.]

[12]—Is it possible for the same star to be both morning and evening star on the same day? Does not Tennyson's Hesper-Phosphor refer to the same star at different periods of its month?—R. A. Bullen. [To the first question, No; to the second, Yes, only for month should be written synodical period, meaning the period in which the planet goes through all its apparent movements with respect to the sun, from being in conjunction with him to its next return to that position.—Ed.]

[13]—Water Spheroids.—If a little water is spilled from a height of a few feet upon a surface of smooth water, a portion of the fluid, instead of mixing with the rest at once, is formed into small globes or spheroids which, I think, seldom if ever exceed ¼ inch in diameter, most of them being very much smaller. These little drops move over the water for distances varying from a few inches to a few feet, and then gradually though rapidly diminish and disappear.

In explanation of this very common phenomenon, I have been informed that a layer of air of greater density than the atmosphere is formed over the surface of the water, and that the part of this layer between the globules and the plain surface of water offers so much resistance that for a time the two bodies of fluid are unable to unite. It would be interesting to know what causes this denser layer of air, and why it is only for a time able to overcome the force of gravity acting upon the spheroids.—E. C. R.

[14]—Velocity of Sound.—I understand Tyndall to say that the increase of temperature in the condensed part of a sonorous wave augments its velocity one-sixth. Is the increase gained by the rise of temperature in the condensed portion not counterbalanced by the decrease of temperature in the rarefied part?—Sound.

[15]—The Missing Link.—What is the "missing link," of which we hear so much in connection with Mr. Darwin's books? Is it what should come between an ape and a man? An answer on this point would much oblige—An Ignoramus.

[16]—German and English.—Is there any work where I can find an account of the progress by which the English and German languages have come to differ so widely in character from each other? In good English writing we find the arrangement of subject, predicate, &c., quite different from that adopted in good German writing. Yet the languages had a cognate origin, and must once have resembled each other somewhat closely in those points in which they now differ. Strangely, too, while the German language has become in structure less simple than the English, the German words for abstract ideas, and their scientific terms, are much simpler than ours. When we speak of oxygen, a German speaks of sour-stuff; but where an English writer would say that a mixture of oxygen and hydrogen will explode, under such and such conditions, a German would say that sour-stuff and wasser-stuff, in certain proportions mixed, and under certain conditions so-and-so treated, explode shall.—Eclecticus.

[17]—Retrogradation of a Planet.—Which planet has the longest arc of retrogradation? And on what circumstances does the length of the arc depend?—Astronomicus.

[18]—Chemical Treatises.—Can any reader of Knowledge tell me what books will give me the best general idea of the so-called new chemistry?

Arctic Navigation.—Advices from Copenhagen state that the news received from the Dutch Polar Expedition on board the schooner *William Barents* is very unfavourable. Owing to the continuous ice barrier which extends nearly to Norway, Spitzbergen could not be reached, nor even the Bear Islands; and after one more attempt to force through northward, the expedition will return home, as the captain is convinced that this year Nova Zembla is completely enclosed in a barrier of ice.

Replies to Queries.

[1]—Ultima Thule.—The expression "Ultima Thule" occurs in Seneca's "Medea," Act. iii., verse 375:

—Venient anni-
Saecula series, quibus oceanus
Vincula rerum laxet, et ingens
Pateat tellus, Typhisque novos
Detegat orbes; nec sit terris
Ultima Thule.

The passage has been quoted to show that the ancients had heard of the New World, as our school books call the ancient continent of America. It seems, however, to prove rather the reverse, as showing that Thule (whether Thule were Iceland or one of the Orkneys, Shetlands, or Hebrides) was, in Seneca's time, regarded as the remotest-known region of the earth. X. Z. Z.

[1]—Ultima Thule.—Pytheas, a citizen of Massilia (Marseilles), previous to the time of Alexander the Great, undertook a voyage of discovery to the far north. The regions discovered by him were enveloped in fog and "chaos" and uninhabited. He designated the farthermost limit of his discovery Thule, whence "Ultima Thule." The actual identity of Thule is shrouded in mystery. Of Jutland, Shetland, Norway, and Iceland, each claims precedence as the Thule of Pytheas. Speaking offhand, I believe Pliny uses the expression "Ultima Thule." I cannot recollect the way in which he used the term. Some imagine Thule as a creation of the poets to express the extreme limit of the world.—W. G. Rolfe.

[1]—Ultima Thule.—If your correspondent is a classical scholar he may refer to Ptolemy, Tacitus, and others. Pliny describes it as "an island in the northern ocean discovered by Pytheas after sailing six days from the Orcades." I quote the following from Brewer:—"Called by Drayton, Thuly. Pliny, Solinus, and Mela take it for Iceland; others, like Camden, consider it to be Shetland, still called Thyleus-el (Isle of Thyle) by seamen, in which opinion they agree with Marinus and the description of Ptolemy and Tacitus." Bochart says it is a Syrian word, and that the Phœnician merchants who traded to the group called it Gezirat Thule (Isle of Darkness); but probably it is the Gothic Thule, meaning the "most remote land," and is connected with the Greek telos, the end.

Where the northern ocean in vast whirls,
Boils round the naked, melancholy isles of farthest Thulè.

Thomson, "Autumn."

Thule was the most northern part known to the ancient Romans.

Tibi serviat ultima Thule

Virgil, "Georgics" i., 30.

—R. T. Wright.

[3]—Flight of Birds.—If "Aërial" considers for a moment the very small proportion the bones of a bird bear to its bulk, and the still smaller cavities he speaks of, I think he will see that the heated air the latter contains can but very slightly assist the bird's flight, or rather buoyancy; besides which, the heat of a bird would only cause a slight expansion of the enclosed air. Is "Aërial" sure the bone cavities do contain air, and not some gas?—E. C. R.

[3]—Flight of Birds.—The flight of birds cannot be aided in any appreciable degree by the presence in the air-passages of the bones of air, lighter (because warmer) than the air in which the bird is flying. The actual supporting power obtained in this way can be easily shown to be utterly insignificant. It is simply the difference between the weight of the air in the passages and that of an equal volume of the outer air. This is less, of course, than the weight of a volume of air equal to the volume of the air-passages, and much less than the weight of a portion of air equal in volume to the bird, which would correspond to a very small fraction of the bird's actual weight, perhaps about one 500th part. The support obtained in this way cannot be at the utmost more than the 10,000th part of the bird's weight, and is not worth considering in dealing with the question of flight.—Fitful.

[4]—The Earth's Inclination.—In reply to "Moonstruck's" query, I should say that if the earth's axis was perpendicular to the plane of the Ecliptic, the weather at the Poles would be much colder than a Polar summer at present, because the rays of heat would fall very obliquely upon the earth surrounding the Poles. At the Equator the heat would be greater than at present, because the sun would daily appear to cross the zenith.—E. C. R.

[4]—The Earth's Inclination.—If the earth rotated on an upright axis, there would be perpetual spring or autumn all over the earth; but it must be remembered that spring and autumn at the equator are the hottest seasons of all, while at the poles they mean a sun just skirting the horizon, so that the coldest winter in temperate regions would not be so cold as this so-called polar

spring. To put the matter more definitely. If the earth rotated on an upright axis, the sun would everywhere, all the year round, rise exactly in the east (apart from the slight effects of atmospheric refraction) and set exactly in the west, attaining at midday an elevation equal to the complement of the latitude—90° at the equator (which would bring the sun overhead, 70° in latitude 20; 40° in latitude 50; 20° in latitude 70; and having no elevation at all in latitude 90, or at either pole.—STUDENT.

[8]—VOLUME OF SPHERE.—The simplest way of showing that the volume of a sphere is two-thirds that of the enclosing cylinder, is given in the following sketch, which, if "Archimedean" is anything of a geometrician, he will have no difficulty in filling in:—Show, first, that the surface of the sphere is equal to the *curved* surface of the enclosing cylinder, by taking any two planes close to each other through sphere and cylinder, parallel to the top and bottom of the latter, and showing that the part of spherical surface between these planes is equal to the part of cylindrical surface between them. This having been shown, imagine the surface of sphere, thus known, divided into indefinitely small areas, each of which may be regarded as the base of a pyramid, having the centre of the sphere as vertex—all these pyramids together giving the volume of sphere. Their combined volume is equal to that of a pyramid having a base equal in surface to the surface of the sphere (that is, of its enclosing cylinder, by what has been already shown), and a height equal to the radius of the sphere. This volume, by well-known property of pyramid, is represented by one-third the product of numbers representing the curved surface of cylinder and the radius of sphere. But curved surface of cylinder

= circumference of base × 2 radius of sphere

= circumference of a great circle × 2 radius of sphere.

Hence volume of sphere

$$= \frac{1}{3} \text{ radius} \times \text{circumference of a great circle} \times 2 \text{ radius}$$

$$= \frac{2}{3} (\text{radius})^2 \times 2\pi\ (\text{radius}) = \frac{4\pi r^3}{3} \text{ (if radius} = r).$$

But volume of enclosing cylinder = area of base × 2 height

$$= \pi r^2 \times 2r = 2\pi r^3.$$

Hence volume of sphere is two-thirds that of cylinder.

MATHEMATICUS.

EFFECTS OF LIGHTNING ON TREES NEAR A TELEGRAPH WIRE.—Some instructive facts in this connection have been brought to light by M. Montigny, in recent examination of poplars bordering part of a road in Belgium, between Rochefort and Dinant. The part in question is some 4,600 mètres in length, and runs westward; it is level for some distance, then rises gradually to a height of 61 mètres, through a wood, traverses a wooded plateau 200 mètres in extent, then descends, still through wood, to a plain. A telegraph wire runs near the row of Virginia poplars on the north side, and it appears that, out of nearly 500 poplars forming this row, 81, or a sixth, have been struck by lightning. Hardly any have been struck in the other row. The trunks have been mostly struck on their south side, and nearly opposite the wire. Comparing different portions of the road, it is found that in the horizontal part none of the (129) trees show injury from lightning, or at most only one (a doubtful case), but as the road rises through the wood, the cases quickly multiply, and on the wooded plateau as many as nine out of 14 trees, or 64 per cent., have been struck. On the slopes the proportion is 25 per cent. M. Montigny distinguishes three kinds of injuries—(1) the bark torn and detached on a limited part of the trunk; (2) a furrow, straight or (rarely) spiral, made on the tree, from near the wire, down to the ground; and (3) a peculiar oval wound, with longer axis vertical, and lips coloured light brown. Now, the furrows, which are probably due to the most violent discharges, are relatively most frequent on the plateau and on the western slope, which the storms usually reach first. M. Montigny is of opinion that the lightning, while attracted by the wire, does not strike this first, then the tree, but strikes the tree directly. His conception of the process is to the following effect:—Suppose a thunder-cloud charged with positive electricity. A long telegraph wire under it, though insulated, may acquire as great negative tension in the nearest part as if in direct communication with the ground, and the tension is greater the nearer to the cloud. While the inductive influence affects the wire most, near objects, such as trees, share in the influence according to their conducting power. The lightning, attracted in the direction of the wire, yet does not strike this, the insulating cups presenting an obstacle to its prompt and rapid escape. It finds a better conductor to earth in a neighbouring poplar, wet with rain. From the facts indicated it results, that of two similar houses, one built on a plain, the other in a wood, and having a telegraph wire fixed to them, the latter is the more liable to injury by lightning, and the danger is greater if the wood enclosing the house be upon an eminence.—*Times.*

Our Mathematical Column.

FROM the way in which logarithms are commonly spoken of, one would suppose that they were originally intended to perplex the student, instead of having been devised specially to assist him. It may be that this is due chiefly to the use of a name whose real meaning is not known, while, were its real meaning known, the use of numbers so named would still remain a mystery to all save mathematicians. The word logarithm is really intended to signify ratio-number. But hundreds who use logarithms, and thousands who would do well to use them, would not be one whit the wiser for knowing that there are tables of numbers which may be regarded as ratio-numbers. If a name had been given to logarithms which suggested to all something of their real use to computers, we should find them more valued and more commonly employed than they are. But unfortunately the singular idea that nothing but a long unintelligible name is worth anything in science—an idea about as worthy of respect as the Barbadoes mother's admiration for the name Chrononhotonthologos which Captain Marryat gave to her baby—has caused these useful tables to bear a ridiculous because un-English name.

In reality, a logarithm *is* a ratio number, though that says very little to most men of its use. The logarithms of the numbers 1, 2, 3, 4, 5, &c., up to 100,000 in our books, are in reality the powers to which 10 must be raised to give the numbers 1, 2, 3, 4, 5, &c., respectively. If we know the power to which 10 must be raised to give the number 13, and also the power to which 10 must be raised to give the number 17, we have only to add these powers together to obtain the power to which 10 must be raised to give the product of 13 by 17, or 221. If our tables give all the powers of numbers from 1 to 221, we need not actually multiply together 13 and 17 to get their product 221. All we need do is to add the logarithm of 13 to the logarithm of 17; the sum is the logarithm of 13 and 17 multiplied together. We look out in our tables the logarithm corresponding to the sum of the logarithms of 13 and 17, and we find that the number corresponding to this logarithm is 221.

Here, of course, we have not been saved a particle of labour. While we were looking out these logarithms, a charity boy could have multiplied 13 and 17 together half a-dozen times.

But, supposing we had occasion to multiply together the numbers 21,714, and 56,912, and to divide the product by 78,124 and 62,315; that is, to divide the product of the first pair of numbers by the product of the second pair of numbers. Then, if we know the powers to which 10 must be raised to give the above four numbers respectively, we can tell, by simple addition and subtraction, the power to which 10 must be raised to give the answer to our little sum; and if we know also what is the number which would result from raising 10 to the power just mentioned, this number is the answer we require. Suppose, for example, that $10^a = 21.714$; $10^b = 56.912$; $10^c = 78,124$; $10^d = 62,315$. Then we know by the properties of ratios that

$$21714 \times 56912 = 10^{a+b}$$

$$78124 \times 62315 = 10^{c+d}$$

while $$\frac{21714 \times 56912}{78124 \times 62315} = 10^{a+b-c-d}$$

Now a table of logarithms gives us for all numbers from 1 to 100,000 the powers corresponding to a, b, c, and d in the above example. (We can find such powers also easily enough from the tables for all numbers from 100,000 up to 10,000,000.) So that all the computer in the above case would have to do would be to look out the powers corresponding to a, b, c, and d, to add a to b and c to d, subtracting then the latter sum from the former. The result would be the power to which ten must be raised to give the answer to his sum; and he would only require to find that power in his tables to get the number he wanted. He would, probably, do all this in about the time that a first-rate computor would have got half way through the multiplying of 21,714 and 56,912 together.

This is, of course, only a general account of the use of a book of such powers, or of a book of logarithms. It should suffice to show that despite their hard name, they are worth understanding by all who have much computing to do; and there are few who would not do well, by studying a little the use of logarithms, to make themselves ready to employ the tables when occasion may arise.

Turn now to a few details.

The logarithms given in the tables are in reality the logarithms of the numbers 1, 2, 3, 4, 5, 6, 7, 8, 9; 1, 1·1, 1·2, 1·3, 1·4, 1·5, 1·6, 1·7, 1·8, 1·9; 2, 2·1, &c.; that is, however large the number in the lefthand column, it is understood to lie between 1 and 10, so that its logarithm lies in value between 0 and 1 (ten to the power *nought* gives 1, and ten to the power 1 is ten). Decimal points are not

shown in the tables but in reality they are implied. Thus, the tables give—

the logarithm of 3191 as 5039268;

this really means that

the logarithm of 3·191 is 0·5039268. (A.)

(The student should here turn to his tables and see for himself how the matter stands; he should also ask himself what statement A really means. On one side we have the number 3·191; on the other, a decimal fraction slightly exceeding ½, which we are told is the logarithm of 3·191. Now, remember that the logarithm of a number is that power to which 10 must be raised to give the number, and we see at once how A is to be interpreted. For 10 to power ½ is the same as the square root of 10, which we know to be rather greater than 3, so that in the equation

$$3 + \text{some small fraction} = \sqrt{10} \text{ or } 10^{\frac{1}{2}}$$

we have a rough approach, near enough to illustrate its meaning to the statement—

the logarithm of 3·191 = 0·5039268.

A few inquiries of this sort, with a book of logarithms in hand, will very soon give the intelligent reader a good idea of their meaning and use. Take one other case. We find from the tables that

the logarithm of 2 is ·3010300.

This means that 10 raised to the power $\frac{30103}{100000}$ is equal (very approximately) to 2. Now let us see whether taking the simple fraction $\frac{3}{10}$ we find 10 to the power $\frac{3}{10}$ approach in value to 2, though, of course, not quite so closely as would 10 to the power ·3010300. We know that $10^{\frac{3}{10}}$ is the same as the 10th root of 10^3 or of 1000; and we know that this is not very far from 2, for 2 raised to the tenth power gives 1024.)

But the tables are not the less complete that they only give the logarithms of such numbers as 3·191, 9·874156, and so forth. For, since shifting a decimal point one place to the right means multiplying by 10, while shifting the point one place to the left means dividing by 10, and since the logarithm of 10 is 1, we have only to add or subtract 1, 2, 3, 4, 5, &c., to the logarithm given in the table, to get the true logarithm of any number whatever within the limits ranged over by the table. Thus—

Logarithm of 3·191 = 0·5039268
Logarithm of 31·91, or of 10 × 3·191 = log. 10 × log. 3·191 = 1·5039268
Logarithm of 319·1, or of 10^2 × 3·191 = 2·5039268
Logarithm of 3191, or of 10^3 × 3·191 = 3·5039268

and so forth, the whole number in the logarithm being always 1 less than the number of digits in the integral part of the original number (that is, of digits on the left of the decimal point).

Again, logarithm of 0·3191, or of 3·191 ÷ 10 = 0·5039268 − 1, which for convenience and symmetry is written—

Logarithm 0·3191 = $\bar{1}$·5039268
Logarithm of 0·03191, or of 3·191 ÷ 10^2 = $\bar{2}$·5039268
Logarithm of 0·003191, or of 3·191 ÷ 10^3 = $\bar{3}$·5039268

and so forth, the whole number under the minus sign being always 1 more than the number of cyphers following the decimal point of the number.

It will be observed that in the case of numbers less than 1 we do not follow what might, at first sight, seem the obvious course, of subtracting the tabular number from 1, 2, 3, or whatever is the number under the *minus* sign, leaving the logarithm negative. Thus we write $\bar{1}$·5039268 short for −1 + 0·5039268; we do not write −0·4960732. The reason is that it is found convenient to have *all* the quantities on the right of the decimal point positive throughout all computations.

Mathematical Question.—Is there any solution of either or both the following sets of simultaneous equations?

$$\begin{array}{lcl} x^2 + yz = a^2 \text{ (i)} & & x^2 + xy + y^2 = a^2 \text{ (i)} \\ y^2 + zx = b^2 \text{ (ii)} & \text{and} & y^2 + yz + z^2 = b^2 \text{ (ii)} \\ z^2 + xy = c^2 \text{ (iii)} & & z^2 + zx + x^2 = c^2 \text{ (iii).} \end{array}$$

A. N. J.

We know of no solution to the former set; that is, it cannot be made, so far as we know, to produce a quadratic equation. The second set may be solved thus ("A. N. J." will probably only need to be shown the steps):—

Subtracting (ii) from (i) gives $(x + y + z)(x - z) = a^2 - b^2$ (iv).

Subtracting the sum of the squares of (i) (ii) and (iii) from twice the sum of the products (i) × (ii), (ii) × (iii), and (iii) × (ii), we obtain

$$xy + yz + xz = \sqrt{\tfrac{1}{3}[2a^2b^2 + 2b^2c^2 + c^2a^2 - a^4 - b^4 = c^4}$$
$$= p^2 \text{ (say) (v)}$$

adding (i) (ii) (iii) and 3 (v) we get

$$x + y + z = \sqrt{\tfrac{1}{2}(a^2 + b^2 + c^2 + 3p^2} = m \text{ (say) (vi)}$$

From (iv) and (vi) $m(x - z) = a^2 - b^2$,

and similarly, $m(y - x) = b^2 - c^2$

whence, subtracting, $m(y + z - 2x) = 2b^2 - a^2 - c^2$
$= m(m - 3x) = 2b^2 - a^2 - c^2$

or $x = \frac{1}{3m}(m^2 + a^2 + c^2 - 2b^2)$

By symmetry $y = \frac{1}{3m}(m^2 + b^2 + a^2 - 2c^2)$; $z = \frac{1}{3m}(m^2 + a^2 + b^2 - 2a^2)$.

Our Whist Column.

By "Five of Clubs."

We give this week a simple whist game, showing the inferences which can be drawn from the play by one of the players (the leader), and making notes also on the play as it proceeds. The inferences are all of the simplest kind, supposing the game to be conducted according to the accepted principles for sound play. This will appear as we proceed, in later papers, to develope these principles.

The Hands.

Diamonds—Q, 9, 7, 2.
Spades—Q, Kn, 10, 3.
Hearts—Q, 6.
Clubs—Kg, 6, 4.

Diamonds—Kn, 10, 8, 6, 4.
Spades—8, 7, 4.
Hearts—Kg, 2.
Clubs—10, 5, 3.

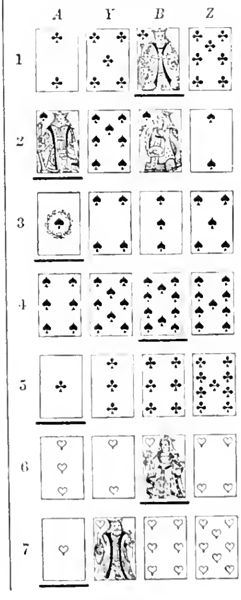
B
Y Dealer Z
Trump Card, Diamond King.
A

Diamonds—A, Kg.
Spades—9, 5, 2.
Hearts—Kn, 10, 9, 8, 4.
Clubs—Q, 9, 7.

Diamonds—5, 3.
Spades—A, Kg, 6.
Hearts—A, 7, 5, 3.
Clubs—A, Kn, 8, 2.

Score:—A B = 0; Y Z = 3.

Note.—The underlined card wins trick, and card below it leads next.



A's INFERENCES.

1. Either 3 C and 4 C are both with *B*, or else *Y* or *Z* is signalling for trumps. *B* has not the Queen.

Note to trick 1.—Having five trumps, one honour, and his partner having an honour, *Y* would be justified in signalling for trumps were the score low, but not as the score stands.

2. *B* has Kn S, 10 S, and probably one or more small Spades. *Z* is not signalling for trumps, and therefore has neither 3 C nor 4 C.

Note to trick 2.—*A* does well to take the trick and return the Ace, thus leaving *B* the command of the suit.

3. *Y* has signalled, and therefore has either 4 C or 3 C; the other being with *B*. As *Z* turned an honour, *Y* and *Z* are probably two by honours, in which case *A B* must make five by tricks to save the game.

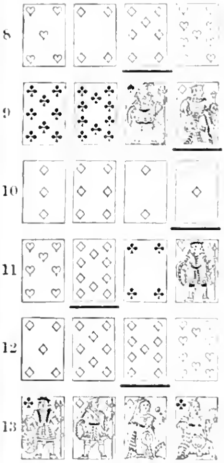
4. The last Spade is with *B* (the Knave).

5. *B* has 4 C, but no more Clubs.

Note to trick 5.—*B* returns the highest of two cards.

6. *Z* has not the King of Hearts; *B* has not the Knave (Hearts must be *Z's* best suit, trumps being *Y's*).

Note to trick 6.—Under the circumstances *Y* should have played the King. It is his best chance of getting a lead.



7. *Y* has the Knave of Hearts. The only chance of saving the game lies in the probability (*A* having four Hearts, and *Z* a long suit of Hearts) that *B* may be able to ruff Hearts next round.

8. If *Y* has played properly, all his remaining cards should be trumps, and the game is lost.

Note to trick 8.—If *Y* trumps at all he should play his highest. His small trump is useless. He should know that the best Heart is with *Z*.

9. *Z* has the Ace of trumps (Kn 8 being a thirteenth card).

Note to trick 9.—*Z's* play here is bad. He knows his partner has an honour, with a strong hand in trumps, and two tricks only are wanted to win the game, besides the two certain tricks *Z* holds in his hands.

10. If *B* has not Queen and 10 or 9 of trumps, the game is lost, for the remaining cards in *Y's* hand must be trumps (one honour at least).

11. *Z* should have led the Queen of Clubs. The Knave of Hearts is equally a winning card of its suit; but the play should have shown *Z* that *B* has a small Club, and that therefore *Y* can win trick 11 with his smallest trump. As it is, *Y* has to play highest third hand. *B* does rightly in not over-trumping. If he did, the remaining two tricks would be *Y's*, but by letting trick 11 pass, *B* remaining with the tenace in trumps (and knowing *Z* to be without trumps), has the two last tricks sure.

Our Chess Column.

Sir,—In your issue of the 11th inst. you gave an admirably-arranged perspective summary of the openings. In reference to the Evans Gambit declined, you say:—Declining the proffered Queen's Knight's pawn subjects the second player to a cramped defensive game. I beg to draw your attention to the fact that recent analytical researches have proved that by declining the Evans Gambit with B to Kt.3, Black is in no way at a disadvantage. The game may be declared even; and should White attempt to advance his Queen's pawns too vigorously Black would obtain the better game.—Mephisto.

Two Knights' Defence.

The game having opened on the line of the Two Knights' Defence, or thus—

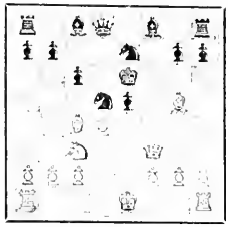
1. P. to Kt.4. / P. to K.4. 2. Kt. to K.B.3. / Kt. to Q.P.3. 3. B. to Q.B.4. / Kt. to K B.3.

White has two ways of continuing the attack, and one line of play which we recommend to the learner as based on the sound principle of developing and strengthening his own position, rather than rushing at his opponents. This last named line of play is simply 4. P. to Q.3., followed presently by Castles, B. to K.3. (or to K. Kt.5. if Black Castles early on King's side), Kt. to Q.B.3., and so forth; bringing all the pieces well into play before unduly pressing an attack. If Black plays a similar game, a steady but interesting and instructive game may be expected.

It seems, however, to be the generally-accepted view that first player has to attack and second player to defend; though theoretically, scarcely the slightest attacking power results from the first move, and what there is may be most readily lost. Accordingly, the usual way of continuing the Two Knights' game is either by 4. Kt. to K.Kt.5, or by 4. P. to Q.4. The latter is probably the sounder move. The former belongs to the class of premature attacks; though White wins a Pawn for the nonce if Black reply correctly. Black's best move in reply is 4. P. to Q.4, on which 5. P. takes P.

Black cannot now safely play 5. Kt. takes P., but we will follow out the interesting attack ensuing if he should play thus. There follows 6. Kt. takes K.B.P. / K. takes Kt. (Black must take the Knight, as it attacks both Queen and Rook), 7. Q. to K B.3 / K. to K. 3. (the only play by which Black can save the Knight), 8. Kt. to Q.B.3. / Q.Kt. to K.2 9. P. to Q. 4. / P. to Q.B.3 (Black cannot take the Q.P. without losing the Knight by 10. Q. to K 4 (ch), 10. B to K Kt.5. The position is then:—

Black.



White.

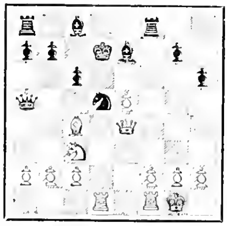
Position after White's tenth move.

It is obvious that White has now a very strong attack. If Black pushes his K. Rook's Pawn to attack the Bishop, White simply takes Knight with Bishop, and on Black's retaking (with Bishop, of course), White Castles on Queen's side with an overwhelming attack. If Black plays, instead, 10. P. takes Q.P., White Castles on Queen's side, with a crushing attack, whether Black take the Queen's Knight or not. If Black play 10. Q. to Q.R.4 White Castles on King's side, and after 11. ——— / P. to K.R.3 12. B. takes Kt. / B. takes B. there would probably follow—

13. Q.R. to Q.sq. / R. to K.B.sq. 14. Q. to K.4 / K. to Q.2 15. P. takes K.P. / ———

and we have the position—

Black.



White.

Position after White's 15th move.

Here White threatens to take the Knight either with Knight or Bishop, and if Pawn should retake to play R. takes P., winning Queen for Rook. If Queen move to Q.B.2, Q.Kt.3, or Q.Kt.5, or if King move to Q.B.2, White would take Knight with Bishop, and if Black then took Bishop with Pawn, White would win by Kt. takes P. (Note, that if Black King remains on Queen's file, or moves there from Q.B.2, he is exposed to a disclosed check by which his Queen's Rook would fall.) If Black plays away his King to K.'s square, White takes Knight with Knight, then, if Black retakes, White checks with Q. at K.Kt.'s 6th, winning the Rook (by B. takes P.), if Black interposes it, and the Queen (for Rook) if Black moves his K. on to Queen's file.

Returning to the position shown in the first figure, Black may play 10. P. to Q.Kt.4, on which White retreats his Bishop to Q.Kt.3, and if Black pushes his Q.Kt.'s P., White takes Kt. with Kt., and Castling on Queen's side obtains an overwhelming attack.

At his ninth move, Black might have played 9. P. to K.R.3. instead of 9. P. to Q.B.3; but 10. Castles, followed by 10. R to K. sq., gives White an exceedingly strong attack.

In fact, on this line, Black's game seems hopelessly compromised; though we believe Zukertort is of opinion that this still remains to be proved, and that precisely as the Muzio attack, formerly thought irresistible, is now shown to be unsound*, so the sacrifice of the

* Even this, in turn, may be questioned; at any rate, Winawer played the Muzio against Zukertort in the Berlin Chess Tournament, and made a drawn game of it.

Knight in this form of the Two Knights' Game may, after all, be unsafe.

It appears to us that Black may perhaps find safety from 10. P to Q K 4 11. B to Q Kt 3 / B to Q Kt 2 (starting from position shewn in first figure.)

Next week we shall consider what seems to be far a better course for Black than 4. P. takes Knight, namely 4. Kt. to Q R 4.

We shall be glad to answer any questions suggested by the opening moves so far considered.

The following end game from Ponziani is of the same class as those given last week.—

No. 3. Black.

WHITE.

White to play, and draw.

Answers to Correspondents.

**** All communications which have to receive early attention should be addressed to the Editor of* Knowledge, *74 and 75, Great Queen-street, London, W.C.*

Hints to Correspondents. 1. *No questions asking for scientific information can be answered through the post.* 2. *Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries.* 3. *No queries or replies savouring of the nature of advertisements can be inserted.* 4. *Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge.* 5. *Correspondents should write on one side only of the paper, and put drawings on a separate leaf.* 6. *Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

W. H. Allen, J. W. Brookes, A. L. J., Perplexed, and others. The illusion must be a strong one, as it remains, though, by a misprint, incorrectly described in Mr. Foster's paper.—Cymro. Your mathematical query appears in mathematical section.—F. W. B. The work you mention is published by Messrs. Spon & Co., Charing-cross, who would inform you of the price. We do not know, and have no list of their works. We scarcely think "Anti-Guebre" would be satisfied by the account given of the sun in Huxley's Physiography; we mean that it would scarcely convince "Anti-Guebre" of the inaccuracy of his position. See Letter 5 in Number 2. The correct answer to the mountain-snow difficulty is not nearly so simple as many imagine. But of course "Anti-Guebre" is mistaken. A. B., Manchester. Thanks for the promised papers on Photography. We have no doubt they will prove very interesting to our readers.—J. K. M. We quite agree with you, but technical terms which appear without explanation in articles meant for general reading are decidedly objectionable.—Inquirer. (Your name is scarcely well chosen; there are so many inquirers.) He has made mistakes, but who that has been active in scientific research has not. He is, we think, *facile princeps* in his own field of labour, though we would not care to say so; comparisons (and the superlative is a form of comparison) are nearly always offensive.—Conicoid. Explain more fully your requirements. If you only want a general knowledge of the properties of the conic sections, Drew's "Geometrical Conic Sections," published by Macmillan, would serve your purpose admirably. But for thorough study of curves of the second degree, you would have to read more advanced treatises, which we will indicate, should you desire it.—Guebre. You will find the information you require in Lockyer's "Physics of the Sun" (Macmillan); but you will do well to read, as a more recent contribution to the subject, the excellent work on the sun, by Professor Young, Appleton & Co., New York.—Edw. Cl. Your recommendations duly noticed, and will be attended to at once. Thanks for the addresses.—A. W., Edinburgh. All exceedingly welcome.—A. C. R. Could not send any copies of No. 1; none at the office could be spared. Twenty-five copies of No. 2 were sent.—Francis Mazin. Your suggestion has, you will find, been attended to. The pagination will now be right throughout, as title-page will replace advertisement leaf.—Pyramidalist. We are not sure whether the interest in the Great Pyramid prophecies is so wide as you suggest; but you will find in a short paper by Mr Jos. Baxendell, the well-known astronomer, much that will interest you.—Dr. Jules Morel. Many thanks for your kind expressions of sympathy with our plan. The work you have sent will doubtless afford much interesting information to our readers on the subject of food. Cycloidal. If you really want to study the Geometry of Cycloids at great length (but is it worth while?) we can only name "Proctor's Geometry of Cycloids," because we know of no other work going over the same ground. But, be warned in time, and take a lighter subject. If "wilful will to water, wilful must wet;" though, by the way, this is the last thing you have to fear, for the book is dreadfully dry. Cycloidal geometry is not of overwhelming importance in scientific study. We should say (but mind, we do not know for certain) that scarce a hundred copies of the work just named have been sold.—Anti-Humbug. Your letter is quite unsuitable for publication in our columns. Its tone is absolutely contrary to that which we wish to maintain. If you contented yourself with the suggestion that those who differ from you are mistaken, we should still object to your letter; but your implied assertion that they *know* they are mistaken is intolerable. If you are so warm yourself against those whose opinions you oppose, consider, at any rate, that among them may be some as warm as yourself, whose feelings would be certainly hurt by your remarks and insinuations. In the words of one of the writers you mention, "Is life worth living?" if we are continually fighting?—Trunsiker Charles Keats. We do not object to the trouble, on which alone you dwell, so much as to the expense; the three works you wish us to send you cost together £6. Consider the effect of multiplied "orders" of that kind.—E. C. Articles of the kind sent are such as sub-editors make with the help of paste and scissors. We must not encroach on their sphere of labour, or, rather, on this portion of it. W. L. Thanks for the drawings; albeit we by no means accept either the two-headed man or the alligator boy. The so-called man-dog and his son were real enough, though not correctly described even as to their appearance.—G. W. Spence. See First Hint to Correspondents. Delaunay's discussion about the Inferiority of Women to Men was a communication to a learned society, and has not, we believe, been published in separate form. S. D. P. The razor-fish is not a fish, but a *Conchiferous Mollusc*, one of the *Solenaceans*, or *Dimyary Bivalves*. "I trust I make myself understood." Seriously, it is what is commonly, but incorrectly, called a shell-fish, the double shell somewhat resembling a razor.—Star-Gazer. See answers to "Perplexed" and others.—W. T. Lynn. Thanks for the correction respecting Palitzsch and Halley's Comet; it shall appear next week, if possible. The mistake is definitely made in Herschell's "Familiar Lectures," p. 114, though, as you say, not in the "Outlines."—Dr. H. Draper, New York. Many thanks.—G. W. D. Your letter is rather long, but shall appear, possibly abridged, as soon as possible.—G. A. Thanks for your interesting article on Buttercups; it shall appear next week.—J. M. A star atlas cannot include all desirable features; some must be sacrificed.—A. B. E. Thanks.—Thomas Witty, Hull. I scarcely think our readers would like to see any space devoted to the absurdities of the school you mention. It is hardly necessary for me to say that I repeatedly saw the sun south of the east and west horizon points when I was in Australasia. I have also repeatedly noticed that two and two make four.—R. M. See answer above to Mr. Mazin.—A. T. C. Yes. That point will be touched on in articles on Comets. A comet is not necessarily seen both when approaching and when receding, or even under either condition. The word unconformable, on p. 27, is not used in a geological sense, or, indeed, in a technical sense at all. It is put between inverted commas because borrowed (from Sir John Herschel); but every dictionary has it. The cribbage query is not suited to these columns; you will find that to make up numbers below nineteen the symmetrical arrangements which give large even numbers, as 6, 7, 7, 8, pairs royal, double pairs royal, are not so essential but that odd scores can be made. For scores above 18 you can only in one way get odd numbers, namely, by the "one for his nob," and this will not give 19, because the 18 which has to be made up to complete the score of 19 cannot be made up from a knave and four other cards; 20, 22, 24, 26, and 28 can. This, after all, shows only *how*, not why it is. The engraver, unfortunately, omitted one of the tails of the comet of 1744. Will consider your suggestion about covers.

E. L. R., I. C. H. W., Beta, W. A. R., J. A. W. O., J. A. W.=O., T. W. Shore, W. D. R., Charles Hamilton, △, G. C. W., G. G. D., J. McG. A., W. J. M., J. J. H. (B.A. Lond.), W. G. (Bird's-eye View), Arthur Black, H. S., &c. Letters received, and will appear or be answered in due course.

Note.—We have received many letters calling attention to the difficulty of obtaining copies of No. 1. The demand for copies was much larger than had been anticipated. The matter had to be entirely reset for a second edition, now publishing. Our publishers will be obliged if subscribers will call their attention to the fact, should they experience any difficulty in obtaining Knowledge at any of the railway book-stalls, or from their local newsagents. To ensure a supply of the back numbers, orders should be sent without delay.—Ed.

PLAINLY WORDED-EXACTLY DESCRIBED

LONDON: FRIDAY, NOVEMBER 25, 1881.

CONTENTS.

THE ORIGIN OF BUTTERCUPS.

By Grant Allen.

HERE, in my hand, I hold a solitary little golden buttercup, picked this morning in an autumn meadow, but still as bright and sturdy as though it had grown up in warmer days beneath the sunny skies of June. Common and familiar as it is, the buttercup is yet a very interesting flower from the point of view of its origin and evolution. Not that it is a highly-evolved or very singular blossom, with a long and intricate history at its back, like some of the orchids and snapdragons, whose complexity almost defies explanation; on the contrary, the importance of the buttercup in the eyes of the historical botanist is mainly due to the extreme simplicity of its typical arrangement. It is a very early type of plant, which has scarcely undergone any alteration from the form it must have acquired already many millions of years ago. There are other flowers of the same family, such as the larkspur, the columbine, and the monkshood, which still bear obvious traces of being derived from an ancestor exactly like the buttercup, but which have diverged widely from the original stock in their curious irregular flowers, sometimes spurred, sometimes hooded, and sometimes so altered from the primitive radial shape as to be scarcely recognisable. What makes our buttercup so interesting, on the other hand, is the fact that it represents an early stage in the history of these more highly-developed forms. In order to understand *them* we must first understand *it*. This buttercup, in short, is one of the most central members of the family to which it belongs; while some of its congeners have diverged in one direction and some in another, it has still kept unaltered for us the primitive lineaments of the common ancestor from which all alike have ultimately sprung.

Buttercups, as everybody knows, are tall meadow weeds, and the one which I hold in my hand belongs to the tallest species of all, which we know *par excellence* as *the* buttercup; for we have in England alone no less than some sixteen representatives of the entire genus. Let us look a little closely into its structure, and see what hints we can gather from its existing shape as to its past history and evolution.

First of all there are the leaves. These, one notices at once, are raised on long stalks, and deeply divided into several segments. Sometimes there are only three divisions to each leaf, sometimes five, and sometimes seven; the reason why they thus run in uneven numbers being, of course, that there is always a single terminal leaflet together, with one, two, or three lateral leaflets on either side of it. Again, each of these segments is itself further divided into three toothed lobes. Now, such a complex leaf as this shows by its very nature that it must be the product of considerable previous development. All very early leaves are quite simple and rounded; it is only by slow steps that a leaf thus gets broken up into many divided segments. In this respect, then, the meadow buttercup cannot be regarded as the simplest member of its class. There are some other buttercups, such as the ivy-leaved crowfoot, which creeps along the mud of ditches, or the lesser celandine, which springs in the meadows in early April, whose leaves are entire and undivided. In the lesser celandine they are almost circular, and in the ivy-leaved crowfoot they are slightly angular; but both these plants, having plenty of room to spread in the unoccupied fields of spring or the unappropriated ditches, have never felt the necessity for subdivision into minute segments. They have free access to the air and the sunlight, and so they can assimilate to their hearts' content the carbon of which their tissues are built up. It is otherwise, however, when similar plants push out into new situations, less fully supplied with carbonic acid or with sunshine. For example, there is the water-crowfoot, a mere divergent variety of the ivy-leaved species, which has taken to growing in ponds or rivers. Here it cannot obtain the materials for growth so readily as on its native mud-banks; and it has been compelled, accordingly, to split up its submerged leaves into long, thin, hair-like filaments; but when it reaches the surface, its foliage spreads out once more into the broad ancestral blades of the ivy-leaved crowfoot. It is just the same with the true buttercups. They have taken to growing in the open meadows, where the competition for vegetable food-stuffs is keen, and the struggle for existence very bitter. Hence they have been compelled to divide their leaves into many finger-like segments; and only those which have succeeded in doing so have managed to hold their own in the struggle, and so to hand down their peculiarities to future generations. As a rule, just in proportion as vegetation is thick and matted, do the plants of which it is composed tend to develope minutely divided and attenuated foliage.

It is the flower, however, that most people think of as the essential part of a buttercup, and it is by means of the flower that all the higher plants are usually classified. Now, the blossom of the buttercup is almost an ideally simple typical specimen. It consists of three parts or series of organs, from within outward. First comes a little central boss or cushion, supporting several carpels or unripe fruitlets. Each of these carpels contains a single embryo seed. Outside these comes a row of many stamens, which are the organs for producing the yellow dust which we call pollen. Now, no carpel can mature into a fruit containing ripe seed until it has been impregnated by pollen from a stamen, and these two sets of organs are, therefore, the only really essential parts of the whole flower. But in common language, what we mean by a flower is not these little central knobs and tassels, but rather the bright-coloured petals outside, which in the buttercup are five in number and golden yellow in colour. What, then, is the use to the plant of these expanded and very strikingly-coloured organs?

A flower is at bottom merely a device for producing seed. But in order that the seed may prove capable of germinat-

ing, the ovules in its carpels must necessarily be fertilised by pollen. Now, all the earliest flowers consisted merely of stamens and carpels; they had no petals at all. But, as Mr. Darwin has shown, flowers which are fertilised by pollen from a neighbouring plant produce more seed and healthier seedlings than those which are fertilised by the produce of their own stamens. Hence, any modification which promoted such cross-fertilisation would benefit the plants in which it occurred by giving them an advantage over their rivals in the struggle for existence. Now, there are two ways in which flowers have thus acquired special adaptations for fertilising one another. Some of them have developed hanging stamens which shake out their pollen to the wind, and such flowers are also provided with feathery collecting surfaces to the carpels, so as to catch the stray grains which may happen to be wafted to them from their neighbours by the breeze. Plants of this type never possess bright-coloured petals. A second class, on the other hand, have learned to utilise the winged insects which visit their blossoms in search of food. These welcome little pilferers, in passing from head to head, carry the pollen of one plant to the carpels of another, and so assist the flower in effecting the desired cross-fertilisation. This class, to which the buttercup belongs, has usually developed various inducements of food, scent, and colour, in order to attract the fertilising insects. Those flowers which best succeeded in alluring their little winged guests would naturally hold their own against all less highly endowed competitors, and would hand on their own constitution to their descendants. In this way insect-fertilised plants have acquired the bright petals and sweet scents which chiefly make them noticeable to our human senses. A brief examination of the buttercup blossom will show us the use which they subserve, and the way in which they act in the simplest forms of insect-fertilised flowers.

Pull out one of the golden petals from the outside of the head, and you will see at its base a small hollow spot, covered by a tiny concave scale. That spot is the nectary, and it contains a single drop of pure honey. The honey is put there to entice bees and other insects; it is the wage offered them by the plant in return for the service which they perform for it in fertilising its seeds. The golden hue of the petals, again, acts as an advertisement for the honey; the bees know that such bright hues are never found in any flowers except those which specially lay themselves out to bid for their favour. When a bee sees the brilliant colour, he flies straight towards the blossom and settles on the little boss of carpels in the centre. Here he sips the honey for his own behoof, and at the same time dusts himself with pollen on behalf of the flower; for, as soon as the blossom opens, the stamens discharge their precious burden, beginning from the outside and slowly ripening towards the centre. At this early stage, however, the carpels are not yet mature for impregnation, and so they avoid being fertilised from the pollen of their own stamens. If the bee flies away to another buttercup which happens to be still in the same stage of development, he only collects more pollen about his head and thighs; but if he alights on a somewhat older buttercup, he finds its stamens withered and its carpels fully mature for impregnation. Some of the pollen is then sure to fall on the sensitive surface of the carpels. Thus, while he seeks honey for himself, he unconsciously affords his host all the advantages of cross-fertilisation; and it is because he does so that the flower has been enabled to develope its complicated arrangement of petals and nectaries for his delectation.

The buttercup, then, with its five separate simple petals, its many stamens, and its central one-seeded carpels, may be regarded as a good example of the earliest type of insect-fertilised flowers. In some other plants, such as the harebell and the primrose, the separate petals have coalesced into a single tubular corolla; while in others, again, they have assumed various fantastic shapes; but all of them are ultimately derived from flowers like the buttercup, which thus contains in itself all the essential elements of a perfect insect-fertilised plant.

SOLIDS, LIQUIDS, AND GASES.

By W. Mattieu Williams.

PART II.

MULTITUDES of examples may be cited illustrating the viscosity of bodies that we usually regard as types of solidity, such, for example, as the rocks forming the earth's crust. In the "Black Country" of South Staffordshire, which is undermined by the great ten-yard coal-seam, cottages, chimney-shafts, and other buildings may be seen leaning over most grotesquely, houses split down the middle by the subsidence or inclination of one side, great hollows in fields or across roads that were once flat, and a variety of other distortions, due to the sinking of the gradual rock-strata that have been undermined by the colliery workings. In some cases the rocks are split, but usually the subsidence is a gradual bending or flowing down of the rocks to fill up the vacuity, as water fills a hollow or "finds its own level."

I have seen many cases of the downward curvature of the roof of a coal-pit, and have been told that in some cases the surrounding pressure causes the floor to curve upwards, but have not seen this.

As Knowledge will doubtless have many readers in the colliery districts, some of them may be able to supply reliable evidence of this, accompanied with careful measurement of the amount of upward curvature or upheaving in a stated breadth of road or working.

Earthquakes afford another example. The so-called solid crust of the earth is upheaved and cast into positive billows that wave away on all sides from the centre of disturbance. The earth-billows of the great Lisbon earthquake of 1755 travelled to this country, and when they reached Loch Lomond, were still of sufficient magnitude to raise and lower its banks through a perpendicular range of two feet four inches.

It is quite possible, or, I may say, probable, that there are tides of the earth as well as of the waters, and the subject has occupied much attention and raised some discussion among mathematicians. If the earth has a fluid centre, and only a comparatively thin crust, as some suppose, there must be such tides, produced by the gravitation of the moon and the sun.

Ice presents some interesting results of this viscosity. At a certain height, varying with latitude, aspect, &c., we reach "the snow line" of mountain slopes, above which the snow of winter remains unmelted during summer, and, in most cases, goes on accumulating. It soon loses its flocculent, flakey character, and becomes coherent, clear blue ice by the pressure of its own weight.

A rather complex theory has been propounded to explain this change—the theory of *regelation*—*i.e.*, refreezing, a theory which assumes that the pressure between the surfaces first thaws a film of ice at the surfaces of contact, and that presently this refreezes, and thus effects a heating or general solidification. Faraday found that two pieces of ice with moistened surfaces united if pressed together

when at just about the temperature of freezing, but not if much colder. Tyndall has further illustrated this by taking fragments of ice and squeezing them in a mould, whereby they became a clear, transparent ball, or cake, and schoolboys did the like long before when snowballing with snow at about the thawing point. Such snow, as we all remember, became converted into stony lumps when firmly pressed together. We also remember that in much colder weather no such cohesion occurred, but our snowballs remained powdery in spite of all our squeezing.

I am a sceptic as regards regelation. I believe that the true explanation is much simpler: that the crystals of snow or fragments of ice in these experiments are simply welded, as the smith unites two pieces of iron, by merely pressing them together when they are near their melting point. Other metals and other fusible substances may be similarly welded, provided they soften or become sufficiently viscous before fusing. Platinum is a good example of this. It is infusible in ordinary furnaces, but becomes pasty before melting, and, therefore, one method adopted in the manufacture of platinum ingots or bars from the ore, is to precipitate a sort of platinum snow (spongy platinum) from its solution in acid, and then compress this metallic snow in red hot steel moulds by means of pistons driven with great force. The flocculent metal thus becomes a solid, coherent mass, just as the flocculent ice became coherent ice in Tyndall's experiment or in making hard snowballs. Wax, pitch, resin, and all other solids that fuse, *gradually* cohere, are weldable, or, in very plain language, "stick together" when near their fusing point.

I have made the following experiment to prove that when this so-called regelation of snow or ice fragments occurs, the ice is viscous or plastic, like wax or pitch. A strong iron squirt, with a cylindrical bore of half-an-inch in diameter, is fitted with an iron piston. This piston is driven forth by a screw working in a collar at one end of the squirt. Into the other end is screwed a brass nozzle with an aperture about one-twentieth of an inch diameter, tapering or opening inwards gradually to the half-inch bore.

Into this bore I place snow or fragments of ice, then holding the body of the squirt firmly in a vice, I work the lever of the screw, and thus drive forward the piston and crush down the snow or ice fragments, which presently become coherent and form a half-inch solid cylinder of clear ice. Applying still more pressure, this cylinder is forced like a liquid through the small orifice of the nozzle of the squirt, and jets or sprouts out as a thin stick of ice like vermicelli, or the "leads" of ever-pointed pencils, for the moulding of which the squirt was originally constructed.

I find that ice at 32° can thus be squirted more easily than bees'-wax of the same temperature, and such being the case, I see no reason for imagining any complex operation of regelation in the case of the ice, but merely regard the adhesion of two pieces of ice when pressed together as similar to the sticking together of two pieces of cobblers'-wax, or softened sealing-wax, or bees'-wax, or the welding of iron or glass when heated to their welding temperatures, *i.e.*, to a certain degree of incipient fluidity or viscosity.

If a leaden bullet be cut in half, and the two fresh-cut faces pressed forcibly together, they cohere at ordinary atmospheric temperatures, but we have no occasion for regelation here. The viscosity of the lead accounts for all. At Woolwich Arsenal there is a monster squirt, similar to my little one. This is charged with lead, and, by means of hydraulic pressure, the lead is squirted out of the nozzle as a cylindrical jet of any required diameter. This jet or stick of lead is the material of which the elongated cylindrical rifle bullets are now made.

But returning to the point at which we started, on the subject of ice, viz., its Alpine accumulation above the snow-line. If the snow fall there exceed the amount that is thawed and evaporated, it must either go on growing upward until it reaches the highest cloud, or atmospheric region, from which it falls, or is formed, or it must descend somehow.

If ice can be squirted through a syringe by mere hand-pressure, we are justified in expecting that it would be forced down a hill slope, or through a gully, or across a plain, by the pressure of its own weight when the accumulation is great. Such is the case, and thus are glaciers formed.

They are, strictly speaking, rivers or torrents of ice; they flow as liquid water does, and down the same channels as would carry the liquid surface drainage of the hills, were rain to take the place of snow. Like rivers, they flow with varying speed, according to the slope; like rivers, their current is more rapid in the middle than the sides; like rivers, they exert their greatest tearing force when squeezed through narrow gullies; and, like rivers, they spread out into lakes when they come upon an open basin-like valley, with narrow outlet.

The *Justedalsbrae* of Norway is a great ice-lake of this character, covering a surface of about 500 square miles, and pouring down its ice-torrents on every side, wherever there is a notch or valley descending from the table-land it covers. The rate of flow of such downpouring glaciers varies from two or three inches to as many feet per day, and they present magnificent examples of the actual fluidity or viscosity of an apparently solid mass. This viscosity has been disputed, and attempts have been made to otherwise explain the motion of glaciers, but while it is possible that it may be assisted by varying expansion and contraction, the downflow due to viscosity is now recognised as unquestionably the main factor of glacier motion.

Cascades of ice may be sometimes seen. In the course of my first visit to Norway, I wandered alone over a very desolate mountain region towards the head of the Justedal, and unexpectedly came upon a gloomy lake, the Styggevand, which lies at the foot of a precipice-boundary of the great ice-field above-named. Here, the ice having no sloping valley-trough by which to descend, poured over the edge of the precipice as a great overhanging sheet or cornice, which bent down as it was pushed forward, and presented on the convex side of the sheet some fine blue cracks, or "crevasses" as they are called. These gradually widened and deepened, until the overhanging mass broke off and fell into the lake, on the surface of which I saw the result, in the form of several floating icebergs that had previously fallen.

Something like this on a small scale may be seen at home on the edge of a house roof, on which there has been an accumulation of snow; but, in this case, it is rather sliding than flowing that has made the cornice; but its *down-bending* is a result of viscosity.

GERMS OF DISEASE AND DEATH.

By Dr. Andrew Wilson, F.R.S.E.

Most readers have heard of the "Germ theory," and there are few persons who do not know what the hypothesis of that name means and implies. Popularly regarded, this theory holds that a very large proportion of the diseases that affect and afflict man and his neighbour animals, owe their origin to minute forms of life—whether animal or vegetable, or both, is still, in most cases, a

matter of doubt. To select a single illustration of the application of this theory, we may take the case of small-pox, and its analogous condition, the fever produced by vaccination. When an infant is vaccinated, the physician introduces into its system, through an abrasion of its skin, a minute quantity of vaccine lymph, which, as everybody knows, is obtained either from the vaccination pustule of an already vaccinated child, or direct from the calf. In either case, there are introduced into the infant body, certain minute germs—suspended in and living naturally amongst the vaccine lymph—and in due course these germs multiply and increase within the frame, thereby producing the characteristic fever, and the equally characteristic pustule at the seat of the operation. So, also, with small pox, which vaccination imitates in a mild way, and of which, moreover, it is a preventive. Here the germs of small pox, obtained directly or indirectly from an already infected person, attack the body. Gaining admittance thereto, they propagate themselves within the tissues and through the medium of the blood. Sooner or later all the characteristic symptoms of the disease are manifested, and having run its course, it dies away as mysteriously, to all appearance, as it came. Now, there is something strikingly analogous in all this to the growth of an animal or plant. There is a period of "incubation" in the fever, just as in the production of the living being there is a period of development. There is a growth of the fever, as the animal or plant grows towards its maturity; and there is a decline of the disease, as the living form passes to its old age and death. So far, then, the parallel between ordinary life and the birth, growth, and decline of a disease, is very close and clear.

But the analogies are not yet exhausted. Each fever produces its like, as do animals and plants. Each disease reproduces its kind, as Tyndall has somewhere observed,* as rigorously as dog and cat reproduce their like. The phenomena, or, as a doctor would call them, the "symptoms," of each disease are, as a rule, highly distinctive. The symptoms of scarlatina are not those of small-pox; measles is different from the other two; whilst typhus fever is again thoroughly different from all three. Analogy may, as Darwin says, be a deceitful guide; but when the facts are so closely allied, as are the facts of epidemic diseases to those of animal and plant development, the use of analogy cannot be doubted in rendering the relationship clearer.

We are now in a position to understand more clearly the utility and strength of the germ theory in certain of those aspects which bear most materially on science at large. It would only serve to strengthen the idea that our epidemic diseases are simply the offspring of lower life, if we reflect in passing that there are known to science a very considerable number of lower plants which produce in man's skin effects and diseases as characteristic as those which a fever induces in his system at large. Thus, the disease known as "ringworm" is caused by the growth in the human skin of a parasitic fungus, and a whole series of skin affections is known wherein lower plants play the part of direct causes. Thus, if it is a matter of certainty that a particular skin-disease is caused by lower plant-growth, so no less is it by analogy likely that all other contagious and epidemic diseases are in reality the products of life.

So much for the general idea that permeates the "germ-theory" of disease. Within the past few months some highly important additions have been made to our knowledge of the part played by lower organisms in the production of disease. M. Pasteur, whose researches into the development of lower organisms have placed him in the foremost rank of scientific workers, has detailed at length the results of his investigations into the causes which produce the curious disease known as *charbon*, *anthrax*, and *splenic fever*. This disease, whilst but rarely attacking man, is fatal to horses, cattle, and sheep. France suffers greatly from this "plague of boils," and it is also known in various other countries as a literal scourge. Pasteur, it should be mentioned, had already acquired much valuable experience in the investigation into the cause of the *pébrine*, or silkworm disease, which in 1863 had devastated the silk industry of France. Pasteur showed that *pébrine* was caused by the growth and multiplication, within the bodies of the insects, of minute "corpuscles," which were practically lower forms of life. Even the eggs from which the worms were hatched were shown to be liable to infection from *pébrine*; the eggs, in such a case, inheriting the disease from the parent moth which laid them. As the result of a long and laborious series of experiments, Pasteur showed that the *pébrine* would spread like an infectious disease by the contact of whole with diseased worms. He showed that, just as man isolates his fever patients, so the French silk-grower had to isolate and separate his diseased worms. But the knowledge which led to this effectual result was knowledge that had been won by an uphill fight, and that had been gained by the object-glass of the microscope, and by the whole-souled devotion of many months' industry.

* Quoting a remark by Miss Nightingale.—Ed.

THE LAWS OF PROBABILITY.

There are few subjects in which men take a more general interest, yet few in which they make greater mistakes, than the subject of probabilities. From the man whose mind is most perfectly trained in the analysis of evidence, down to him whose thinking apparatus can scarcely be regarded as a mind at all, all men endeavour to guide their conduct in matters uncertain, or at least to form their opinion on such matters, according to the probabilities. They would use different words in describing their purpose. A mathematician might, perhaps, speak definitely of the *à priori* and *à posteriori* probabilities in favour of an opinion or of a course of conduct. Wendell Holmes' "lout," he "who lies outstretched on a tavern bench with just mental activity enough to keep his pipe from going out," would hardly use the same expressions; but in his imperfect way he is all his life doing the same thing. He does not even stretch out his ungainly limbs on one bench rather than on another, or in one attitude rather than another, without to some degree considering his chance of comfort or security. But in all the ordinary relations of life he more definitely weighs the chances, though often, if not always, in an utterly inexact balance.

It is not the loutish mind only, however, nor the average intellect, which inexactly estimates probabilities. The most profound knowledge of the mathematics of chance does not save men from error. Often, indeed, the grossest blunders have resulted from an attempt to weigh ordinary matters in a mathematical balance. The fault has not lain, however, with the balance, but with the user. If a man chooses to weigh groceries in a chemical balance, paying no attention to the fact that either the parcels he weighs come in contact with other things lying round, so that the balance cannot possibly show their true weight, or else, perhaps, that the construction of the balance is such as will only permit of its indicating true results within certain very

narrow limits of weight, he will obtain a much less satisfactory result than he would if he used a common weighing machine incapable of showing differences of a few grains or scruples. Yet he should not condemn the balance, but himself for misusing it.

Not unfrequently mathematicians have fallen into a parallel error. Indeed, there are those who assert that mathematicians are more apt than other men to err in this way, because they try to apply the exact laws of probability to matters about which they only have inexact knowledge. To use an illustration of Huxley's, mathematicians possess a mill of exquisite perfection, which grinds you stuff of any degree of fineness, but they are apt to put peacods into it and to regard the product of their grinding as wheaten flour.

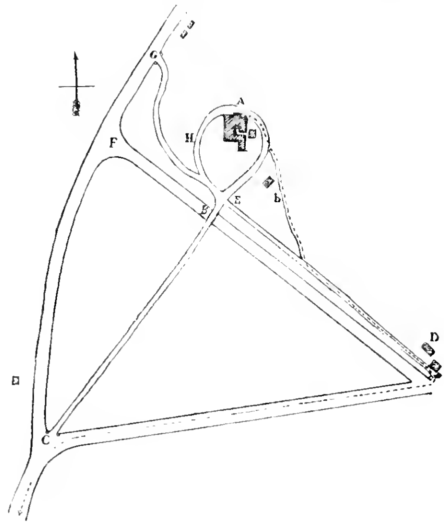
However, there is no real connection between profound mathematical research and utter absence of common sense. Mathematicians do not often err in this way. The laws of probability would be worth knowing even if they did. Nor is the application of these laws to many cases where they really are applicable likely to detract from what is commonly called the common sense way of viewing matters. Indeed, the common sense method may be regarded as only a rough way of applying the just method. The probability of its leading to a tolerably correct result is much less than the probability of a correct result when due account is taken of details; just as the chance of correctly estimating the cost of a complicated work by roughly adding a number of roughly-estimated items is less than the chance of a correct estimate when these items, separately estimated as exactly as possible, are properly added together. In neither case do we get an exact result, but the chances of gross error are much greater in the former than in the latter; for to the chances of error arising from an exact estimate of the several items in the latter case there is added the chance of a large error in a rough estimate of the totality of these items.

It must be admitted that by justly combining the various probabilities on which a question depends, we are more likely to attain a correct opinion than if we formed only a rough idea of what would result from such a combination. Yet the incautious application of the laws of probability, combined with undue reliance on results which, at the most, had been only shown to be probably true, has often led to absurd blunders.

INTELLIGENCE IN ANIMALS.

PASSING over several cases which seem to carry the matter no further than those already cited, we come next to a case which appears to us one of the most striking ever recorded. The writer, Mr. E. H. Pringle, remarks that it is an instance of sagacity which finally set at rest any doubts he had ever entertained that the difference between human and animal intelligence is one of degree only. We can see no way in which the story can be explained without assuming the exercise of something more than that mere practical reasoning which probably underlies all the so-called instinctive actions of animals:—

Mr. J. W. Cherry, of the Madras Forest Service, is owner of a dog, a bull-terrier, called "Bully." (This breed is notoriously not the most intelligent of the canine tribe, so that the behaviour of Bully appears all the more striking.) "We lived," says Mr. Pringle, "in the bungalow A,* the compound of which was bounded south and west by public roads DC and GFC, both leading to the cantonment of Bangalore in the direction C. There were three gates into the compound at C, D, and G, the main approach to the bungalow leading over a bridge B that spanned a public road FD. The compound was filled with trees and shrubs, and bordered by dense lantana hedges, so that with the exception of a portion of the western road at F, neither of the cantonment roads were visible from the bridge, nor could the footpaths be seen thence. Now, Bully had a lady friend (canine) living in the cantonment, and at times she was so attractive, that absences without leave on the part of the dog were frequent. After one of these excursions, Bully had been brought back and chained up for the night. Next morning, while his master and I were sitting at early breakfast, it was decided that he should be released, and to effectually



stop further delinquency, a peon was sent down to the bridge with orders to intercept him if he started for the cantonment. Bully was brought in and unchained; he had that unmistakable air of detected guilt deservedly punished, and spent some time in begging for scraps from the table in a most deprecatory manner. Shortly, however, he strolled into the verandah, and then down the front steps on to the gravel walk. After wandering about aimlessly for a few minutes, he quietly started down the approach AHB. We followed, keeping out of his sight. At the turn of the road, Bully met with the unexpected apparition of the peon standing on the bridge. In a moment, though not a word was spoken by the man, the dog turned and came straight back to the room, whither we had in the meantime slipped back unobserved, and re-entered it, wagging his tail violently, and looking exceedingly sheepish. He now lay down, and closed his eyes. The cocked ears showed that sleep was mere pretence, and he soon rose again, went out into the front garden, and hunted for buried bones—purely imaginary ones, I believe. His search gradually led him down the hill by a footpath leading from A to G, we keeping him in sight, as before, and he finally reached the road at the bottom. There all disguise was dropped, and he started off for the cantonment. As he neared the spot F, the peon

* The figure presents all the features essential to a correct understanding of Mr. Pringle's narrative.

espied him, and shouted out his name. He turned at once, climbed the hill, and came into the bungalow, where the same farce of repentance was gone through. Bully now seemed to have made up his mind that escape was impossible; he lay down on a mat in the verandah, and remained there for a long time. But for the persistent cock of the ears, we should have imagined the animal really asleep. Mr Cherry eventually went to his office-room, and I remained in the verandah, reading the morning paper and occasionally glancing at Bully. He lay very still, but once or twice I detected him opening his eyes and raising his head to look round him. Each time he caught my eye he wagged his tail vehemently for a moment or two, and then resorted to his sham sleep. It may have been for half-an-hour or thereabouts that this state of things continued. I then became interested in an article in the paper, and when I next looked up, Bully was gone. I called Mr. Cherry, and the house was searched for Bully. The peon was sent for and interrogated; he had not seen the dog. As a last resource, inquiry was made of the horse-keepers down at the stables, D. The reply was "Yes, the dog had passed through the gate, D, some time before." Taking advantage of my occupation, and the absence of his master, Bully had left the house and taken his way to the cantonment by the only path by which he could have escaped unnoticed by the peon—that shown by the dotted line.

It seems to us quite impossible to account for the dog's action, as above narrated, without attributing to him the exercise of reasoning powers, not merely in selecting the route by which he finally escaped, but in the manœuvres by which he endeavoured to assure those who were watching him that he had given up all hope of escaping. Doubtless, if he had reasoned more perfectly, he would even have allowed his ears to seem asleep, instead of leaving them cocked. But very few of us human beings simulate sleep without some such error, by which any observant person would be enabled to detect the trick. Either the muscles of the face are not perfectly relaxed; or the hands or feet are left in a constrained attitude; or the position of the body generally is unlike that which a sleeping person would assume; or else the breathing is unnaturally restrained. And again, though Bully was too demonstrative in his contrition, and afterwards in his attempts to hide the consciousness of failure, it was not for want of reasoning power. Few of us know how to act such parts as he tried to play, with perfect correctness; nor do those who know succeed always in acting such parts as they could wish. Probably Bully was as sensible as the onlookers that he was not quite successful in his acting. It is obvious, however, that he directed his efforts as carefully to the end he wished to obtain as a human being of average reasoning powers and skill in counterfeiting sleep, &c., could have done.

ILLUSIONS.

By Thomas Foster.

In my last paper there were two mistakes, or rather a single mistake, for it amounted really to the inversion of one of the figures. In Fig. 5, the lines marked AB, CD, should have been put opposite the letters EF, GH, and *vice versâ*. As they actually stand, the description should run as follows: The lines AB, CD appear to be curved, so as to be farther apart at the middle than at either end; whilst the lines EF and GH, in the same figure, appear to be so curved as to be nearer in the middle than at either end.

Such illusions as are illustrated at pp. 11 and 12 vary in effect according to the position from which the illusory drawing is seen. Thus, if we so place Fig. 1 that the eye looks along, or nearly along, the direction AB, we see at once that CD is in the same straight line with AB. Again, although we cannot look simultaneously in the directions BC and ED in Fig. 3, it will be found that when we look along BC, so that the illusion ceases so far as the part of the circle near C is concerned, the illusion ceases altogether, the part near D no longer appearing to form part of a smaller circle. In Fig. 4, the illusion is not at all effective when we hold the lines AB, CD, &c., upright, but is very marked when they are looked at aslant. But again, even when we look at them aslant, and the illusion is strong, we yet find that running the eye backwards and forwards along the parallels, the illusion varies all the time; for the eye cannot fail then to perceive that the distance between the parallels does not vary as the illusory effect seems to suggest. Thus, the lines CD, EF, which, when the eye is at rest, seem to draw closer at D and F, are found not to do so when the eye is carried from CE to DF; and a singular effect of motion is produced, the lines CD and EF seeming to move apart as the eye runs down them towards DF. The other lines seem to move correspondingly, and thus we have an illusion of motion, which will be considered later among illusions of that sort.

In the illusory figures now to be considered, the lines which appear curved, though straight, are set in different positions so as to be differently affected, and thus we have illusions affecting the shape of enclosed figures such as shall be considered separately further on.

If we look at Fig. 8 as it stands, that is with the point A uppermost, we find the lines AB, AE looking strongly curved; BC and ED rather less curved; and DC looks almost straight—at least, this is the effect to my eye. (I find EA most curved of all.) Thus the figure, which is

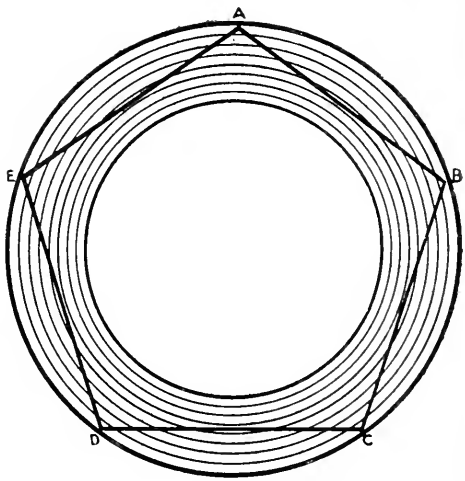


Fig. 8.

really a true pentagon with straight sides, looks like a figure having unequally curved sides. Turning the picture round in its own plane, we find that as the sides of the pentagon by this turning motion pass to the top, they appear more curved, so that they appear to change in shape as they move, or to have a motion of their own.

The apparent curvature of the really straight lines in

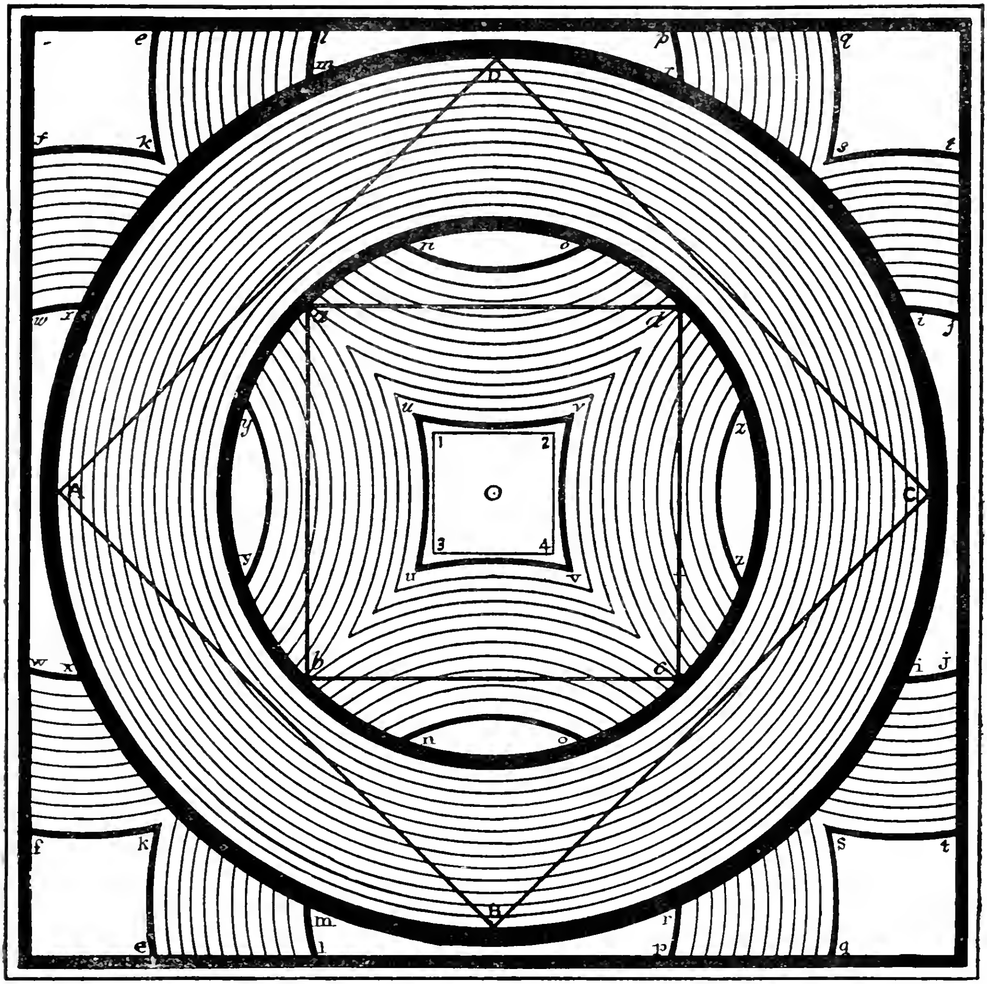

Fig. 9.—A Nest of Illusions.

Fig. 8 has been regarded by Mr. Proctor as having possibly some bearing on the irregular shape, which the outline of the planet sometimes seems to have. It is referred to by Mr. Webb in his "Celestial Objects for Common Telescopes," who illustrates it, however, by a figure in which the distinctive characteristic is lost; the straight line in his figure does not cross the curved lines, and the suggestion of curvature, if it exist at all, is too slight to be readily recognised.

The effect of position on illusions of this sort can hardly, I think, be better illustrated than it is in Fig. 9, which may be described as "a nest of illusions."

Thus, First, the sides of the square ABCD, which are really straight, appear to be curved inwards.

Secondly, the sides of the square *abcd*, which are really straight, appear to be curved outwards, as (in less degree) do the sides of the square 1234.

Thirdly, the space between the two large heavy circles *mir* and *nzn*, appears to be superposed on the rest of the figure.

Fourthly, arc *no* (lighter curve) appears to belong to a smaller circle, instead of belonging, as it really does, to the same circle as the arcs *lm* and *pr*, the same holding with the other corresponding circular arcs of the figure.

Fifthly, it is difficult to realise that the space between the arcs *st* and *ij* is as broad as that between the arcs *xy* and zz, &c.

Sixthly, the circles between *no* and zz appear to draw closer together, though in reality concentric, as they approach the heavy circle *noz*, &c.

Seventhly, the [illegible] appear to draw further apart along the region $2cd$, &c.

But it will be found that the illusion varies in amount for corresponding parts of different portions of the figure; and that, as in the simpler case illustrated in Fig. 8, the different parts of the figure seem to vary in shape as the picture is turned round.

Reviews.

AUTHORS AND PUBLISHERS.*

THIS work, we are told in the preface, is intended chiefly for those who for the first time are about to commit their literary productions to the press, and who are unacquainted with the prevailing practices in regard to printing and publication. "The information contained in it will, no doubt, be more or less familiar to experienced authors." This may be so, but all the same, it is a work which every author, whether experienced or not, should undoubtedly possess. And, unless we mistake, it is a work in which the general public will find much to interest them. It is described as a rudimentary handbook, giving just those particulars concerning paper, printing, binding, and publishing, the preparation of copy, the correction of proofs, the embellishment and illustration of books, and the relations of publishers and their clients, &c., with which an author requires to be acquainted. The publishers have endeavoured to touch upon every point which is likely to arise between the period of the preparation of the manuscript for the press and the actual publication of the book, presenting at the same time a precise and accurate account of the mechanical details of printing. There are also most valuable notes on advertising, reviewing, and the law of copyright.

I am myself tolerably familiar with the matters dealt with in this work. At least, I have written nearly forty works, which have been published for me by five or six firms, with all of which I have had pleasant relations. Yet even for so old a hand as myself, the work before me is full of interest. When I began to write, it would have been still more valuable to me. It would have taught me one lesson, at any rate, which many have only learned by a rather dear experience. Publishers have made mistakes, we know; but, as a rule, the advice of an experienced publisher should be followed by a comparatively inexperienced author, and it should always be carefully weighed. I well remember how thoroughly mistaken I supposed Messrs. Longmans to be when they advised me to print no more than a thousand copies of my first work—"Saturn and its System." I had put so much hard work into that treatise, had filled so many pages with long and complex calculations, had drawn the illustrations so elaborately, that I thought many thousands must needs care for my book, and buy it if it were not too dear; while if but a thousand copies were printed, it must of necessity be rather dear. When they told me that very few cared for formulæ and diagrams, for the "great inequality" of Jupiter and Saturn, and so forth, I thought they underestimated the intelligence of the general reader. That was sixteen years ago, and the first edition of "Saturn and its System" is only just approaching exhaustion.† They knew, and I did not, what was best and wisest.

The advice of publishers about advertising, selection of journals to which a book should be sent for review, and other matters of that sort, is nearly always sound, and is always based on sound considerations. When advertising is left entirely to publishers, they are apt, in some cases, to be a little extravagant, so far as my experience goes. At least, I have found two books, separately published by one firm, selling no better than two precisely similar books, published under similar conditions at another time, by another firm, which were much less expensively advertised. But the selection among so many serials as exist, of those in which a publication should be advertised, is so difficult, and requires so much experience, that the author does wisely to avail himself of his publishers' advice in this respect.

The choice of a title is a point which authors would not care to leave entirely to their publishers; yet more than one of my own books bear titles which were either invented by the publishers, or modified at their suggestion. In the work before us, many curious illustrations of authors' mistakes and weaknesses on this point are given. The most curious, perhaps, are the titles selected by Puritan writers, whose title-pages exhibit such eccentricities as these:—

"Eggs of Charity, layed by the Chickens of the Covenant, and boiled in the Water of Divine Love. Take ye and eat."

"Some fine Biskets baked in the oven of Charity, carefully conserved for the Chickens of the Church, the Sparrows of the Spirit, and the Sweet Swallows of Salvation."

"A Reaping Hook, well tempered for the Ears of the Coming Crop."

"Hooks and Eyes for Believers' Breeches." (May we infer, by the way, that in the seventeenth century hooks and eyes were used "in this connection"—that is, where buttons and button-holes are used in our time?)

"High-heeled Shoes for Dwarfs in Holiness."

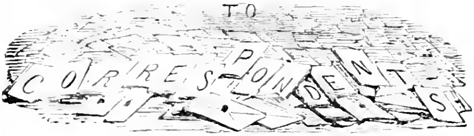
The matter relating to choice of paper, sizes of type, and corrections (this last especially) should be carefully studied by all who write or intend to write books. Others will find it interesting and instructive.

"Authorship and Publication" is eminently readable throughout. Technicalities are avoided where possible, and explained where they cannot be avoided. There is an amusing collection of technical expressions for the various names used to define correctly different degrees of anonymity in authorship, the student of which will be able thenceforward to distinguish an *allonym* from an *anonym*, and a *cryptonym* from a *boustrophedon*.

* "Authorship and Publication: A Concise Guide to Authors in matters relating to Printing and Publishing, including the Law of Copyright and a Bibliographical Appendix." (London: Wyman & Sons.)

† I was gratified to learn a few years since, from a criticism of Mr. Geo. Holden (then of the Washington Observatory, now of Ann Arbor), in which he rather severely denounced a book of mine, which is still in manuscript and was then unwritten, that the sales of my first book had been so great as to tempt me to seek a fortune by writing scientific treatises. Otherwise I should have thought the book had involved a rather heavy loss. But we should always believe what we see in print.

IMITATION FLOWERS MADE WITH LIQUID FILMS.—A pretty experiment has been recently described by the well-known Belgian physicist, M. Plateau. He bends fine iron wire so as to present the contour of a flower of six petals. The central ring, to which the petals are attached, is supported on a forking stem, which is stuck in a piece of wood. After oxidising the wire slightly with weak nitric acid, the flower is dipped in glyceric liquid, so as to receive films in the petals and the central part. It is then turned up, placed on a table near a window, and covered with a bell jar. For a little while it appears colourless, but soon a striking play of colours commences. In the experiment M. Plateau describes, the flower continued showing modifications of colours for ten hours, when dusk stopped observation. Next morning several petals had burst. The liquid used was of very mediocre quality. M. Plateau recommends preparation of the liquid thus:—Dissolve a fresh piece of Marseilles soap, cut up into small pieces, in 40 parts by weight of hot distilled water. Filter after cooling, and mix thoroughly three volumes of the solution with two of Price's glycerine. The solution should be left at rest till all air bubbles are gone.—*The Times.*



Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. He requests that all communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All communications should be addressed to the Editor of KNOWLEDGE, *71, Great Queen-street, W.C.*

All Cheques and Post-Office Orders to be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

TO OUR READERS.—NOTICE TO CORRESPONDENTS.—THE SUN'S HEAT.—WASTE OF ENERGY.—THE EARTH'S REVOLUTION.—THE FIFTEEN PUZZLE.—FLIGHT OF BIRDS.—CORRECTED SUN-DIAL.

WE begin to see more clearly than we did at first the lines on which our Correspondence columns will have to be conducted, though we shall always be glad to have hints and suggestions from our readers towards the improvement of this section of KNOWLEDGE. Dropping the editorial "we," let me note that from the beginning I have proposed to take my share in the Correspondence, not only in answering queries, explaining difficulties, &c., in subjects I am able to deal with, but also in asking questions, inviting explanations, and so forth. It will be found, also (indeed, I think the last and present numbers give some illustration of the fact), that space will as readily be found for corrections of the mistakes I make myself, as for those into which others may fall. In the two first numbers I appended, in several cases, my replies to the respective letters to which they related; but hereafter I propose to reply each week to letters and queries falling into my department which have appeared in the previous week. Others have promised me their assistance in dealing similarly with other inquiries. But I hope many who have information to give on subjects of interest respecting which inquiries may be made, will do so, as occasion may suggest. We wish to leave as few inquiries unanswered as possible.

I take this opportunity of reminding correspondents that their letters should reach the office by Saturday at latest, if they are to appear in the number for the following week. Already, owing to the unexpectedly rapid growth of the correspondence, it has been found necessary to arrange that no letters received after Monday shall be even read till the matter for the following week has been made up; and, of course, in making room for letters, the rule "first come, first served" must be attended to, not indeed with absolute stringency, but in the main. We must also beg our correspondents to bear with us if we are obliged to abridge some letters. There shall be no favouritism, either in selection, or in inserting more or less from letters which reach us; in every case we shall be guided by our view as to the wishes and requirements of our readers. Nor need correspondents be surprised, any more than we are, if every letter they may send us, or every part of each letter, should not be thought precisely what would suit the plan and purpose of KNOWLEDGE.

Taking first letter 2, p. 15, I note that "Anti-Guebre's" difficulty is one which I have found, during my lecture tours in Great Britain, America, and Australasia, to be more common than any other whatsoever. I suppose I must have received more nearly a thousand than five hundred letters presenting precisely "Anti-Guebre's" difficulty, so that, I may remark in passing, Mr. Newton Crosland must not regard himself as sole inventor and patentee of the paradox in question. The answer is not so simple as many seem to suppose. None of our correspondents have, indeed, answered "Anti-Guebre's" difficulty correctly and fully. If we remember that the existence of snow in large quantities on mountain tops and of ice particles in the cirrus clouds, implies the prior existence at those heights of large quantities of the vapour of water, we shall see that the asserted dryness of the higher air (and, therefore, the unimpeded passage of heat rays through such air) can hardly be regarded as demonstrated. Again, to say that rarefied air has no capacity for heat is, in reality, to speak in terms belonging to the old and erroneous theory of heat as a sort of fluid. Many seem to imagine that the mere rarefaction of a gas is a cooling process, overlooking the statement which accompanies all correct accounts of experiments on the subject, that it is not the rarefaction itself, but the work done in expansion that causes loss of heat. In like manner, when gas is compressed, it is not heated because of its greater density, but because a considerable part of the extraneous work applied to produce compression is transformed into heat. In one case we have force obtained at the expense of so much heat, in the other heat is produced by the expenditure of such and such force. If the air around lofty mountain tops were simply very thin, and there were never any interchange between the higher and lower air, not a particle of snow would ever be seen on our mountain tops, nor should we ever see the cirrus or feathery snow clouds in the upper air. But because there is interchange, because the air which rises along mountain slopes expands and does work in expanding, it is made cooler and cooler, till at great heights it becomes altogether refrigerated, while the air which descends to replace the air which has risen becomes warmer, because in descending it is compressed by the action of gravity (an extraneous force) and a portion of the force thus exerted appears in the form of heat. Again, in the case of the upper feathery snow-clouds, the refrigeration comes mainly from the ascent of aqueous vapour. The wool-pack clouds which we see on a summer day are the upper parts of columns of ascending aqueous vapour, where the vapour has been condensed to water particles or vesicles, and so appears in the form of visible cloud. At the upper surface of these clouds a process of evaporation is continually taking place, and currents of vaporous air are continually ascending. When these ascend high enough to be sufficiently refrigerated, they form in turn into water-drops or vesicles, but under different circumstances from those prevailing where the cumulus or wool-pack clouds are formed. The refrigeration is more rapid owing to the rarity and *relative* dryness of the higher air, and thus the water particles up there form snow-crystals, and (under the conditions stated) cirrus clouds are formed. That they are not always formed is due to the circumstance that these conditions do not always prevail.

As to the waste of solar and stellar energies referred to in the same letter, it is probably only the limited nature of our knowledge which causes that to seem like waste which may, for aught we know, involve the most perfect adaptation possible of the energies in question. We may say of such inquiries, with the poet :—

> "Reason, alas! it does not know itself:
> Yet man, vain man! would with this tiny plummet
> Measure the deep profound.
> He sees but part of the chain—the nearest links—
> His eye not reaching to the equal beam
> That poises all, above."

We need not infer that what we see is seen incorrectly because we see not all.

In letter 5, p. 35, Mr. Crosland uses arguments which only require to be understood to be refuted. What meaning can be found in the statement that "light and heat are phenomenal products, caused by magnetic and electric forces, in a state of intense activity, acting upon atmospheric conditions"? Why not equally well say "Magnetism and electricity are phenomenal products, caused by luminous and calorific forces, acting under aqueous conditions"? Again: the sun might "possess the power of producing the phenomena of incandescence, without being itself incandescent." But, as a matter of fact, he is incandescent, if incandescence means, as it does, glowing. Electricity produced in another room may make a wire on the table at which I write white hot; but when looking at the wire I see it to be glowing white, and when by actual tests I find it to be radiating heat, I cannot agree that it is neither incandescent nor hot, because something which is neither glowing nor a source of radiant heat may yet produce both light and heat.

Several correspondents think "Tyro's" letter (6, p. 35) should not have appeared. It is not very pertinent, but it serves to show one chief way in which paradoxes arise, viz., from want of thought. "Tyro" must have seen hundreds of cases where a luminous body causes a distant opaque body to appear bright, without any flood of effulgence along the space between; yet he expects to see that on the large scale which he does not see on the small scale. I do not take exception to his remarks as relating really to light, not to heat, because I assume he considers that where there is lustre (inherent) there is also heat. It is not always, though it is generally the case.

"Tyro's" other query (letter 9, p. 36) is one often made, though most text-books insufficiently explain the difficulty. The only kind of revolution which some readers of astronomical works seem capable of understanding is such as we see where a ball at the end of a rigid rod is swayed by the rod round a centre. The real revolution of the earth more nearly resembles the motion of a spinning top when thrown (on a curved path) through the air, the axis moving all the time parallel to itself, or retaining an unchanged direction while changing constantly in place.

In my remarks on letter 13, p. 37, the words ten millions, last line but two of second paragraph, should be ten billions. There are in all more than twenty millions of millions of possible positions in the "fifteen puzzle," though some, overlooking the circumstance that every change in the position of the blank square changes the puzzle, suppose there are only about 1½ millions of millions.

As regards query 3, p. 30, on the flight of birds, it is quite certain, as others, I see, have pointed out, that the air in the passages of the bones cannot help the bird by adding to its buoyancy. If an absolute vacuum could be produced in these passages, which (if the passages remained unchanged in volume) would give the maximum degree of buoyancy, the only lifting power which would result would be simply equivalent to the weight of so much air at the actual temperature of the air in which the bird is flying at the moment, as would fill the passages in the bones. Air equal in volume to the bird itself would not have more than a 100th part of his weight; how much less, then, would the counterpoising of his weight by a raising power corresponding to the weight of the tiny quantity of air which would fill the passages, be of any appreciable avail in helping him to fly?

I will describe and sketch in an early number a very simple instrument for telling time from a shadow (as in the case of the sun-dial), without any appreciable error arising from the shadow not being sharp. RICHARD A. PROCTOR.

THE MISSING LINK.

[33]—I am glad to see a correspondent ("An Ignoramus") has asked for an explanation regarding the "Missing Link" of Darwinism and Evolution. Briefly stated, here is the problem. If, as evolution postulates, the various forms of animal life have "sprung from one, or, at most, a few, primitive forms, then we must conceive of living nature as a tree of which all the parts are connected together from root to topmost twig. Now, if man exists, as he unquestionably does, at the top of the highest twig, it is evident he must be connected, by some forms more or less like himself, with lower quadrupeds, and through these latter, with still lower animals, and so on. Where, then, in the case of man, are the animal links that lead from the human to the pre-human, and from the pre-human to the purely animal? When evolution was first promulgated, everybody asked "Where are the missing links?" That common ignorance, which too often passes for common sense or for science, at once inquired where was the link that connected man with the monkey? This question is founded on gross ignorance of what evolution requires. No evolutionist assumes that man is descended *from any existing ape, or from any extinct ape either*. Mr. Darwin, in his "Descent of Man," is very careful to point this out. What evolution does say is, that probably man and apes originated far back in some common root-stock, whence the human branch proceeded, diverging for ever, from the ape branch, on its own way of development. If we take the four highest apes—gorilla, chimpanzee, orang, and gibbon—we find no one of the four to approach man as a whole more nearly than any other of the four. If an approach to the human frame were to be made from the ape-side, we should require a bit from each and all of the four to make up such a representation of the human type. The orang's brain is, for instance, more like man's than the gorilla's, but the latter approaches man's more nearly in some other points. It is the same with the gibbon and the chimpanzee. The "old ladies of both sexes," who used to assume that the gorilla as the "missing link" was a failure, did not know that the evolutionist thoroughly agreed with them. Where the "links" that connect man to his lower neighbours are to be found, is a difficult question to answer. Possibly we must go first to lower human life, and find an approach to animal characters in the skulls of savages and primitive men (*e.g.*, Neanderthal skull); but the geological record is imperfect. There are long gaps in the series which can never be filled. All living forms have not been preserved in the fossil series. With human remains, the chances of preservation are few and far between. Even primitive man buries or burns his dead; and thus the record of man's past history may ever remain obscure. But all the evidence points indubitably to man's origin from lower life. His development shows this idea to be true; the presence of rudimentary organs (such as ear-muscles, which are of no use to him) tells the same tale; and anthropology, in its researches into savage life and customs, verifies evolution. I hope "Ignoramus" will feel satisfied with the above answer. He should read Darwin's "Descent of Man" and Mr. Tylor's "Anthropology," and an article on "Missing Links," in a recent volume of the *Gentleman's Magazine*, will also help him in his endeavour to understand what evolution demands and implies.

ANDREW WILSON.

THE SUN'S HEAT.

[34]—I must confess I was somewhat surprised to read "Anti-Guebre's" letter in your first issue, considering the preceding remarks about "paradoxers;" but since he asks for information, I shall be glad to give it him.

In the first place, the air is not capable of being directly warmed by the rays of the sun, but it is warmed by contact with the heated earth; consequently the air is much warmer in the valleys than on the tops of the mountains. Again, in the valleys the air is not so subject to disturbance by winds, &c., as it is at a higher elevation; so when we ascend a mountain or rise in a balloon, we recede both from the body of the earth and from the heat thereof, for air is a very bad conductor of heat; but though the *air* is colder, the *sun's rays* are not. If "Anti-Guebre" had ever ascended a snow-capped mountain, he would know that the rays of the sun are insupportably hot there: for two reasons; first, the traveller is *nearer* the sun, and unprotected by clouds and aqueous vapour; secondly, he is exposed to the reflection from the snow. The snow protects the mountain itself from being much warmed, and is only very slowly melted, as it reflects the greater part both of the heat and light. The deposition during the night makes up for the loss experienced during the day. Alpine climbers usually complain that their lower limbs are nearly frozen by the snow, while their heads and shoulders are almost roasted by the sun.

Aqueous vapour plays a very important part in the warming of air, for it is the vapour rather than the air itself that receives the heat. Dry air cannot be warmed so easily as damp air. This is the reason why the air feels warm in dry, frosty weather, as it cannot conduct away the heat from the body; whereas, damp air feels cold, since the aqueous vapour *does* conduct away the animal warmth of our bodies. (Of course, I am not considering the subject of evaporation.) At high elevations the air is colder and dryer than at the surface of the earth.

With regard to the icy nature of cirrus clouds, there is nothing absurd in the supposition.

Anyone who watches the sky in summer will see clouds disappear and reform, often with great rapidity. This is due to the varying temperature of the air, or rather of the air currents, which either condense or volatilise the aqueous vapour in the air, according to their temperature. We know that certain clouds *do* consist of icy particles when we see a halo round the moon making a particular angle with the observer's eye. If "Anti-Guebre" thinks an ice-cloud ought to be instantaneously melted by the heat of the sun, he is in error, as, putting on one side the diathermancy of ice, and granting that the action of the sun would be to melt it, the evaporation at that altitude would be so rapid as to freeze again the water formed, consequently, the volatilisation of the cloud would take some time.

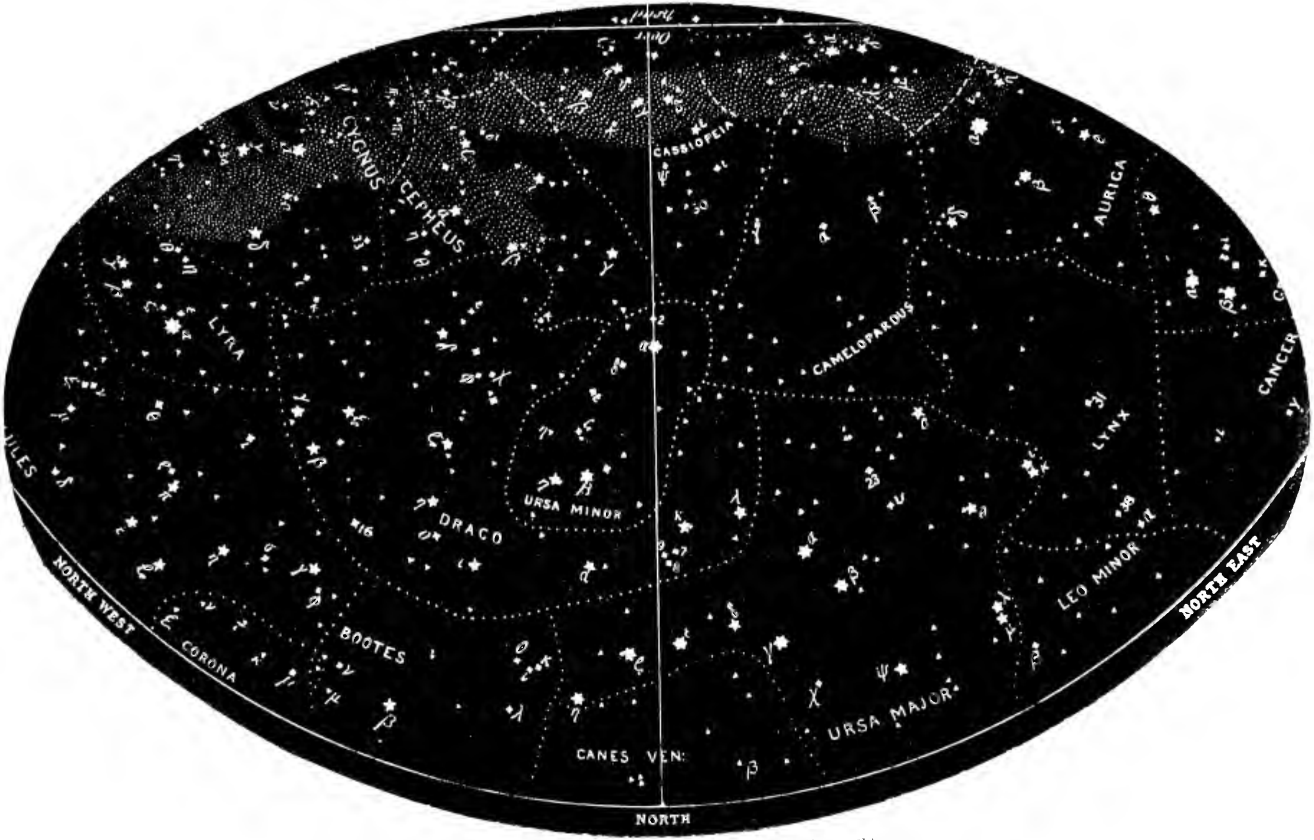
"Anti-Guebre's" "profit and loss" ideas of the solar system are too deep for me. It is true that we only receive $\frac{1}{2,070,650,000}$ of the sun's light and heat; but what right has he to say that the rest is wasted? He must first find out what becomes of it, and prove that it does no work. He might, with equal truth, say his own time is wasted when in bed, because he is not conscious of what takes place when he is asleep.—I am, &c., SM.

THE SUN'S HEAT (*Abstract*).

[35]—"Anti-Guebre" says that when he approaches the fire he feels warmer, but that, on the contrary, an approach to the sun produces a cooling effect, hence the sun is cold. In the case of the fire we make a very great difference in the absolute [it should be relative] distance between us and it, by a very small movement on our part; whilst in the case of the sun, any difference in the absolute [relative] distance between us and that orb which we are able to make is immeasurably small compared with the absolute distance; and though it may be said there *would* be an *augmentation*, though small, there are other causes at work which more than neutralise this augmentation.

It has, I think, been fully proved that the air itself is transparent for heat, and that the air is *warmed* by contact with the earth; the higher, therefore, we rise above the sea-level, the colder does the air become, and this effect is ample to overcome any slight increase in the heating power, owing to a decrease in the direct distance of

THE NORTHERN SKIES IN NOVEMBER.



This Map shows the position of the stars in the Northern Skies:—

On November 3, at 11¼ o'clock.	On November 10, at 10¾ o'clock.	On November 18, at 10¼ o'clock.	On November 25, at 9¾ o'clock.	On December 3, at 9¼ o'clock.
On November 7, at 11 o'clock.	On November 14, at 10½ o'clock.	On November 22, at 10 o'clock.	On November 29, at 9½ o'clock.	On December 7, at 9 o'clock.

The stars in the northern skies are carried from left to right under the pole, and from right to left above the pole, descending to the left or west of the pole, and ascending to the right or east of the pole. They are carried, in fact, round the pole in a direction contrary to that in which the hands of a watch move.

*** Stars of the first magnitude are shown with eight points, those of the second with six, of the third with five, of the fourth with four, of the fifth with three.

the sun. It seems to me that the matter is of far greater complexity than your correspondent imagines.—Yours, &c., VERAX.

---

[36]—Your correspondent "Anti-Guebre" (p 15, No. 1) takes up rather a large amount of what I expect in future will be very valuable space, with his question as to whether the sun is hot, and in proof that it is not so, he brings forward the apparent fact that as we ascend high mountains we get cooler. This, however, is not exactly a fact, and it is very difficult to convince the unscientific public that it is not so, as I found to my trouble during a twenty years' residence as a medical man in India. Now the amount of heat which we are sensible of on a hot day does not come to the body directly or entirely from the sun, but from the earth, which has been heated by the sun's rays. In the hills (I refer more especially to tropical countries), the heat received by the soil during the day is radiated to such an extent during the night, that the surface becomes thoroughly cooled down. In the plains below, probably from the greater density of the superjacent air, the radiation is very small, and the heat is retained, to be added to by the succeeding day's sun. The movement of currents of air, also, is much more constant in the hills, and this acts like a fan in continually changing the air which has become heated by contact with the surface of the earth. The heat received directly from the sun should, of course, increase the higher we ascend, not because we are a few thousand feet nearer to it, but because so much less of its power is absorbed by the lower and denser layers of the atmosphere. And so it does, as is proved by the fact, not so generally known, that the black bulb thermometer indicates the increased temperature as the elevation increases. The readings of this at Ootacamund, in South India, average about 14° above those taken simultaneously at the coast towns. I have repeatedly noticed that Europeans who come from the low country up to the hill sanitaria, while enjoying the cool atmosphere, yet had their faces completely peeled by the increased direct action of the sun's rays. I have seen a child's hat blown off, and before it could be picked up again the child was stricken down by sunstroke, and this at a time when there had been ice on the plain during the night, and I have always noticed that while it was possible to walk short distances in the sun in the low country with an ordinary green silk umbrella, yet that at six or seven thousand feet elevation this became quite insufficient, the heat seeming to strike right through it, at once rendering the addition of a white calico covering absolutely imperative. B. M., F.R.C.S.

Nov. 18.

---

[37]—In letter 2, page 15, your correspondent says that "the sun is not himself hot'; but, of course, he is the source of heat to the earth." How does he reconcile the two statements? He might as well maintain that his fire, which he uses as a conclusive proof to himself of the non-incandescence of the sun, is not in itself hot, though it is a source of heat to things surounding it. He also uses that question which has been so often advanced by inquirers, and as often replied to by scientists. Why is it that the higher you go from the earth the colder it becomes, if, as people say, the sun be hot? He forgets the important part the atmosphere plays with regard to our earth. I maintain that the nearer the earth is to the sun, not the nearer we get up through our atmosphere to it, so the heat transmitted becomes greater. When the earth is at its perigee, the sun transmits more warmth than when it is at its apogee. To this he may advance the argument that the perigee occurs in January. So be it. From this very cause winters are milder and summers cooler in the northern than in the southern hemisphere. Then, as he says the sun is not hot, can he explain why the earth should derive more heat from the sun when its rays fall vertically than when they fall obliquely? If the source of heat be contained in the earth itself, then should the poles be warmer than the equator. We know the opposite to be the case. In Letter 5, page 35, your correspondent says, "Light and heat are surely phenominal products, caused by magnetic and electrical forces in a state of intense activity." If so, why is there greater heat when the sun's rays are vertical, if it has nothing to do with the production of heat? In this letter there is more dealing with probabilities than with facts. Probabilities do not exist in Nature, and I trust that through your columns we may arrive at a clearer idea of the truth concerning this question of the sun's heat. I hardly see that Letter 6 requires an answer, as this is not so much a question of light as of heat.—Yours, very faithfully, G. G. D

Nov 15, 1881.

STAR NAMES.—COMETS' TAILS.

[38]—May I suggest, in regard to your excellent star maps, that it might be some improvement to them if the names of well-known stars, such as Capella, Aldebaran, &c., were marked in the map, as well as the name of the constellation and the α, β, γ, &c.; or, at least, attention might suitably be called to them in a note naming the brightest star in each particular map.

I have annotated your first map for the benefit of my boys, writing at the side—

Aldebaran = α Tauri,
Rigel = β Orionis, &c., &c.

No explanation I have yet heard as to the material, &c., of comet's tails appears very satisfactory. Has the idea ever occurred to you that a comet repels matter from its nucleus in the form of vapour, or a highly-attenuated condition of solid particles, not in one direction only, but *laterally* as well? And that we might only see the portion of this matter through which a ray of light was projected from the sun or from the glowing mass of the comet itself, at such an angle as to render its path visible to us in the same manner as we see sun-rays at sunrise and sunset, or when the sun is emerging from a cloud?

Would not this account for the apparently incredible rapidity with which comets' tails swing round the sun at perihelion, and also for comets, when distant from the sun, not exhibiting any tail at all?

There are other points I wished to mention, but have not time to-night. I heartily wish your excellent paper every success, and am, yours faithfully, SPECULUM.

PRACTICAL WORK WITH THE TELESCOPE.—MAP OF EASTERN SKIES.

[39]—I am very much pleased with the first two numbers of KNOWLEDGE, and I am doing all I can to make it known amongst friends. I have had some difficulty in getting the numbers, but perhaps this will be all right hereafter.

I have been a "star-gazer" for a few years, and have read a good many of the treatises on astronomy, but have never been able to turn my knowledge into any practical shape. If you could throw out a few hints as a guide for those desiring to start in this study, I think they would be of great service. What particular branch would you recommend to start with, and how ought the study to be carried out? What handbooks and instruments would you recommend?

Surely there is some mistake in your map of the eastern sky issued with No. 1. In your map you place Saturn highest above the horizon, then Jupiter, then the Pleiades; whereas the reverse is the order, Orion is placed very much on its side, and so on. Wishing you every success, I remain, yours, &c.,

Edinburgh, *Nov.* 16, 1881. G. M.

[With reference to the last question, has "G. M." understood that the circular outline of the map is the horizon? Thus it must be held with the word SOUTH-EAST lowest to show the position of the objects he names, which all lie, speaking generally, towards the south-east at the hour corresponding to the map. Note, however, that by an unfortunate error, corrected in part of the present issue, the hours named under the maps in Nos. 1, 2, and 3 are all, without exception, one hour too late. This should be corrected in each map, as the maps, apart from the planets shown, will be as correct for next year, or for twenty years hence, at the same dates, as for the present year.—ED.]

CELESTIAL OBJECTS.

[40]—I have obtained the first two Nos. of KNOWLEDGE, and am much pleased with the contents; the star maps especially I was very pleased to see. Would it be in accordance with your plans to publish, from time to time, a few notes descriptive of interesting and remarkable objects in the constellations? Several of my friends to whom I have shown KNOWLEDGE have promised to become subscribers; and to those of us who dabble a little in astronomy, the name of the Editor is a sufficient guarantee of the information we shall get on that subject, at any rate. Wishing KNOWLEDGE the success it deserves,—I remain, yours, &c. W. J. C.

ARE WOMEN INFERIOR TO MEN? (*Abstract.*)

[41]—I perused with some interest in the first issue of your paper an article on the question whether women are inferior to men. The study of the human mind and character seems to be neglected by most publications, although it is a most interesting subject. I am sure if you will open your columns for such subjects, you will not fail to gain appreciative and constant readers. The

subject in question is one of which different views may be taken, and I need therefore make no apology for writing a few words on it. The writer of the article seems to be under the impression that he has only to prove the fallacy of M. Delaunay's arguments to show that woman is not inferior to man. I have no doubt but what such a question will more frequently present itself to the public mind as the competition in the labour markets between men and women becomes keener. The author of the article throws just ridicule on the comparisons made by M. Delaunay, yet he himself does not hint in the least that the comparisons are altogether improper and most unjust to the fair sex, as they really are. Men are too apt to forget that the first duty of woman is to keep a home and rear their young; to unite with, and not struggle against men. Man and women united form a perfect being; they are one in every sense of the word; apart they are both imperfect. Wishing KNOWLEDGE every success, Yours, G. W. D.

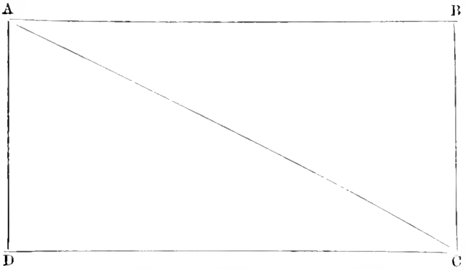
---

[42]—In your review of the above, in Vol. I., No. I, p. 8, you say, "We come next, in M. Delaunay's paper, to the more important question of cranial capacity and form; for, certainly (setting aside, of course, phrenological absurdities)," &c. 1. How do you *prove* your "*assumptive statement*" as to phrenology being *absurd*, *ergo*, false? 2. How do you account for your *special* knowledge relative to capacity and form, apart from phrenology? 3. Does the brain shape or mould the form of the cranium or skull?—Yours truly,

CHARLES HAMILTON.

SPEED OF AMERICAN ICE-YACHTS.

[43]—I think I can show non-mathematical readers a way in which they can satisfy themselves that an ice-yacht *may* sail faster than the wind.



In a board or card cut a groove, or slit from A to C; in it fix a freely moving slider; lay a ruler along A B, and, keeping it parallel to itself, slide it down to CD. The slider represents the yacht, the groove the effect of the yacht's runners, and the ruler the front of an advancing body of wind. As, then, the slider moves faster than the ruler, describing AC, while the latter describes AB, so the yacht may move faster than the wind. Of course, I do not say that the above arrangement explains all the forces in action; but I think it removes the chief difficulty, which seems to be in failing to see how the effect (so to speak) can be greater than the cause.

W. J. M.

[The reader will notice that "W. J. M." carefully limits the application of this reasoning. It shows only—as he mentions—that an ice-yacht *may* move faster than the driving force. Any amount of energy may be applied to move the ruler until the resistance of the slider is overcome. The ruler cannot move as described unless the slider gives way in the only way in which it can move; in the case of the yacht, the wind may blow over and past the yacht. But "W. J. M.'s" experiment shows all he claims for it.—ED.]

ARE MEN'S HEADS SMALLER THAN OF YORE?

[44]—In a letter on "Are Men's Heads Smaller than of Yore" in your Nov. 11 issue, a quotation is given from Professor Flower, in which several suggestions are thrown out as to reasons why hats should be smaller than they were twenty years ago, without a corresponding diminution in the size of heads. As a seller of hats for many years, I am able to verify several of those reasons to account for smaller-sized hats being required. No doubt, the hair being cut closer makes at least half a size difference, but the present manner of wearing hats on the top of the head, instead of down over the back of head and ears, as formerly, would make the most difference (at least half an inch), which any one can prove for themselves by measurement. Again, youths and young men now wear hats instead of caps, so that in sorting up sizes for sale, I find it necessary, if it is a fashionable shape, and likely to be worn by young men, to order—

Sizes	$20\frac{1}{4}$	$20\frac{3}{4}$	$21\frac{1}{4}$	$21\frac{1}{2}$	22 inches	
Relative numbers ..	1	2	3	2	1	

while for older styles, just because older men wear their hats further on the head, and like an easy fit, and not because their heads are larger, I have to order—

Sizes	$21\frac{1}{4}$	$21\frac{1}{2}$	22	$22\frac{1}{2}$	$22\frac{3}{4}$	$23\frac{1}{4}$ inches
Relative numbers ..	1	2	3	3	2	1

Yours, &c. HATTER.

ARE MEN'S HEADS SMALLER THAN OF YORE?—THE FLAT EARTH THEORY. (See letter 12, p. 36.)

[45]—Has it ever been noticed that most grooms, and such men, wear their hats, generally, on the *side* of the head? Possibly this may have something to do with the supposed change.

The following is from an article on Physical Geography, which appeared in a book published a short time ago:—

"It is remarkable that persistent efforts are still made, and supported by a great display of mathematical technicalities, to prove that it (the earth) is a circular disc; and within the last few years elaborately illustrated books have been produced in advocacy of the supposition."

I should be glad if you would say who are the publishers and what is the price of the books. Or if you could tell me on what facts the writers base their theory.—BETA.

[See reply to John Hampden in Answers to Correspondents.—ED.]

"KNOWLEDGE," TECHNICAL TERMS, SCIENCE, AND RELIGION.

[46]—I have been very much pleased with the first two numbers of KNOWLEDGE. If the forthcoming numbers be as good as Nos. I. and II. promise, you will supply a great want, and deserve an equally great popularity. I have done what little I can to advertise it, by placing it in our school reading-room, and by sending it by post or otherwise to various friends.

I had intended to suggest what "A.T.C." has mentioned, the advisability of printing the technical terms side by side with the more popular modes of expression; by this means a double education would be carried on.

I congratulate you upon your article maintaining the harmony, real if not apparent, of the teachings of science with revelation, and your remarks on the wickedness of neglecting to use the minds God has given us in the study of the "outward and visible signs" of His power. Your article must, I feel sure, have given great pleasure to many whose belief in evolution is no less devout than their belief in revelation. Would that all our religious instructors could act in the spirit in which you intend to conduct KNOWLEDGE. With every wish for your success, which I shall do all in my power to promote,

I am, yours, &c.,

J. JOHNSON HOYLE, B.A.Lond.

[Have omitted remarks relative to some of the questions in No. I., though fully agreeing with you.—ED.]

INFLUENCE OF SEX ON MIND: CRANIAL CONTOUR.

[47]—To say woman's skull is less than man's is ambiguous and misleading. Of course, it is *absolutely* less, otherwise woman's head and body would be disproportionate. I think male and female skulls relatively equal. Artists divide the male figure into eight heads, and the female into seven and a half. Grant, then, the female skull relatively somewhat larger than the male. "The brain diminishes and the nerves increase from man downwards; in the fœtus and child, the nerves are proportionately larger than in the adult." (Lawrence: "Lectures," chapter vi.) Walker states that the nerves connecting the brain with external organs of sense are comparatively larger in woman than in man. The eyes excepted, external organs of sense are smaller in woman than in man. Does anatomy support Walker's statement? If so, it helps to explain observed fundamental differences in male and female intelligence. Woman is perceptive; man reflective. Woman excels in sensibility and observation. Man is a being of the intellect; woman of instinct and emotion. Man reasons and reflects; woman perceives and feels. Man is active; woman passive. To man belongs the kingdom of the head; to woman the empire of the heart. Chamfort epigrammatically says:—"Woman has a cell less in the head, a fibre more in the heart."

The sexes cannot exchange sovereignties. Women is less guided by intellect than by feeling and impulse. Her movements are more

easy and prompt, though less sustained, favoured by ready obedience of muscular action and short stature. She is less combative than man. (This rule has serious exceptions.) She desires to please. Man's mission is to protect and defend. Her disposition to sustain mental and bodily exertion is much less than man's. She is fonder of change, and more fluctuating in opinion. *Varium et mutabile semper fœmina. La donna è mobile qual piuma al vento.* Not by her understanding or mental force, but by her prompt and easily-affected sensibility, is woman eminently adapted to surmount maternal suffering; through affection and pity, to be interested in children and household cares. Where her heart is touched, a woman will make incredible sacrifices for a lover, a husband, a child, a parent. She is constitutionally fitted to be wife and mother, to "guide the house," for minutiæ of details. A girl of sixteen makes a better housekeeper than a man of sixty. Woman is more sedentary than man. Her disposition is milder. She is less addicted to great crimes.

Woman's face resembles the child's in absence of beard, rounded form, smooth skin, and brilliant complexion. The infantile type of head appears in smallness of features relative to skull, and perpendicular forehead. Welcker says, woman displays orthometopy (perpendicular forehead) and a decided tendency to prognathism. I have seen both combined in the same skull, though a retreating forehead and projecting jaws generally go together; and orthometopy generally accompanies orthognathism. Camper's facial angle is a very uncertain measure of intelligence; according to it alone, the child would stand higher than the man. "If skulls are ranged according to Camper's angle, the infant's skull, contrasted with any animal's, occupies a higher place than the adult's; but if skulls are ranged according to the increasing angle of the sella, the series stand—man, woman, child, animal." (Welcker.) A front view of head and face is well defined by the outline of an egg. The big end represents the skull, the small end the chin. The egg's short diameter gives the position of the eyes, which bisect the oval. If in man, the part above be greater than that beneath the eyes, it is not objectionable, because we associate this excess of coronal elevation with intellectual qualities characteristic of sex. In woman's head, a similar excess in the superior region is a fault in beauty, for which the masculine qualities corresponding to this head-type do not compensate. Ancient Greek sculptors perfectly understood this important distinction in the cranial contour of the sexes. The female head contrasts well with the lofty, massive square brows of male heads. Of the Venus de Medici, Walker observes:—"The size of the head is sufficiently small to leave that preponderance to the vital organs in the chest, which makes the nutritive system peculiarly that of woman. This is the first and most striking proof of the profound knowledge of the artist, the principles of whose art taught him that the vast head was characteristic of a very different female personage. Phrenologists have told us that the head of the Venus is too small. They might as well have said that the head of Minerva or the Jupiter is too large, or a hundred other ignorant, inapplicable, or ridiculous pedantries" ("Analysis of Beauty"). The Gradgrind utilitarian school depreciate the fine arts. Independently of intellectual pleasure, what actual knowledge in these masterpieces! Ancient sculptors could learn nothing of beautiful forms from phrenologists. The latter may learn much from ancient sculptors of the influence of sex on mind.

Nov. 14. J. McGregor Allan.

SPEED OF ICE-YACHTS.—THE FIFTEEN PUZZLE.—CHEAP TELESCOPE AND MICROSCOPE. — TECHNICAL TERMS RELATING TO TELESCOPES.

[48]—There are two things in last week's Knowledge that I wish to mention to you:—1. In explaining the ice-yacht, you say the parallel wind HG (diagram) will increase the yacht's velocity, *which already exceeds that of the wind.* It seems to me that you do the very thing which you take exception to "Upsilon," doing, viz., take it for granted; but, perhaps, I may have missed your meaning.

The other thing (2) is the "Fifteen Puzzle." I am sure many of your readers would like, as well as myself, to hear more of this puzzle; what "the true won position" means; in fact, to explain what the puzzle means, as I candidly confess I have never heard of it before.

There is another matter I wish you would help me in. For some time past I have wished to become the possessor of a telescope and a microscope, but have not been able to see my way to doing so. I could afford to give about £5 each in purchasing them. With regard to the microscope, my ambition is to take, were it years hence, a degree, both in surgery and medicine. I know that a monocular is best suited for histological work; but I should like the time that I would spend at the microscope to materially serve me afterwards. Which should I purchase, a binocular or monocular? Could I get one to serve my purpose for £5, or would I require to pay more? Then, as for the telescope, I am puzzled at the various technical terms used in the magazines I come across, for instance:—(1), Equatorial telescope; (2), astronomical telescope; (3), terrestrial eyepiece; (4), reflector; (5), refractor; (6), 11-inch achromatic; (7), $6\frac{1}{3}$-inch object-glass; (8), $9\frac{1}{3}$-inch mirror; (9), altazimuth stand; (10), equatorial mountings and divided circles, &c. I shall feel obliged if you will tell me what to purchase and WHERE. I should like one that would do some good work for me, and repay me the cost in knowledge obtained. I may add that I have done my part by getting you another subscriber, and I sincerely wish Knowledge success.—Yours, &c., Twenty.

[The explanation at p. 36 shows that there remains a driving wind whose velocity is represented by HG when the yacht's velocity is represented by CE, or is greater than that of the actual wind FE. *A fortiori*, there is a driving wind for all smaller velocities. Starting from rest under the action of a wind in the quarter represented by FE, the yacht will travel with constantly-increasing velocity until the driving force is just balanced by frictional resistance, and it is shown at p. 36 that even when a velocity exceeding that of the wind has been attained, a driving wind remains, which may be quite sufficient to do more than merely maintain the speed attained. Suppose, for instance, that FE in Fig. 2, p. 36, represents a 40-knot breeze, then HG represents (it will be found, on measurement), a six-knot breeze. Now, an ice-yacht moves freely from rest under a six-knot stern wind, so that the velocity of the ice-yacht under the conditions illustrated in Fig. 2 would still increase, though CE corresponds to a velocity of more than 50 knots per hour.

I supposed every one knew the Fifteen Puzzle. It consists simply of a square space, within which are placed, first, sixteen square blocks, numbered in order from 1 to 16. Block 16 is removed. The rest are placed in any random position within the square space; and the puzzle is, by sliding the blocks successively into the vacant square which remains after each sliding motion, to get them into the order shown in the adjacent figure. A prize is said to have been offered in America to any one who should bring the blocks into this position—called the won position—starting from a position differing only from the "won position" in having the three blocks in the fourth line arranged 13, 15, 14, instead of 13, 14, 15 (a position which has been called the "lost position"), and thousands wasted hours on hours of their time in the attempt to do this impossible thing. Some said they had done it, but were assuredly mistaken. Others thought they had satisfied the conditions of the problem by getting some such arrangement as these:—

1	2	3	4
5	6	7	8
9	10	11	12
13	14	15	

	1	2	3
4	5	6	7
8	9	10	11
12	13	14	15

4	8	12	
3	7	11	15
2	6	10	14
1	5	9	13

But the true won position never can be obtained from the lost position. The problem, however, like squaring the circle, trisecting an angle, duplicating the cube, and finding the perpetual motion, has had a singular charm for many, and especially for those to whom the word impossible is as a red rag to a turkey.

The question relating to telescopes and microscopes I must leave others to answer; I have never possessed a £5 telescope, and have but little idea what an instrument can be made to do at that price.

The technical terms mentioned by "Twenty" are no more mysterious than the terms binocular (for two eyes), and monocular (for one eye), which he uses himself. An astronomical telescope is one which shows objects inverted (avoiding the loss of light which results from use of lenses for making the object appear upright); a terrestrial eye-piece is the tube (next the eye) containing such lenses; it is sometimes called an erecting eye-piece; an equatorial is one which, instead of turning round on an upright axis, and moving upwards and downwards round a horizontal axis, like ordinary terrestrial telescopes, is carried round an axis directed to the pole of the heavens, moving also on another axis, so as to be inclinable at any angle to the polar axis; and so forth. But any guide to the use of the telescope explains these points. We may presently publish in these pages some simple papers on such matters.—Ed.]

Queries.

19.—Comparative Anatomy of Birds and Animals.—Can you kindly tell me through your paper the corresponding bones in man and other mammals to the furcula of birds? I have consulted all the books to my hand, and cannot find out. Wishing all success to your interesting paper.—Charles Sherborn.

[20]—Orrery.—Can you or any of your readers kindly inform me where an Orrery can be seen?—Vulcan.

[21]—Deep-Sea Soundings.—Could you tell me where I can find an account of "Deep-Sea Soundings" taken off the coast of New Guinea?—Stanhope T. Speer.

[22]—Fomalhaut.—Is this visible in England at about 9 p.m.? My little daughter having decided, by a study of your star maps, in the affirmative.—Stanhope T. Speer.

[Yes, it is the star α, in constellation Piscis Australis, shown near the south-west horizon in map illustration No. 2.—Ed.]

[23]—Faure's Accumulator.—Would the editor oblige a reader of Knowledge by stating how De Faure's battery for the storage or accumulation of electricity is constructed, or in what publication such an account is to be found?—Nameless.

[24]—Dreams.—What position does science take on the subject of dreams? Does it deny positively that dreams ever have been sent as warnings, or that the warnings which dreams have apparently conveyed have ever been fulfilled except by accident? I have seen it stated that faith in dream warnings is as much out of date now as faith in astrology. Yet many accounts which have been given of dreams which have been apparently fulfilled, seem scarcely to be explained away so lightly.—A Dreamer.

[25]—Forms of Food.—Would not a short article, explaining the meaning of some of the terms used in Dr. Carpenter's interesting article on the "Relation of Food to Muscular Work," be of great use to many whose studies have not yet shown them the real meaning of such words as hydrocarbons, non-nitrogenous, and so forth?—Desdichado.

[26]—Training.—It seems to me that it would follow from Dr. Carpenter's theory of the "Relation of Food to Muscular Work," that the system of training followed by our athletes is unsound. Ought we not to return to the system of the ancients, who trained their athletes on barley cakes and oil?—Oarsman.

[27]—Effects of Marriage on the Death-rate.—I should be glad if the editor of Knowledge, or any reader who can give the desired information, could tell me how far it has been made out, or whether it has been made out, that marriage acts as a preservative. Is the death-rate of the married lower than that of the unmarried?—Benedict.

[28]—Stone on Rolling Wheels.—A long stone is rolled forward on wheels 2ft. in diameter, or say 75in. in circumference. There is no sliding. How far does the stone advance for each revolution of the wheels on the top of which it rests? A mathematical friend says the stone advances 150in.; but I cannot see how it can advance more than 75in.—Queensland.

A New Comparison of Poisons.—Comparative experiments with different poisons have often been made by injecting a given quantity of each into the veins of animals, and noting the effects. M. Richet has recently tried another method (which offers some advantages)—viz., poisoning the medium in which the animal breathes. If a fish be put in a poisonous solution, it dies sooner or later, according to the concentration of the poison. M. Richet adopts as the "limit of toxicity," the *maximum* quantity of poison (referred to one litre of water) allowing a fish to live more than 48 hours. This limit he has determined for various metals, always using the same acid radical—viz., chlorides. The limit of toxicity was calculated, not per weight of chloride, but per weight of combined metal. The figures show that there is no precise relation between the atomic weight of a substance and its poisonous power. Copper is 600 times as poisonous as strontium, though its atomic weight is less. Lithium, with an atomic weight only the twentieth of that of barium, is three times as poisonous, &c. Even with metals of the same family, no relation between the two things was discoverable. Cadmium (112) is only about half as poisonous as zinc (65); lithium (17) is 70 times as poisonous as sodium (23), &c. Nor could any relation be made out between the chemical function of a body and its toxical power. Thus, potassium and sodium, the chemical properties of which are so similar, have very unequal toxicity; one gramme of potassium is nearly 250 times as poisonous as one gramme of sodium. M. Richet means to prosecute the subject further.—*The Times.*

Replies to Queries.

[1]—Ultima Thule.—In answer to Query No. 1 in Knowledge, Nov. 11, "Alpha Sigma" will find "Ultima Thule" mentioned in Virgil's "Georgics," Bk. 1, line 30, in the sense of some remote country.—G. R. F.

This query is answered in a similar way by many correspondents.]

[1]—Ultima Thule.—The following account is given by Lemprière in his "Classical Dictionary":—"Thule, an island in the most northern parts of the German Ocean, to which, on account of its great distance from the continent, the ancients gave the epithet of *Ultima*. Its situation was never accurately ascertained, hence its present name is unknown by modern historians. Some suppose that it is the island now called Iceland, or part of Greenland, whilst others imagine it to be the Shetland Isles. *Stat.* 3. *Sylv.* 5, v. 20.—*Strab.* 1.—*Mela*, 3, c. 6.—*Tacit. Agric.* 10.—*Plin.* 2, c. 75, 1, 4, c. 16.—*Virg. G.* 1, v. 30.—*Juv.* 15, v. 112.—*Solin.* 20.—*Servius ad Virg. loco. cit.*—W. E. M.

[2]—A Fifteen Puzzle.—It is easier to solve the Fifteen Puzzle than to give the demonstration for which "Rusticus" seeks. The solution is as follows (or at least this is one solution): Let the fifteen girls be called A, B, C, &c., down to O, then the seven arrangements are these—

ABC	ADE	AFG	AHI	AJK	ALM	ANO
DIJ	BFH	BIK	BJL	BMO	BND	BGE
EFL	CKM	CLN	COE	CDF	CGI	CHJ
GKO	GJN	DHO	DGM	EIN	EHK	DKL
HMN	ILO	EJM	FKN	GHL	FJO	FIM

It is very easy for nine girls to go out on four days. The arrangement runs thus—

ABC	ADE	AFG	AHI
DGH	BFH	BDI	BEG
EFI	CGI	CEH	CDF

Mathematicus.

[4]—The Earth's Inclination.—Were the Earth to rotate on an upright axis, the greatest amount of heat would always exist at the equator, while the least would be at the poles. At all points of longitude between, the heat would be in proportion to the distance from the equator. I would express it so: perpetual summer would reign at the equator, as the sun would be always vertical to some point there, and perpetual winter at the poles, as the sun would always be on the horizon.—L. T. F.

[5]—Hot Winds, Cause of.—There is usually an inrush towards hot areas, but at times the action is reversed. There is no reason why at times a sandy region, like the Desert of Sahara, should not become a region of high pressure (especially when we remember the rapid radiation of heat at night), and in that case the flow of air would be from that region to surrounding regions, the air carrying before it the heated air. Again, the heated air which has flowed upwards may descend not far from the region of greatest heat, and travel as a hot wind from the hot, sandy region.—Meteorological.

Nature's Respirator.—The season of cold, raw, damp, and foggy weather is upon us, and many will be its victims. Among other causes, the inhalation of cold, and especially of dirty, air must take a high place. Man is, however, provided with a safeguard against this danger. The double passage to the lungs through the nose and through the mouth suggests some difference in use, and this become certain when we find such a difference in the two routes as actually exists. The air passing into the lungs through the nose in quiet respiration is warmed as it passes over the lower turbinated bone, with its very vascular mucous membrane, while, as the cavity is so narrow, it is also to a great extent filtered, and in this way deprived of its two dangerous characters even before it reaches the larynx. Those, therefore, who in the cold and in the fogs wish to avoid catarrhs should be careful to inspire only through the nose. With most this will require some practice, but it will be well repaid. Some, too, will find the impure air of a London fog very irritating to the nasal mucous membrane, and thus a demonstration of the irritant properties of the suspended matter which in breathing through the mouth gets free access to the lungs may be obtained. Those who are specially anxious to preserve their voice—as preachers, singers, and judges—stand in special need of this precaution, which is as effective as it is simple, and has many and great advantages over all the artificial respirators yet invented.—*Lancet.*

ANNIVERSARY MEETING OF THE BIRMINGHAM AND MIDLAND INSTITUTE UNION OF TEACHERS AND STUDENTS.

By W. Mattieu Williams.

In the first number of Knowledge I communicated a sketch of the history of the Scientific Department of the Midland Institute, so far as the classes are concerned. But there is another element, viz., the Students' own Associations for Mutual Improvement, which is well worthy of notice and imitation.

One of these, the Institute Scientific Society, has been remarkably successful. It possesses a scientific library of no mean character, and its members read admirable papers and carry on discussions of considerable interest. Some of these papers or lectures on the Birmingham trades, written by practical workers who, at the classes, have attained sufficient scientific knowledge to discuss the philosophy of their daily avocations, supply a kind of information not easily attainable from books or the lectures of ordinary professors.

The Union of Teachers and Students, another and larger society, held its anniversary gathering on Tuesday evening, Nov. 22. The programme included a tea-party, the whole arrangements of which were conducted by the female students, without external aid of contractor or purveyor. This was followed by a meeting in the new theatre, under the presidency of the Mayor, where an address was read by the retiring President of the Union, Mr. C. J. Woodward. The subject was the history of the institute. I must not be tempted to quote any more than the following—viz., that when Mr. Rickard commenced the Penny Arithmetic Classes, he had six pupils to the first lessons. This session the attendance to the first lesson was two hundred, and there are now held every week no less than sixty-five "Penny" classes on different subjects in the central institute and its branches, besides all the other classes.

Then followed a general *conversazione*, distributed through the various class-rooms and lecture-theatres, including an exhibition of microscopes contributed by the members of the Institute Scientific Society, scientific experiments by students of the Chemistry and Physic Classes, vocal music by members of the Singing Classes, German recitations, a French play—"Un Quartier Tranquille"—by members of the Institute French Dramatic Club, with the usual social and loyal conclusion of "Auld Lang Syne" and "God Save the Queen" by everybody.

Criticism would be out of place here, and description of details possibly tedious. I need only add that the whole programme was successfully carried out.

The attendance, which commenced with 450 at the tea-party, grew to above a thousand later in the evening, *i.e.*, after working hours.

The feature to which I wish to direct particular attention is the spontaneous, self-originating, and self-supporting character of these proceedings, and of all the other doings of these student associations. They constitute what appears to me to be a most important adjunct to the classes and public lectures of the Midland Institute, and one which may be very advantageously introduced in other kindred institutions, especially those of London. One of the most shallow and mischievous of popular delusions on the subject of education is the supposing that when we have completed a certain prescribed course of study, and passed our examinations on any subject, we have completed that part of our education—the fact being that all class teaching and all book reading is but the first stage of true, comprehensive education; self-teaching, original thought, the digesting and co-ordination of such school knowledge, must follow, to render it truly fruitful, and social co-operation in such supplementary work is most desirable. The meeting of old students with their younger successors, the revisiting of the old teachers, and sustaining of the old friendships between them and their former pupils, gives vitality and moral warmth to the whole institution, prevents the possibility of that decay which too often falls upon such institutions, when their existence is allowed to depend upon the efforts of outside patrons and the beneficence of mere endowments. Besides all this, the governing body is kept justly informed of the real requirements of the students—those who have good reason to be grateful to it, and know its workings by their own experience as former pupils, remain attached to it, join in its management, and otherwise substantially express their gratitude.

The genuine enthusiasm and hard-working efforts in carrying out the evening's programme, the genial friendship and high moral tone which I witnessed as pervading all the proceedings of Tuesday's meeting, convinces me that if such unions and friendly gatherings of teachers and students, old and young, male and female, should become one of the essential elements of all our literary and scientific institutions, their general prosperity and practical effectiveness would be greatly promoted.

Our Mathematical Column.

PRACTICAL USE OF LOGARITHMIC TABLES.

Let us now take a few examples of the practical use of a table of logarithms, noting that the former paper was intended to explain all that is necessary to be known respecting the theory of logarithms. I did not then think it necessary to draw any distinction between the logarithms of our tables and logarithms to any other base than 10; for the computers who mostly employ logarithms, use the decimal notation.

Let us first take the example afforded by Mr. Harding's calculation at p. 55, noting that the result, corrected for a "printer's error," is

$$= 21{\cdot}9912 . \frac{143303}{153664}$$

We have to take out the logarithms of these three numbers. Take first 21·9912. We turn to the number 2199 in the table and run our eye to the second column above which is the next digit, 1, getting the logarithm 3422450. (The first three digits of this are shown in the first column, the other columns only giving the next four for each number). But we still have to provide for the last digit, 2. Now we might do this from the part of the tables already used. Thus they show:—

logarithm of 2·1991 is 3422450,
and logarithm of 2·1992 is 3422647, or 197 more.

Now, we see that 2·19912 is only two-tenths of the way from 2·1991 to 2·1992, so that we should add only two-tenths of 197 to the logarithm of 2·1991 to get the logarithm of 2·19912, assuming that the logarithm increases, for such small differences, proportionately with the number of which it is the logarithm—which is shown to be true by the circumstance that we have the difference 197 or 198 (*often er the latter*) for several logarithms on either side of the one we are using. Manifestly if in passing from 21990 to to 21991 and thence to 21992, 21993, and so forth, we have the same difference*, the logarithm is here growing in the same proportion as the anti-logarithm (that is, as the number of which it is the logarithm). Hence, we take two-tenths of 198 (note italicised words above), or 39·6 (the nearest whole number to which is 40), and add this to 3422450, the logarithm of 2·1991, to get the logarithm of 2·19912. Thus

$$\log. 21{\cdot}9912 = 1{\cdot}3422490.$$

But we are saved even this slight labour by good tables. All tables give the difference as 198 in our example; but in good tables there is shown on the right the table of proportional parts, giving the amount to be added for digits 1, 2, 3, 4, 5, &c., respectively, and opposite 2 is set 40, the amount to be added.

Let us proceed in the same way with 143303 and 153664. We find in the tables, logarithm 1·4330 is 1562462, the "difference" is 303, and 3-10ths of this are 91, which added to 1562462 gives us

$$\log. 143303 = 5{\cdot}1562552.$$

Again, we find in the tables, logarithm of 1·5366 is 1865608, "difference" is 283, and 4-10ths of this are 113, which added to 1865608 gives

$$\log. 153664 = 5{\cdot}1865721$$

Thus, according to the principles on which logarithms are used, our "sum" is worked thus:—

$$\begin{aligned} \log.\ 21{\cdot}9912 &= 1{\cdot}3422490 \\ \log.\ 143303 &= 5{\cdot}1562552 \\ \hline \text{Sum} &= 6{\cdot}4985042 \\ \log.\ 153664 &= 5{\cdot}1865721 \\ \hline \text{Difference} &= 1{\cdot}3119321 \quad [=\log.\ 20{\cdot}508]. \end{aligned}$$

We now turn to the tables, and looking first along the left hand column of logarithms (next to the column of numbers) for the part 311 of the logarithm we have found. This comes next the number 2047, but running along this part of the tables for the remaining part, 9321, or what comes nearest to it, we find it opposite 2050 under the ninth column, corresponding to digit 8 (shown at the top of this column). The logarithm given here is 3119233 while that next larger is 3119445; the former is nearest to the logarithm above obtained, 3119321. Thus, if we are content with this degree of approximation to the result we want we write down 20508 as the digits representing that result, but as in the bracketed part of above computation we set the decimal point after the *second* digit, because our logarithm has 1 on the left of the decimal point. As a matter of fact, it would be absurd not to be content with this degree of approximation, simply because we cannot get more out of the

* The same difference, for though the actual difference alternates hereabouts between 197 and 198, this is only due to the circumstance that the last digit has to be the *nearest* to the true value, and cannot represent the exact value.

numbers we are using. Having 21·9912 correct only to the last place but one (the real number runs 21·991485, &c.) our result cannot be correct to a greater degree of approximation. Therefore, we set down only the third decimal figure.

If, however, our *data* would allow us to take more out of our logarithmic result than what was *put in* would permit, we could easily do it. Thus:—

log. of result = 1·3119321
log. of 20·508 = 1·3119233

Difference = 88

But we see from the tables that difference between the logarithms to 20509 and 20508 is 212, so that we must add to 20·580 $\frac{88}{212}$ ths of ·0001, or ·00088 divided by 212, or ·00012, making our answer 20·50812.

But it may be said all this is very long and complicated: might one not as well multiply 21·9912 by 143303 and divide the product by 153661. It will be found, however, that with a little practice it takes but a few moments to take out a logarithm, or to find the number corresponding to one. A few points have to be carefully attended to, which we shall discuss with further illustrations of more difficult examples in our next.

Our Chess Column.

LEAVING to next week the further analysis of the "Two Knights' Defence," we give this week an illustrative game in that opening, and a singularly pretty end-game which occurred in actual play with "Mephisto."

GAME No. 2.

Played by "Mephisto" and Mr. Marriott, of Nottingham.

Two Knights' Defence.

White. Mr. M.	Black. "Mephisto."
1. P. to K.4.	1. P. to K.4.
2. Kt. to K.B.3.	2. Kt. to Q.B.3.
3. B. to Q.B.4.	3. Kt. to K.B.3.
4. P. to Q.4. (a).	4. P. takes P.
5. Castles (b).	5. Kt. takes P. (c).
6. R. to K.sq.	6. P. to Q.4.
7. B. takes P.	7. Q takes B.
8. Kt. to Q.B.3.	8. Q. to K.R.4.
9. Kt. takes Kt.	9. B. to K.3. (d).
10. Kt. to K.Kt.3. (e).	10. Q. to Q.4.
11. B. to K.B.4.	11. Castles.
12. R. to Q.B.sq.	12. B. to K.Kt.5.
13. Kt. to K.4.	13. P to K.R.3.
14. P. to K.R.3.	14. B to R.4.
15. P. to Q B.4.	15. Q to K.B.4. (f).
16. Kt. to K.Kt.3.	16. Q. takes B.
17. Kt. takes B.	17. Q to K.B.4.
18. Kt. to K.Kt.3.	18. Q. to Q.2.
19. Q. to Q.R 4.	19. P. to K.Kt.3.

43. P. to Q Kt.5.	43. Q R. to K.2.
44. P. takes R.P.(ch.)	44 K. to R sq.

White resigns.

NOTES BY "MEPHISTO."

(a) Although, strictly considered Kt. to K Kt 5 is the stronger move, P. to Q.4 nevertheless gives the first player a good attacking game; it mostly leads to interesting variations of the Giuoco piano kind.

(b) If, instead of 5. Castles, White plays 5 P. to K 5, the game is transformed into a Giuoco piano. Black replies with 5 P. to Q.4, and by proper play he will withstand the subsequent attack of White, and retain the Pawn.

(c) If, instead of 5. Kt. takes P., Black plays 5. B. to Q B.4, then we have the Giuoco piano variation known as Max Lange's attack, from the name of its author, in which White again proceeds with P. to K.5, as before.

(d) 9. B. to K.2 is given as best for Black, but we prefer the move in the text.

(e) Here 10. B. to K Kt.5 is given by the books, with the object of preventing Black from Castling, if then P. to K.B.3, B takes P. The move in the text, however, shows a steady determination to attack the Queen's side, as shown in his 11th and 12th move.

(f) 15. P. takes P. *en pass.* would have been correct; Black had nothing to fear from White's attack; *e.g.*, if, instead of Q. to K.B.4, 15. P. takes P. *en pass.* 16 $\frac{\text{Q takes Q.}}{\text{R. takes Q.}}$ 17. $\frac{\text{Kt. takes P.}}{\text{B. takes Kt.}}$ 18. $\frac{}{\text{P. takes B.}}$ (if Kt. takes R. then B. takes Kt. with a far better game). 18. $\frac{\text{R. to K.B.4}}{}$ 19. $\frac{\text{R. to K.8 (ch.)}}{\text{K. to Q.2}}$ 20. $\frac{\text{R. to K.4.}}{\text{P. to K.Kt.4.}}$ with a good game.

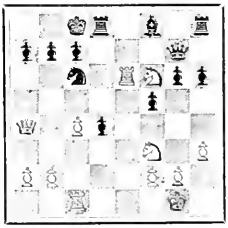
(g) This is weak. Black, by P. to K.Kt.3, tried to prevent the entry of the Knights into his game. The move in the text allows the Knight to play to K.B.6, and, if so inclined, afterwards to the commanding position on Q.5. Black ought to have played 20. B. to K.2, in order to prevent this, followed, perhaps, by P. to K.B.4.

(h) 21. Q. to K.B.2 was the correct move. White would then have obtained a very fine game by playing his Kt. to Q.5, followed by the advance of the Queen's Pawns.

(i) This is a very fine move, and initiates a combination belonging to the highest order of Chess play. We give a diagram of the position.

Position after White's 22nd move.

Black.



White.

(j) The position is one of great difficulty for Black. If Black plays 22. $\frac{}{\text{Q. to K.B.2}}$ 23. $\frac{\text{R. takes Kt.}}{\text{P. takes R.}}$ 24. $\frac{\text{Q. to R.6. (ch.)}}{\text{K. to Kt.sq.}}$ 25. Kt. to K.5 winning.

(k) In reply to 25. R. takes Kt. instead of Q.R. takes B. Black would play 25. B. takes Kt.

(l) The only move to save the game. If, instead, Kt. takes Kt. (ch.), with the idea of winning another piece, then Black loses his Queen, *e.g.*, 26. $\frac{}{\text{Kt. takes Kt. (ch.)}}$ 27. $\frac{\text{P. takes Kt.}}{\text{P. to B.3}}$ 28. $\frac{\text{R. takes P. (ch.)}}{\text{P. takes R.}}$ 29. $\frac{\text{Q. takes Q.}}{}$; whilst the move in the text wins.

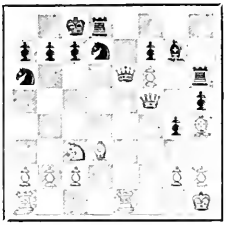
(m) White still tries for a favourable chance by pushing his Queen's Pawns on to the Black King, which plan Black, however, frustrates by forcing the exchange of Queens.

(n) Played to stop the advance of the Knight's Pawn; the Pawn cannot be captured, as, after P. takes P., and R. takes P., White plays Kt. to K.5.

(o) Threatening to Queen or win a piece if Kt. takes P.

Ending which occurred in an actual game played by "Mephisto" on Nov. 15, 1881, at 18A, Regent-street.

AMATEUR.
BLACK.



WHITE.
MEPHISTO.
Black to move.

White. MEPHISTO.	Black. AMATEUR.
. . . . .	1. Q. takes Q.
2. P. takes B.	

This fine move, as will be seen, wins the game. If White had played, B. takes Q. instead, then B. takes P., would give Black the better game.

2. Q takes B.

Best! for if the Queen should retire on B.4. or R.4., then White would play B. takes R., and his Pawn on Kt.7. could not be prevented from Queening, which would leave White with a Rook ahead and a winning position.

3. B. takes R.

This again is right, as will be seen

White.	Black.
	3. Q. to R.2.
4. R. to K.8. (threatening mate).	4. Kt. to B.3. If Black plays 4. P. to Kt.3. then White Queen's.

If White would play 5. B. to Kt.5, discovering check, and on the Black King moving to 5. Kt.2. 6. B. takes R. 6. Kt. to B.3. (best.) 7. R. to R.sq. 7. Q. to B.4. 8. Kt. to K.4. 8. Q. takes Kt. 9. B. to Kt.5. 9. Kt. to Kt.sq. (best.) Q. to R.; and White would have a very unsatisfactory game.

White.	Black.
5. B. takes Kt. ch.	5. K. to Q.2.
6. Q.R. to Q.sq. (ch.)	6. K. to B.3. (If K. takes R. 7. R. to Q.8. mate.)
7. R. to K.R. 8.	7. Q. to Kt.3.
8. R. takes R.	8. Q. takes R.
P. Queen's	Q. takes B.

And White mated in two moves.

CHESS QUERIES.—[2]—A few errors occur on page 20 of KNOWLEDGE which may confuse young chess-players, viz.:—*Game No. 1*: White's 17th move should be Kt. to Q.2; Black's 31th move should be R. to Q.R.5. *In Notes to Game No. 1*: (b) White's 18th move should be P. to Q.6; variation A, Black's 19th move should be B. to R.2; (l) White should be if K. to Kt. 3; (n) This note I do not understand; *In Notes on "Chessikin"*: Black's 7th move should be Q. takes R.P.(ch.); Black's 8th move should be K.Kt. takes P.—WHITE PAWN.

[3]—I beg to call your attention to what I think is an error in Mephisto's note (g), KNOWLEDGE, No. 1, page 20. Having 16. $\frac{\text{B. takes P.}}{\text{B. takes K.B.P.,}}$ it says if White takes B. Black would win his Queen by P. takes P. should this not be R. takes Q.?—Yours, G. N. SHERBORN.—[Mr. Sherborn misunderstands Mephisto's note. It is at move 15 that White cannot take B. Of course, if White played 16. B. takes B., Rook would take Q.—CHESS EDITOR.]

BLACK PAWN.—Your game is very interesting, and shall appear, with some additional notes.

ILL-HUMOUR.—A great deal of what we commonly call ill-humour springs from the ill-conditioned state of the body. We familiarly talk about people "rising from bed on the wrong side," and there is a very suggestive meaning in the phrase. They may have been sleeping all night in a very badly-ventilated room, or have gone to bed after taking a heavy and indigestible supper. The consequence is, that in the morning, from want of pure oxygen, or from overloading the stomach, the whole organism is out of order, the nerves are on edge, and they rise fretful and impatient, and continue so throughout the day.—Paterson's "Health Studies."

Our Whist Column.

By "FIVE OF CLUBS."

SO soon as we have accepted the general principle that in whist each player is to consider his partner's hand as well as his own, and that for this purpose each must inform his partner by every legitimate means of the nature of his own hand, we are at once able to decide on the proper way of conducting whist strategy. Were it otherwise, the first consideration of each player would naturally be the nature of his own hand. He would play so as either to make all his strong cards at once, or to adopt the course which seemed to him best for making them in the long run. If he had a short suit, he would try to get rid early of the cards of that suit, in order presently to trump the remaining good cards of the suit. And he would play his trumps solely with the object of making as many of them as he could. If every player followed such a course as this, the fortunes of the different hands would run very much as they do with good play, but the game would not be whist. It would be simply a chance game, each player's success depending on the number of good cards which happened to fall to his share, or on the fortuitous occurrence of short suits with opportunities for trumping them. The advantage of the scientific game is that it requires skilful strategy, and calls into action many useful faculties.

To tell my partner anything about the constitution of my hand, I must in the first place follow a systematic and generally understood method of selecting a suit to lead from, and, in the second place, I must open a suit so selected in the correct way.

Now, considering first the selection of a suit, we note that there is only one quality which, being common to all hands, can be adopted for systematic guidance. A player tells his partner nothing useful by playing out his good cards, even if he made the best use he could of them for himself by showing them at once. Leading from a short suit again is not only bad in itself—especially the atrocious lead from a single card which young players affect.—but it is not a method of leading systematically available, for not every hand possesses a suit of fewer than three cards. But every hand must possess a suit of four cards, at least—that is, a long suit. If, then, for no other reason, still for this, that, by so opening the hand, partner learns that one holds four, at least, of that suit (save in a few exceptional cases), the long suit would be a good one to lead, if that were always understood to be the meaning of the lead. But, apart from this, there is a manifest advantage—other things being equal—in leading from the long suit. This suit always has an element of strength, even though every card be small. Suppose, for instance, I have 2, 3, 4, 5 of a suit, an opponent have Ace, King, Queen, and the remaining six cards equally divided between the other players. Then, though we by no means advise a lead from 2, 3, 4, 5, if the holder of Ace, King, Queen drew three rounds, I should remain with 5; and, when trumps are drawn, that small card, if I get a lead, is as good as a trump; or, if I obtain a lead before all the trumps are drawn, that small card would either make a trick or draw a trump from the enemy as well as an Ace or a King. By leading from a long suit, and getting that suit so far exhausted that I have commanding strength in it, I secure an element of strength for my hand which comes next in efficiency to strength in trumps.

For the double reason, then, first and chiefly that in that way I can tell my partner the chief constituent of my hand; secondly, that by so playing I am likely to strengthen my hand, my first lead should be from my longest suit.

Of course, this rule, like all rules relating to a game so varied and complex as Whist, is not without exceptions.

I showed just now that a hand of four very small cards has a certain element of strength, which is wanting in a suit of the three highest cards; yet the latter has, of course, the greater strength. If you have two suits thus constituted, one long, but very weak, the other a three-card suit of great strength so far as the individual cards are concerned, you would be showing your partner best the chief constituent of your hand by leading from the shorter very strong suit, than by leading from the other. But a three-card suit must be very strong, or a four-card suit very weak, for the former to be preferred in this way. There are several reasons for this, besides the general reason that long-suit leads, followed systematically, instruct the partner best. A suit which is short with you is likely to be long with one or other of your opponents; and, if so, you are playing their game by leading it. Again, commanding cards of a short suit are more useful as cards of re-entry, that is to give you a lead later in the game, than they can possibly be if used early in the play of the hand. If your long suit is very weak, your partner will very soon find that to be the case, and by showing you where his strength lies, can serve your game, as a rule, better than you can serve his by opening a three-card suit, unless it be of absolutely commanding strength.

I — WHIST QUERY.—I have read your introductory article on Whist in this week's KNOWLEDGE, and was much interested by its good sense, but allow me to point out to you what seem to be two errors in the only illustration you give. You say, "I lead Ace, and follow with Queen of my best suit. My partner knows that I have the Knave and a small card left." This is by no means a necessary inference. It is a necessary inference, according to the best play, that the leader has not Ace, Queen, Knave, to five; and the play would be proper if he had Ace, Queen, Knave, to four; but he may equally have Ace, Queen, Knave alone, in which event he would also play Ace, followed by Queen.

You say also (and for this purpose I must assume the leader to have Ace, Queen, Knave, and a small one, and the partner to have King and two small ones, as in your illustration), "suppose that instead of following the recognised line of play for such cards, I lead the second round with my small card. My partner plays his King, and, let us suppose, wins the trick. So far as he can understand me at all he thinks I have three small cards of the suit left, and that the Queen lies with one of the adversaries." It is true that the lead would have simulated a lead from five, but why is it a necessary inference that the Queen is not with the leader. It is the commonest thing at Whist to lead from Ace, Queen, to five, Ace and then a small one. The only inference a partner from such play could draw (as the leader ought not to have both Queen and Knave, is that one or the other of these two cards was with one of the adversaries. Excuse my pointing out to you what seems to me to be worth your re-considering, if you ever collect your article for re-publication. I am, yours, &c.

FRED. H. LEWIS.

[Our correspondent is, of course, quite right in his criticisms. What the partner of leader in the case supposed would *know*, if lead were made correctly, is only that *Knave* remains with his partner. If, subsequently, he finds that his partner has not been forced to lead from a short suit, he knows that a small card of the suit remains; but otherwise he cannot be certain of this. In the case where the play is incorrect, a small card being played after Ace, the inference would be that three cards remain, and that Queen and Knave are certainly not *both* among the three. It is two to one (nearly) that Queen lies with an adversary, but it is not certain.

"FIVE OF CLUBS."

DIXON K. Thanks; your letter being marked private, we assume you do not wish your remarks in *Field* to be touched on here.—MARTIN HINTON. See reply below to "Old Christian," in so far as they relate to the general subject on which you have written.—M. B. ALDER. Later.—J. C. H. W. You ask whether the remark of Huxley's, quoted at p. 4, is not incompatible with his views as a materialist. Of one thing you may be well assured—it represents his real views. Prof. Huxley's views as a materialist are indicated in his admirable lecture on Descartes' "Discourse." He says there: "When the materialists stray beyond the borders of their path, and begin to talk about there being nothing else in the universe but Matter, and Force, and Necessary Laws, and all the rest of *their* grenadiers, I decline to follow them." Perhaps if you carefully ascertain what *are* Prof. Huxley's views as a materialist, you may find them to be less inconsistent than you suppose with his opinion on "True Science and True Religion."—JOHN HAMPDEN. We are quite "aware that you take a position antagonistic to all the professional astronomers and geographers of the present day." We are not, however, "disposed to earn the everlasting gratitude of the upholders of the Newtonian theory by showing the impropriety of" your "charges against it." You say "if the professors are too cowardly to defend their own system, they are not competent to write upon any subject." When the Newtonian system needs defence, it will be time enough to undertake the work. How could reasoning avail with the followers of Parallax? They believe that the earth is shaped like a flat wheel about 25,000 miles in diameter, and that the sun travels in a path always parallel to this flat disc, and some 4,000 miles above it. On a spring or autumn day the sun's path, they tell us, is appreciably a circle, vertically above the equatorial circle, from which circle no part of the flat earth is more than 6,250 miles away! Reasoning would be thrown away on any one who could even for a moment imagine this to be the case. Repeatedly they have been shown what should be perfectly obvious—that, were this the case, (i) the sun could never set; (ii) that he would vary greatly in apparent size as seen from different places, or from the same place at different hours, or on different days; (iii) that all the phenomena of the heavens would be entirely different from those we see; (iv) that there could be but one pole of the heavens, and that many other consequences would follow which are utterly unlike any actually observed. Their answer to this has always been simply vituperation and abuse of those who happen to possess some reasoning power. It would be utterly contrary to the dictates of common sense to find room for any arguments against the absurdities of Parallax and his followers, in any journal intended for sensible beings. We will not insult our readers so grossly. To yourself personally, as undoubtedly believing what you profess to believe (incredible though such credulity may seem), we would remark (though the rudeness of many of your letters would justify absolute silence on our part) that the phenomenon which you said we should never see—viz., the sun to the south of the east and west points—in Australasia, we saw repeatedly, and that on every day the sun moved in the southern skies precisely as he should move on the accepted theory, and as he never could move were the theory of Parallax true. But we must ask our readers' forgiveness for making so unnecessary a statement, even in this corner of the paper, and in the smallest type our printers use.—LOMBARDIAN. We know of no Woman's Rights Association. There is a Society for the Protection of Women and Children, Secretary, Rev. J. G. Roberts, 85, Strand.—J. J. G. Portions of your letter appear in the "Correspondence" columns.—B. H. T. (F. C. S.) Thanks for your encouraging note.—W. C. T. Have not yet seen the work you mention. Doubtless the communications you promise will be of interest to our readers.—G. G. I can well believe it.—H. AMBROSE SMITH. The article on the Fifteen Puzzle to which you refer appeared in the *Gentleman's Magazine*, but the date and number of the magazine we do not know. It must have been some time last spring. We were in Australia when the article was written. It forms one of a series of "Familiar Science Essays," which Messrs. Chatto & Windus are about to publish.—M. Y. W. One tail omitted in engraving. The editorial note at foot of left hand column of page 36 related to a letter which was at the last moment removed to make room for another relating to the November meteors. The note should have been removed too.—G. G. D. and L. T. F. Your replies to "Tyro's" query in letter 9, involve the same difficulty which has perplexed him in the text books and primers. These all speak of the axis remaining in the same direction (they all use the knitting-needle illustration also); but "Tyro" finds a difficulty, it seems, in understanding what is meant by "the same direction." The expression, "moving always parallel to itself," is equally perplexing to many beginners. Your answers are, of course, quite right.—A. HART. "To settle a dispute," we inform you that though the planets are often called stars, a star is not a planet. We do "get light from a planet;" but it is not the planet's own light; it comes from the sun, and is reflected by the planet.—A. H. SWINTON. The general idea that, after all, the sun's heat may be some form of electricity, without confirmation by facts or reasoning, would hardly justify us in publishing so long a letter as yours.—AN OLD CHRISTIAN. With some regret, we find ourselves obliged to decline publishing your letter on science and religion. So far as we are concerned, we should have been glad to do so, because it chiefly relates to our own remarks on the same subject. But you emphasise the differences which you believe to exist between "the notions of modern scientists, and the plain statements of the Bible," and we emphatically decline to discuss the question whether such differences even exist. We are only concerned here with the question whether scientific statements are correct or not. Any scientific opinion expressed in these pages you are free to oppugn on scientific grounds. When you find a line here suggesting the opposition of scientific opinions, sound or otherwise, to any religious opinion whatsoever, then—and not till then—you, or any man, may express or defend religious views in these columns. "In such a then, I write a never." To use the words of Professor Huxley, "Science and Philosophy, within the range of which lie all the topics on which we can venture to speak here, are neither Christian, nor un-Christian, but are extra-Christian." I entirely agree with you that "no intelligent Christian" (or Buddhist, or Mahometan, you might have added) "can raise an objection to modern science on the ground that it enlarges unduly our ideas of the vastness of God's domain in space, or of the immensity of the time periods during which He acts;" but the objections raised by many well-meaning persons to modern scientific teachings amount in effect to this. They do not see that to believe in the evolution of a solar system or of a system of such systems, no more amounts to setting the Almighty on one side in the name of universal evolution, than does belief in the growth of a plant, or even of the tiniest bud or leaflet. It may save correspondents, and it will save ourselves some trouble, to define our position precisely, which we may do as follows:—"With religion, properly so called, all the truths of science are in necessary accordance; and so far, what is taught in these pages will be essentially religious; but this journal is intended to spread scientific knowledge; and DOGMATIC RELIGION SHALL HERE BE NEITHER ATTACKED NOR DEFENDED."—BIRD'S EYE VIEW. You may be very right, but this is hardly the place for advocating your views. *Remaining letters unavoidably crowded out.*

CONTENTS.

OUR FIELDS.

By E. W. Prevost.

IT is not probable that very many of the readers of KNOWLEDGE have ever thought, when walking through the fields, how those fields came to be in the condition in which they now are; not as regards the crops which they bear, but as regards the fine powdery state of the earth, when below are only to be found hard rocks. We do not propose to enter into the question why the rocks below occupy their present position, but rather to consider some of the means whereby rocks generally have yielded, and still do yield, a material different in character to themselves, and one suited to the growth of plants. For simplicity's sake we will assign the origin of a soil to two rocks known as Granite or Trap; for although a soil is not wholly nor directly derived from these two, yet the changes, such as those experienced by granite and trap, are the same in character, though differing in degree, in whatever be the rock under consideration.

Granite, a substance produced by the agency of heat in the early geological ages, is a mixture of three different minerals—quartz, a white lustrous mineral, also known in certain forms as rock-crystal, felspar, and mica. Felspar, of which there are several kinds, is a silicate of the metal aluminium, together with the silicates of potash, lime, or soda, according to the variety of felspar. Mica appears in the form of small bright shining scales, and is a silicate of potash or magnesia. Together with these three minerals, which may be called the elements of the soil, there are always present small quantities of other substances, such as iron, &c.

The trap rocks, divisible into two great classes, called diorite and dolerite, contain soda, lime, magnesia, and potash; and phosphoric acid is also present, but not to a large extent. Here, then, we have the materials necessary for the formation of soil, but its quality is dependent not only on the composition of the minerals contained in the rocks, but also upon the proportion in which they have contributed their constituent parts. The first agency to which the disintegration of a rock is due, reducing it from the original massive condition to that of a powder, is frost in conjunction with water. Most persons must be well aware of the fact that when water freezes, it expands to a considerable extent at the moment of solidifying, and that this expansion is irresistible, the vessels enclosing the water being destroyed. This same irresistible force is continually at work during the winter, destroying the cliffs on the sea-shore and inland; for there are always a number of clefts or fissures that admit of the entrance of water, which, when the temperature is low enough, is there frozen, and in freezing expands and splits the stone; and then, if the position be favourable, this splinter from the main rock falls down as soon as the ice melts, in consequence of a rise of the temperature. Again, the alternations of heat and cold, without the intervention of water, produce rifts, because the rock, being composed of substances which are not affected to the same extent by the same rise of temperature, expands unequally, and the result is the separation of the parts from one another. It is thus that the beds of torrents, rushing down glens, are in part filled by stones of various sizes, which, raising the level of the bed at the same time by their removal from the banks, alter the character of the glen. Even before the boulders become detached from the cliff, they are subjected to a slow but sure process of destruction, for every drop of rain which beats against the bare stone has its effect in wearing the surface away. In these processes of destruction we recognise mechanical agencies: but this is not all; chemistry plays also a very important part in reducing a block of stone to powder. The rain, in falling through the air, dissolves some of the oxygen and carbonic acid gas which it contains, and then, when this rain, holding carbonic acid in solution, comes in contact with the rock, a part of the more soluble portions is dissolved. It is, therefore, evident that the rain is a very powerful destroyer of stone, in that it works in two distinct ways—mechanically, whereby the rock is powdered, and chemically, whereby a part is carried away in solution.

Now, let us see what is the result of this partial solution of an apparently insoluble material. In the case of granite, bearing in mind that there are at least three different substances present, which are firmly and solidly mixed together, simple powdering would result in a separation from one another of the quartz, felspar, and mica; and if a current of water be passing over the rock at the time, the heavier particles would be left behind and the lighter ones would be swept away. This is what actually occurs: the quartz, finally known as sand, is left behind, while the lighter particles of felspar and mica are removed; now, seeing that the water, whether rain or river, contains carbonic acid, the felspar is slowly acted upon by the acid, is decomposed into silicate of alumina, and potash, which passes into solution, while the silicate of alumina remains behind or suspended in the water, and is now known as clay. As for the mica, it is not easily affected chemically, and may either be left behind with the clay, or, if the stream be rapid, it is carried away and deposited elsewhere. Such a process as is here described explains the destruction of a rock, and the consequent formation of beds of sand and clay, which are ill-fitted for the growth of plants, and to explain this we pictured to ourselves the rock in its original position, and undergoing all the processes at one time. To account for the production of loam, it is not necessary that every process should occur at once; but rather that, firstly, the boulder, removed by frost from the main rock, should be further broken up in the bed of a stream, and the particles so produced be then carried down by the stream and deposited where the current is less swift; this deposit, in time, becomes bare of water, as the stream alters its course, and finally becomes dry land. Now our new soil is not yet fit for plants, and as it consists of particles of the

original rock, it will, if subjected to the same influences, yield the same products when decomposed; lying exposed, as it does, to the rain and air, the slow changes above described take place, and we finally have a mixture of sand, clay, potash, lime, &c. To aid this slow action, which at the present day is not yet complete, the farmer ploughs his field, which, bringing up fresh soil from below, exposes it to the air and rain. We have before stated that the fertility of a soil is dependent upon the minerals of the soil and the extent of their decomposition. If, therefore, no aid is given to the solvent action of rain by ploughing, no great amount of fertility can be expected. The variety of felspar, whether it be a soda or a lime felspar, is of great importance—the second kind, when decomposed, producing tolerably fertile land, the former not so. When mica is present in large quantities, extreme infertility is the result, and for reasons before stated. It would occupy too much space to allude to all the various circumstances productive of the various classes of soils, and we therefore proceed to account for the production of the humus, or vegetable matter, which generally gives the dark colour, for a soil destitute of humus would be of varying shades of yellow and red. It has been proved by experiment that plants can grow without humus, or vegetable mould, and we need only refer to the growth of lichens on stones, &c., as an example; therefore, the first crop which grew on the new soil, whatever that crop or its origin might be, would flourish to a certain extent, and, dying, leave its remains behind; these would render the growth of the next generation of plants more vigorous; these, in their turn dying, the supply of humus would gradually increase. It might be supposed that the formation of humus would in time become excessive, but, as a rule, this is not so, because humus gradually decomposes, and in decomposing supplies carbonic acid to the soil, so aiding in the decomposition of the minerals present. In all these changes we see the marvellous usefulness of that gas which, under certain circumstances, is so fatal to man; but here we find it as a most useful servant, for not only does it supply air-food to the plant, being absorbed by the leaves, but, entering into the earth with the rain, it there prepares that food which the plant must have, and which it absorbs by its roots.

COMETS AND COMETS' TAILS.

By the Editor.

BEFORE we proceed to consider the theory by which alone, so far as can be judged at present, the phenomena of comets' tails can be explained, it may be well that we should consider the evidence derived from other comets than those hitherto considered.

In the first place we would direct special attention to the comet of 1811. In this comet, as may be seen from its picture in Fig. 1, the various parts of the comet and its tail could be distinguished by the naked eye. There was the condensed part, called the *nucleus*, which in this case was apparently globular in form; the nebulous envelope which surrounds the nucleus, the so-called *coma*; the bright side parts of the tail where it seems to be swept away from the coma, leaving a comparatively dark region behind the head, and the tail, widening and growing fainter with distance from the head. No one, we think, who considers this picture will for a moment imagine that the comet is a mere lens, and its tail merely the track of light condensed by this lens along the region behind the head. Here, again, the hollow structure of the tail seems indicated by the bright tracks on either side, though, as we shall endeavour to show later, the exceedingly well-defined nature of the dark track behind the nucleus in many comets seems to force upon us a different interpretation of this singular and characteristic feature.

In some respects the comet of 1811 tells us more of cometic possibilities, so to speak, than any other comet that has ever yet been observed. Discovered on March 26, 1811, this comet remained visible for a longer time than any yet seen, viz., for 16 months, 22 days. It had a tail 120 millions of miles in length, and 15 millions of miles in diameter at the widest part. The diameter of the nucleus was about 127,000 miles, that of the envelope round the head about 643,000 miles. But what was so remarkable about this comet was, that it obtained this remarkable development without approaching the sun, as other comets have done. The usual rule with comets is that the nearer they approach to the sun, the more their heads and tails are developed. But the least distance of the comet of 1811 from the sun was little less than 100 millions of

Fig. 1. Comet of 1811.

miles. Again, although it made so remarkable an appearance, as seen from the earth, the distance of that comet from us was at no time less than 110 millions of miles. Its true magnitude, therefore, as Professor Kirkwood well remarks, "has probably not been surpassed by that of any other comet which has yet been observed." If its path had carried it nearer to the sun, its appearance would probably have been terrible in the extreme. If we consider the enormous volume occupied by this comet and its tail, its

Million cubic miles of head,
Ten billion leagues of tail,

we shall see that the phenomena we have to interpret ought not to escape us in virtue of minuteness of scale.

Next consider the great comet of 1861. This comet was discovered on May 13, by Mr. John Tebbutt, jun., of New South Wales, and first accurately observed at the Sydney Observatory, on May 26. It passed northwards from the southern skies, and first became visible in Europe in the last week of June, 1861. The first recorded obser-

vations were made on the evening of June 30, nineteen days after it had passed its point of nearest approach to the sun. We remember well observing it on the morning of July 2, 1861. For some reason, we found it impossible to sleep that morning, and getting up about three in the morning (the exact hour we do not remember, but it must have been very early), we saw in the east what looked at first like the rays of an aurora borealis. But presently we noticed that these rays proceeded (unlike those of the aurora) from a bright centre, which had been hidden by clouds when our observations began. We used at that time to keep a four-inch telescope, mounted on a three-legged stand, in our bedroom. This we had quickly ready for action (noting that the object, owing to the approach of sunrise, was getting fainter every minute), and turning it on the comet, we drew a picture of the nucleus and coma so closely resembling that which appeared a week or two later in the *Illustrated London News*, that we might have supposed our picture had been surreptitiously sent to the office of the *Illustrated*, had we not found it resting just where we had put it in our scientific portfolio.

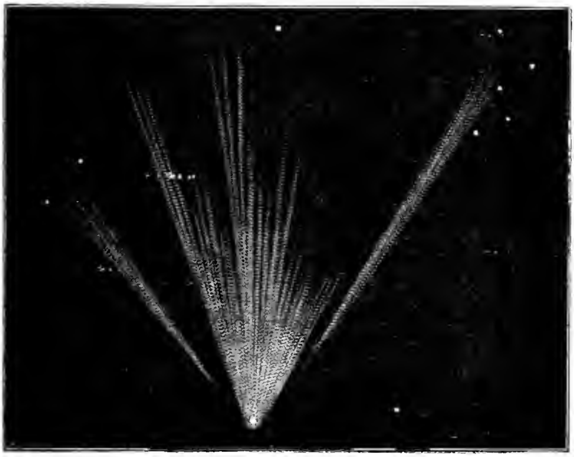

Fig. 2.

The comet appeared to the eye as shown in Fig. 2. Sir John Herschel, who observed it at Collingwood, in Kent, remarked that it was far more brilliant than any comet he had ever seen, not even excepting those of 1811 and 1858. The Padre Secchi, at Rome, found that in the clear skies of Italy the tail was fully 118° in length, corresponding to nearly one-third more than the distance between the horizon and the point overhead. This comet, by the way, though only favourably visible for a very short time, remained within the range of telescopic vision much longer. Hind remarks that the number of separate observations for the determination of its orbit exceeds 1,150, and extend over a period of 11½ months. It travelled on a course favouring observation, coming from remote distances south of the plane in which the earth travels to the northern side of that plane—and as it chanced, crossing the plane (about five-sixths of the way from the sun to the earth's orbit) just when the earth lay in the same direction from the sun, so that for a time she was within the bounds of the comet's tail-like appendage—and then travelling northwards on a path almost at right angles to the plane of the ecliptic. Thus the comet could be tracked on its retreat until, finally, distance concealed it from our view.

Now, the tail of the comet of 1861, as seen in Fig. 2, had something of the fan-like expansion observed in the tail of the comet of 1744; but what was known of the comet's position at the time when this fan-like form was seen, explained the peculiarity, and showed the necessity of taking into account the position of a comet before attaching undue importance to the apparent figure of its tail. For the fan-like form seen on this occasion was a mere effect of perspective. The end of the tail appeared very much wider than the part near the head—not that it really was so, but simply because it was very much nearer to the observer on earth. When we were actually immersed in the tail, the part nearest to us, being all round, had, to all intents and purposes, an infinite extension. But even when the comet was beyond that position, or a few days earlier, before it had reached it, the end of the tail was much nearer to us than the comet's head, and thus appeared far more proportionately widened than was actually the case.

Such considerations must always be taken into account in dealing with cometic phenomena. Comets, more than any other celestial objects (the Milky Way, regarded as a whole, being, perhaps, alone excepted), are affected in shape, and apparently, even in their very nature, by position, and consequent foreshortening.

SOLIDS, LIQUIDS, AND GASES.

By W. Mattieu Williams.

PART III.

THAT the solid and liquid states of matter are not distinctly and broadly separable, but are connected by an intermediate condition of viscosity, which is more or less common to both, has, I think, been sufficiently shown in the previous papers, and the proofs of this are familiar enough.

We now come to the question whether there is any similar continuity between liquids and gases. Ordinary experience decidedly suggests a negative answer. We can point to nothing within easy reach that has the properties of liquid and gaseous half-and-half; that stands between gases and liquids as pitch and treacle stand between solids and liquids.

Some, perhaps, may suggest that cloud-matter—London fog, for example—is in such an intermediate state. This, however, is not the case. White country fog, ordinary clouds, or the so-called "steam" that is seen assuming cloud-forms as it issues from the spout of a tea-kettle or funnel of a locomotive, consist of minute particles of water suspended in air, as solid particles of dust are also suspended. It has been called "vesicular vapour," on the supposition that it consists of minute vesicles, like soap-bubbles on a very small scale, but this hypothesis remains unproven. London fog consists of similar particles, varnished with a delicate film of coal-tar, and interspersed with particles of soot.

In order to clearly comprehend this question, we must define the difference between fluids and gases. In the first place, they are both fluids, as already agreed. What,

then, is the essential difference between liquid fluidity and gaseous fluidity? The expert in molecular mathematics, discoursing to his kinematical brethren, would produce a tremendous reply to this question. He would describe the oscillations, gyrations, collisions, mean free paths, and mutual obstructions of atoms and molecules, and, by the aid of a maddening array of symbols, arrive at the conclusion that gases, unless restrained, are liable to indefinite or vast expansion, while liquids, of their own accord, retain definite limits or dimensions.

The matter of fact experimentalist demonstrates the same by methods that are easily understood by anybody. I shall, therefore, both for my own sake and my reader's, describe some of the latter.

In the first place, we all see plainly that liquids have a surface, *i.e.*, a well-defined boundary, and also that gases, unless enclosed, have not. But as this may be due to the invisibility of the gas, we must question it further. The air we breathe may be taken as a type of gases, as water may of liquids. It has weight, as we may prove by weighing a bottle full of air, then pumping out the contents, weighing the empty bottle, and noting the difference.

Having weight, it presses towards the earth, and is squeezed by all that rests above it, and thus the air around us is constrained air. It is very compressible, and is accordingly compressed by the weight of all the air above it.

This being understood, let us take a bottle full of water and another full of air, and carry them both to the summit of Mont Blanc, or to a similar height in a balloon. We shall then have left nearly half of the atmosphere below, and thus both liquid and gas will be under little more than half of the ordinary pressure. What will happen if we uncork them both? The liquid will still display its definite surface, and remain in the bottle, but not so the gas. It will overflow upwards, downwards, or sideways, no matter how the bottle is held, and if we had tied an empty bladder over the neck before uncorking, we should find this overflow or expansion of the gas exactly proportionate to the removal of pressure, provided the temperature remained unaltered. Thus, at just half the pressure under which a pint bottle was corked, the air would measure exactly one quart, at one-eighth of the pressure one gallon, &c.

We cannot get high enough for the latter expansion, but can easily imitate the effect of further elevation by means of an air-pump. Thus, we may put one cubic inch of air into a bladder of 100 cubic inches capacity, then place this under the receiver of an air pump, and reduce the pressure outside the bladder to $\frac{1}{100}$th of its original force. With such atmospheric surrounding, the one cubic inch of air will plump out the flaccid bladder, and completely fill it. The pumpability of the air from the receiver shows that it goes on overflowing from it into the piston of the pump as fast as its own elastic pressure on itself is diminished.

Numberless other experiments may be made, all proving that all gases are composed of matter which is not merely incohesive, but is energetically self-repulsive; so much so, that it can only be retained within any bounds whatever by means of some external pressure or constraint. For aught we know *experimentally*, the gaseous contents of one of Mr. Glaisher's balloons would outstretch itself sufficiently to occupy the whole sphere of space that is spanned by the earth's orbit, provided that space were perfectly vacuous, and the balloon were burst in the midst of it, and the temperature of the expanding gas were maintained.

Here, then, in this self-repulsiveness, instead of self-cohesion, this absence of self-imposed boundary or dimensions, we have a very broad and well-marked distinction between gases and liquids, so broad that there seems no bridge that can possibly cross it. This was believed to be the case until recently. Such a bridge has, however, been built, and rendered visible, by the experimental researches of Dr. Andrews; but further explanation is required to render this generally intelligible.

Until quite lately it was customary to divide gases into two classes—"permanent gases" and "condensable gases" or "vapours." Gaseous water or steam was usually described as typical of the latter; oxygen, hydrogen, or nitrogen of the former. Earlier than this, many other gases were included in the permanent list; but Faraday made a serious inroad upon this classification when he liquefied chlorine by cooling and compressing it. Long after this, the gaseous elements of water, and the chief constituents of air, oxygen, hydrogen, and nitrogen, resisted all efforts to condense them; but now they have succumbed to great pressure and extreme cooling.

We thus arrive at a very broad generalisation, viz., that all gases are physically similar to steam, (I mean, of course, "dry steam," *i.e.*, true invisible steam, and not the cloudy matter to which the name of steam is popularly given,) that they are all formed by raising liquids above their boiling-point, just as steam is formed when we boil water and maintain the steam above the boiling-point of the water.

But some liquids boil at temperatures far below that at which others freeze; liquid chlorine boils at a temperature below that of freezing water, and liquid carbonic acid below even that of freezing mercury, and liquid hydrogen far lower still. These are cases of boiling, nevertheless, though it seems a paradox according to the ideas we commonly attach to this word. But such ideas are based on our common experience of the properties of our commonest of liquids, viz., water.

When water boils under the conditions of our ordinary experience, the passage from the liquid to the gaseous state is a sudden leap, with no intermediate state of existence that we are able to perceive; and the conditions upon which water is converted into steam—the liquid into the gas—while both are at the bottom of our atmospheric ocean, are such as to render an intermediate condition rationally, as well as practically, impossible.

We find that the expansive energy by which the steam is enabled to resist atmospheric pressure is conferred upon it by its taking into itself, and utilising for its expansive efforts, a large amount of calorific energy. When any given quantity of water is converted into steam, under ordinary circumstances its bulk *suddenly* becomes above 1,700 times greater—a cubic inch of water forms about a cubic foot of steam, and nearly 1,000 degrees of heat (966·6) disappears *as temperature*. Otherwise stated, we must give to the cubic inch of water at 212° as much heat as would raise it to a temperature of 212 plus 966·6, or 1178·6° if it remained liquid. This is about the temperature of the glowing coals of a common fire; but the steam that has thus taken enough heat to make the water red hot is still at 212°—no *hotter* than the water was while boiling.

This heat, which thus ceases to exhibit itself as *temperature*, is otherwise occupied. Its energy is partly devoted to the work of increasing the bulk of the water to the above-named extent, and partly in conferring on the steam its gaseous speciality—that is, in overcoming liquid cohesion, and substituting for it the opposite property of internal repulsive energy which is characteristic of gases. My reasons for thus defining and separating these two functions of the so-called "latent" heat will be seen in the next paper, when we come to the philosophy of the interesting researches of Dr. Andrews.

GERMS OF DISEASE AND DEATH.

By Dr. Andrew Wilson, F.R.S.E.

Part II.

Turning now to the *Charbon* or *Splenic Fever*, we witness another veritable triumph of Pasteur's industry and research. In 1850, certain observers noted the interesting fact that minute, rod-like bodies, which appeared to be lower forms of plant life, existed in the blood of animals affected with this disease. The "rods," it was observed, originated from particles which might, with perfect accuracy, be called "Germs." And as we watch the "rods" in turn, we see that, sooner or later, microscopic specks appear in their substance: these grow to form regular bead-like rows within the "rods;" and when finally the "rods" themselves break up and fall to pieces, these beads are liberated as the "germs," which in time will grow into new rods. Thus countless myriads of rods and germs grow and are reproduced within the body of the animal suffering from *splenic fever*. The fever, in a word, is the result of the growth and development within the living soil, of these rod-like plants. But exact demonstration of the truth of the latter statement can be had.

If we grow and cultivate in a proper fluid—such as the aqueous humour of the eye of an ox—the "rods," we may inoculate with our "rods" the body of a healthy animal. We may *sow* in that animal's body the germs of splenic fever. Thus a drop of a solution containing the "rods" sown within the body of a guinea-pig, produces splenic fever in that animal. And more wonderful still, it has been shown that the dried blood taken from an animal affected with this fever will reproduce the fever, even after an interval of four years, if the dried particles of blood with their "rods" be introduced into the body of a healthy animal.

Pasteur, armed with knowledge of the kind just detailed, set himself to ascertain the "reason why" splenic fever should suddenly appear in districts which knew it not, and wherein only healthy animals lived. Obviously, if the germ theory were true, such sudden and apparently isolated outbreaks must be capable of being explained on this hypothesis. The idea of the "spontaneous," or *de novo*, or *ex nihilo* origin of the disease would, if supported by facts, prove fatal to the "germ theory." Here, then, was a typical case for scientific investigation. Let us see how the genius of Pasteur overcame the difficulties of the situation.

The localities in which splenic fever seemed to burst out suddenly and without warning were, as Pasteur learned, former seats of the disease. But the interval between the visitation was to be measured by years. How, then, could the new outbreak be accounted for? It seemed, in truth, as if the one outbreak had little or nothing to do with the other. The infected animals which had died, or had been killed, whilst suffering from the fever, were duly buried, and that very deeply, in the soil. Such a method of interment would seem to obviate all risk of infection. But the possibilities of nature are illimitable, and no man knew this better than Pasteur. If the poison had been buried in the soil, why should it not be there still? And, further, why should it not be conveyed upwards to infect the fresh flocks that fed on the graves of their predecessors? With a gift of scientific divination, Pasteur sought in the earthworm, the type of the "middleman" betwixt the living and the dead. He now examines the bodies of the worms which live in the soil wherein the bodies of the animals infested with splenic fever, years before, were entombed. By experimental means, he solves his problem. He makes a preparation of the contents of the digestive system of the worms. This he administers in the food of healthy animals, entirely removed from the pastures. And once again a scientific principle dawns in view. The rabbits and guinea pigs which devoured the matter obtained from the worms at once developed splenic fever, whilst in their blood the rods were seen developing in full force. Once again Pasteur had sown the fever, and had argued thus from the result, backwards to the cause. It has also been proved that even grain may convey the subtle "rods" to healthy animals, and may in this way engender splenic fever. Following close upon the heels of the discovery of the germ-origin of this fatal malady comes the gratifying announcement that, as small pox is modified by vaccination, so splenic fever may be modified by an analogous process. Pasteur has proved that we can inoculate sheep and cattle with a mild form of the fever which protects the animal from a recurrence of the disease; and this protective influence, as we write, is being practically utilised by the breeders of France.

Such is a brief recital of a new step towards a perfect knowledge of the nature of the diseases which decimate, not merely animal life, but human existence as well. It may not be inappropriate if, by way of close, we remind our readers of two very noteworthy points in connection with this all-important topic, bearing, as it does, in the most intimate manner upon the physical welfare of man.

The first of the points to which we refer concerns the apparently trivial origin of an all-important subject. It was in the city of Florence, some two hundred or more years ago, that a certain physician, Francesco Redi by name, demonstrated to the Florentine wiseacres that the maggots in meat do not arise from the dead meat by "spontaneous generation," but were produced from the eggs of the flesh-flies. This result he achieved by covering over the meat with gauze, so that whilst the meat-decay proceeded, there was likewise a convincing absence of maggots. Childishly simple as was Redi's experiment, it laid the basis and method of all succeeding research; for from his day down to ours the progress of the "germ theory"—or of that doctrine which holds that all life, however mysteriously generated, must spring from pre-existing life—has been uniform and triumphant.

But the second point to which attention is worthy of being directed, exists in the statement that the practical and actual benefits which have flowed to human health, and which are likely to flow in the future as well—the saving of life by the prevention and extermination of disease—arise from a simple study in natural history. So-called "practical" minds are often given to loudly express their disapproval of any science which deals with what, to them, seem mere abstractions. Doubtless, to such minds the study of the development of the "rods" of splenic fever under a watch-glass must seem a piece of scientific *dilettantism*; just as information respecting the solar system may seem despicable enough, because its results cannot be measured by a profitable currency, or, in plain language, because it "doesn't seem to pay." The best answer to such foolishness is found in a recital of the results to human and animal life to which natural history study seems likely to lead. Just as two hundred years ago, in Florence, Redi began the good work by a simple study in zoology, so to-day we are reaping the reward of the earnest work of the botanists and zoologists who toil and labour to spread abroad their saving knowledge.

BRAIN TROUBLES.

Impaired Memory (*continued*).

The following case is one of those in which sudden failure of memory implied serious cerebral mischief. "An eminent provincial surgeon, of large and anxious practice, was seized with a sudden failure of memory. He forgot all his appointments, and to such a degree was the faculty of retention impaired" (so far as the names and cases of patients were concerned) "that he was obliged to make memoranda of every trifling and minute circumstance which it was important for him to remember, and to these he was constantly referring in order to refresh his memory. This attack was preceded by headache, of which he had complained for nearly a fortnight." Up to the period of the case being brought to the attention of Dr. Forbes Winslow, who treated it, no suspicion had been entertained of the existence of any prior state of cerebral ill-health, sufficient to account for the patient's sudden loss of mental power. Dr. Winslow ascertained, however, that "about eight weeks, or nearly three months previously" (not a very clear way of putting the matter, by the way), the patient had been seized, whilst in the act of applying a stethoscope to the chest of a patient, with severe epileptic vertigo. For about a second he lost consciousness. This had been succeeded by an attack of distressing sick headache. "Three days subsequently he had a second paroxysm of giddiness, and nearly fell out of the carriage in which he was sitting at the time. His spirits subsequently became much depressed, but in a few days he again rallied, flattering himself that he had quite recovered. He made no mention of these attacks to any member of his family, and carefully avoided all conversation on the subject of his health with his medical brethren." "When I saw this gentleman," says Dr. Winslow, "the only appreciable mental symptom was inability to retain in his mind, for many consecutive minutes, any recent impressions. His pulse was feeble, face pallid, and general health shattered. His spirits were, however, at times buoyant, and the prognosis which he formed of his own case was favourable." The result showed that he was a false prophet. Two weeks later he had an epileptic fit. He then became rapidly worse, and ten months after he died "in a deplorable state of mental imbecility."

But against such a case as this, which was obviously exceptional, may be set the following case, in which, under similar conditions, so far as appearances were concerned, a complete cure was effected:—A barrister complained to Dr. Winslow of occasional attacks of enfeebled memory. "He attributed this mental impairment," says Dr. Winslow, "to the fact of his having been engaged as counsel the previous year in several anxious and severely-contested election cases. I advised an entire cessation from all professional work, but had great difficulty in persuading him to recognise the necessity for a complete abstinence from mental occupation. He promised a guarded acquiescence in my strict injunctions, but finding himself relieved after an interval of a few weeks, he returned, in opposition to my solicitations, to his chambers, and recommenced active practice. As I predicted," proceeds Dr. Winslow, "he soon broke down, and I was once more conferred with. He then acknowledged it to be a matter of vital necessity that he should give his mind prolonged rest, and agreed unreservedly to do so. I kept him for a period of *two years* from all anxious and severe mental occupation, and by that time his powers of mind had rallied to a surprising extent; in fact, they became, according to his own impression, more vigorous than they were prior to his attack of illness. For many years this patient has continued steadily at work, never having had a return of loss of memory. I should premise that I exacted from him a promise that he would read no briefs after dinner. He has rigidly adhered to this understanding, but being an early riser and a man of remarkable quickness of apprehension, he is enabled to master a large amount of work before breakfast. I also made it a *sine quâ non* that he should go abroad every year for a period of two months, thus ensuring for him a complete diversion and relaxation of mind from all injurious pressure. He has scrupulously complied with my instructions, and the result is an entire freedom from all symptoms of mental impairment and cerebral disorder." A case such as this is full of encouragement, because here it would seem that at the outset overwork had seriously injured the brain, yet attention to a few simple rules resulted in a complete cure.

Apart from actual injury to the substance of the brain, transient loss of memory seems to be usually caused by a deficient supply of blood to the brain, whether through loss of blood generally, or owing to defective circulation. This is illustrated by the following case: A lady had been reduced to a state of such extreme prostration by hæmorrhage, that for nearly a week she seemed simply lingering between life and death. After this she remained for a long time in a state of extreme mental depression and vital prostration. When she was able to articulate, her husband was astonished to find that her memory was paralysed. "She had forgotten where she lived, who her husband was, how long she had been ill, the names of her children, and, in fact, her own name was obliterated from her recollection. She was unable to call anything by its right name. In attempting to do so she made the most singular mistakes. She had been in the habit, before her illness, of speaking in French, her husband being a Frenchman; but while in the state of mind described, she seemed to have lost all recollection of the French language. When her husband spoke to her in French, she did not seem to understand in the least what he was saying, though she could at this time speak English without difficulty. Seven or eight weeks elapsed before her memory began to improve, and months passed before her mind regained its original strength."

Intense cold seems to have the power of paralysing the memory. During the retreat from Moscow, many of Bonaparte's officers and men found their memories greatly enfeebled. Bonaparte himself was affected, especially as to dates and names. "For a time he was constantly confusing one person with another, and making odd mistakes in dates." In his case the affection of the memory lasted only a few days;* but one of Bonaparte's *aides-de-camp* lost his memory for several years.

Instances such as these enable us to understand the true meaning of those comparatively slight attacks of failure of memory which most of us experience from time to time. In the first place, we do not find much evidence enabling us to assign to one or other of the two classes of memory-failings above indicated a greater or less degree of importance, whether such failings occur in a marked or slight

* During this time Bonaparte's mind seems to have been affected. "He merely made some gestures of melancholy resignation on every occasion when," during the battle of Semenowska, the *aides-de-camp* sent by Ney "informed him of the death of his best generals. He rose several times to take a few turns, but immediately sat down again. Everyone looked at the Emperor with astonishment. Hitherto, during these great shocks, he had displayed an active coolness; but here only a dead calm, a mild and sluggish inactivity." Count Segur, referring to Napoleon's state at this time, says: "The Russian autumn had triumphed over him."

degree only. Inability to commit new matter to the memory with customary facility seems as likely to be a sign of mischief as inability to recollect matters forming (ordinarily) a part of our stock of familiarly known facts. Again, it is clear we need not fear that mind is necessarily going astray because for a time the memory fails in slight degree. We see that very serious failures of the power of memory may occur where the brain has suffered no irreparable mischief. But since we see that much overwork will cause serious temporary mischief of this particular kind, we learn that where a slight lapse of memory is noticed, the indication may be taken as a sign that rest is needed. But there are, as we have seen, other ways in which this special power may come to be affected; so that if the memory should show signs of failure where we have no reason to believe that overwork has caused the mischief, we may infer that some one or other of the causes which, as we have seen, may affect the memory seriously have operated injuriously in slight degree. Nor in general need we be in much doubt as to the true nature of the cause, simply because we cannot fail (usually) to recognise in the circumstances preceding the attack the origin of the mischief. Thus, although a serious failure of the memory considered apart from the circumstances preceding it might leave the physician in doubt whether depletion or plethora (to mention two possible causes) had produced the mischief, yet the physician, apart even from an examination of the patient's condition, could learn at once from him whether either of these two opposite conditions had existed before the attack. In like manner, any person whose memory suddenly seemed weakened could, as his own physician, ascertain (unless, indeed, his memory failed to remind him how he had passed the hours or days preceding the attack) whether the mischief resulted from deficiency or excess in the amount of food or stimulants he had previously taken, whether the proper remedy would be, on the one hand, some such medicine as a glass of wine and a chop, or, on the other hand, a diminution during two or three days of the amount of food consumed or the avoidance of some of the more stimulating articles of diet. Here, however, we are considering rather those mental troubles which are produced by mental work, whether relating to subjects of great difficulty or carried on too long. We would notice also that in dealing with other indications of mental mischief we need not be careful to show how the more serious cases of each kind suggest the significance of the slighter and far commoner mental troubles which form our real subject of inquiry; for this reason, simply that what we have here said about failure or loss of memory applies equally to other signs of temporary mischief.

MAN A FRUIT-EATER.*

MAN'S nearest of kin among the animals is the ape. This is shown not only by those outward features which all can recognise, but more clearly and more certainly by the structure of the nervous system. The animal in which this system resembles most closely the nervous system in man is the ape, and of all apes, that which comes nearest to man in this respect is the orang. The brain convolutions, which in rodents (gnawing quadrupeds—rats, squirrels, &c.) and edentates (toothless quadrupeds—ant-eaters, ground-hogs, &c.), are very simple, in the flesh-eating animals are more developed, and in the apes, especially the orangs, they are developed still more fully. "We are authorised in concluding," says Professor Mivart, that "the difference between the brain of the orang and that of man, as far as yet ascertained, is a difference of absolute mass; it is a difference of degree, and not of kind."

Starting from this relationship, Miss Kingsford, in the book before us, proceeds to indicate the bearing of man's kinship to apes on the vexed question of man's proper or natural food. Carefully studying the entire digestive apparatus of animals and men, and especially comparing this apparatus in men and apes, she is led to the conclusion that man approaches nearest in this respect to those animals which are eaters of fruits and herbs. "If," she says, "we have consecrated to this sketch of comparative anatomy and physiology a paragraph which may seem a little wearisome in detail, it is because it appears necessary to combat certain erroneous impressions affecting the structure of man, which obtain credence, not only in the vulgar world, but even among otherwise instructed persons. How many times, for instance, have we not heard people speak with all the authority of conviction about the 'canine teeth' and 'simple stomach' of man as certain evidence of his natural adaptation for a flesh diet? At least we have demonstrated one fact, that if such arguments are valid, they apply with even greater force to the anthropoid apes—whose 'canine' teeth are much longer and more powerful than those of man—and the scientists must make haste, therefore, to announce a rectification of their present division of the animal kingdom in order to class with the carnivora (flesh-eaters) and their proximate species all those animals which now make up the order primates (men and apes). And yet, with the solitary exception of man, there is not one of these last which does not in a natural condition refuse to feed on flesh!" Pouchet says that all the details of man's digestive apparatus, as well as his dentition, are proofs of his frugivorous (fruit-eating) origin. Professor Owen agrees that the close analogy between apes and man demonstrate his frugivorous nature. So Cuvier, Linnæus, Lawrence, Bell, Gassendi, Flourens, and a host of other authorities.

Yet another belief is as common as it is erroneous, viz., that "flesh food contains the elements of physical force, and that to be strong, robust, and endowed with muscular energy it is necessary to partake largely of animal food." Yet no flesh-fed animal rivals in strength the herb-eating rhinoceros, in endurance the horse, the mule or the camel. A gorilla feeding on fruits and nuts is more than a match for the far heavier lion. "The buffalo, the bison, the hippopotamus, the bull, the zebra, the stag, are types of physical power and vast bulk, or of splendid development of limb. Only in ferocity are flesh-eating animals superior (?) to those who find their food in fruits and herbs."

As regards man himself, the idea that the flesh-eaters are the most powerful, is erroneous, as is the cognate idea that to acquire strength, a man should eat daily large quantities of flesh meat. "In the palmy days of Greece and Rome, before intemperance and licentious living had robbed those kingdoms of their glory and greatness, their sons, who were not only soldiers but heroes, subsisted on simple vegetable food, rye meal, fruits, and milk. The daily rations of the Roman soldier were one pound of barley, three ounces of oil, and a pint of thin wine. It was no regimen of flesh that inspired the magnificent courage of the Spartan patriots who defended the defiles of Thermopylæ, or that filled with indomitable valour and enthusiasm the conquerors of Salamis and Marathon." Among the nations of

* "The Perfect Way in Diet; a Treatise advocating a return to the natural and ancient fruit of our race." By Anna Kingsford, Doctor of Medicine of the Faculty of Paris. (London: Kegan Paul, Trench, & Co.)

to-day, also, we find the fruit eaters and herb eaters as enduring, to say the least, as the flesh eaters, and healthier.

Are we then to infer with our author that a diet of fruit and seeds, preferably uncooked, is the best for the human race? Or, if we infer this, may we conclude that all would do well to adopt such a diet? It might be unsafe to accept the latter inference, for habit and custom count for something in such matters. But we may very safely adopt the opinion, now generally prevalent among experienced physicians, that fruit and seed, herbs and vegetables, should form a larger proportion of our food than they do. Precisely as many who do not accept, in its entirety, the views of Dr. Richardson about alcoholic stimulants, yet hold that these stimulants, if taken at all, should be taken in much smaller quantity than is customary, so, many who would not agree with Miss Kingsford, that animal food should be entirely displaced (which is Dr. Richardson's opinion also), yet see that it would be well if flesh meat were taken in much less quantity than at present.

How much custom has to do with the use and effects of flesh meat is shown by cases such as Miss Kingsford mentions, in which persons unaccustomed to flesh meat have been actually intoxicated by its use. Dr. Dundas Thompson tells us of some Indians accustomed to vegetable food, who, dining luxuriously on meat, showed an hour or two later, by their jabbering and gesticulations, that the same effect had been produced upon them as if they had taken some intoxicating spirit or drug.

Apart from the special doctrine which Miss Kingsford advocates, her little treatise is well worth studying for its clear and correct account of the various forms of food used by man. There is much matter for reflection, also, in what she says about slaughter-houses, fox-hunting, pigeon-shooting, and the cruelties of the fur trade.

THE SPECTROSCOPIC ANALYSIS OF LIGHT.—We may illustrate this process by a similar one, which we might imagine mankind to perform. Suppose Nature should loan us an immense collection of many millions of gold pieces, out of which we were to select those which would serve us for money and return her the remainder. The English rummage through the pile, and pick out all the pieces which are the proper weight for sovereigns and half-sovereigns; the French pick out those which will make 5, 10, 20, or 50-franc pieces; the Americans the 1, 5, 10, and 20-dollar pieces, and so on. After all the suitable pieces are thus selected, let the remaining mass be spread out on the ground according to the respective weights of the pieces, the smallest pieces being placed in a row, the next in weight in an adjoining row, and so on. We shall then find a number of rows missing—one which the French have taken out for 5-franc pieces; close to it another which the Americans have taken for dollars; afterwards a row which have gone for half-sovereigns, and so on. By thus arranging the pieces, one would be able to tell what nations had culled over the pile, if he only knew of what weight each one made its coins. The gaps in the places where the sovereigns and half-sovereigns belonged would indicate the English, that in the dollars and eagles the Americans, and so on. If, now, we reflect how utterly hopeless it would appear, from the mere examination of the miscellaneous pile of pieces which had been left to ascertain what people had been selecting coins from it, and how easy the problem would appear when once some genius should make the proposed arrangement of the pieces in rows, we shall see in what the fundamental idea of spectrum analysis consists. The formation of the spectrum is the separation and arrangement of the light which comes from an object on the same system by which we have supposed the gold pieces to be arranged. The gaps we see in the spectrum tell the tale of the atmosphere through which the light has passed, as in the case of the coins they would tell what nations had sorted over the pile.—*Newcomb's Popular Astronomy.*

A MILD NOVEMBER.

THE weather of the month that has just elapsed has been so unusually mild, that a few statistics respecting mild Novembers in general, and the past one in particular, may not be without interest.

It appears that in London the average temperature of the first twenty-five days of the past month has been as much as 7° above the mean of twenty years' observations; and, if it is fair to compare the London temperatures with those of Greenwich, the past November has been decidedly the warmest experienced during the present century. Relatively warm Novembers were observed in the following years: 1806, 1817, 1818, 1821, 1822, 1824, 1845, 1846, 1847, 1850, 1852, 1857, 1863, 1865, 1866, and 1877. The warmest of these was 1852, when the mean temperature in London was 48·9°, or rather more than a degree lower than that of the month that has just passed away. The maximum readings observed during the month under review have been exceptionally high, and those of the 5th and 10th, when the thermometer in the shade rose to 64°, have only been exceeded once during the present century. This was on Nov. 8, 1847, the reading then being as high as 67°.

On looking over the meteorological returns from several English stations, we find that, while the thermometer has been unusually high throughout, there have been three periods of especially warm weather. The first of these occurred on the 5th, the second about the 13th or 14th, and the third about the 20th or 21st. In the subjoined table, the temperature on each of these occasions has been compared with the mean for the corresponding day of thirteen years:—

STATIONS.	5th.		13th or 14th.		20th or 21st.	
	Temp.	Difference from mean.	Temp.	Difference from mean.	Temp.	Difference from mean.
	deg.	deg.	deg.	deg.	deg.	deg.
North Shields	51·0	+ 6·2	55·0	+12·2	50·0	+ 8·5
York	51·5	+ 6·7	55·0	+12·0	50·0	+ 8·4
Yarmouth	52·5	+ 6·5	52·5	+ 8·9	50·0	+ 7·6
Cambridge	58·0	+12·8	54·5	+11·3	52·5	+10·5
Nottingham	56·0	+10·5	57·0	+13·7	52·5	+10·7
Leicester	54·6	+ 9·2	55·3	+12·0	50·1	+ 9·3
Birmingham	56·1	+10·6	56·6	+13·2	50·0	+ 7·4
Hereford	56·6	+ 9·8	57·9	+13·6	51·0	+ 8·1
Oxford	57·0	+10·6	54·5	+10·6	54·5	+12·3
London	59·5	+19·7	56·0	+11·1	54·5	+11·6
Marlborough	51·2	+ 7·5	55·5	+11·2	49·6	+ 6·8
Dover	54·5	+ 6·9	52·0	+ 6·8	53·0	+ 9·7
Hastings	54·5	+ 6·9	52·7	+ 7·5	52·5	+ 9·2
Silloth (Carlisle)	49·7	+ 4·7	54·1	+10·8	49·7	+ 7·1
Barrow-in-Furness	50·5	+ 5·2	51·5	+ 8·3	50·0	+ 7·2
Manchester	50·2	+ 5·0	55·0	+11·9	47·6	+ 5·7
Liverpool	53·0	+ 6·8	56·5	+12·3	51·5	+ 8·7
Holyhead	54·5	+ 7·5	53·0	+ 7·5	52·5	+ 8·3
Pembroke	54·0	+ 6·2	54·0	+ 7·7	53·0	+ 7·3
Plymouth	56·8	+ 7·2	51·8	+ 7·5	53·8	+ 7·7

It will be seen that on the 5th, the average temperature was from 5° to 7° above the mean in the north of England, and also on the south coast, but that in the Midland counties it was between 9° and 11° above, while at Cambridge and in London the excess was nearly 13°. On the 13th or 14th—for in some places the greatest heat was on the former date, and in others it occurred on the latter—the excess was between 7° and 8° on the west and south-west coasts, but between 11° and 13° at most of the inland stations, while at Nottingham and Hereford it amounted to more than 13½°. On the 20th and 21st the weather was not quite so warm, but even then the temperature was more than 10° above the mean in many parts of central England, and as much as 12° in excess at Oxford.

On examination, it appears that a warm November is usually associated with great storms, and frequently accompanied by disturbance of an electrical nature in the shape of thunderstorms and displays of aurora borealis. The month under review has certainly been distinguished for these phenomena, although their influence has been chiefly confined to the more western and northern parts of the kingdom.

Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. He requests that all communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All communications should be addressed to the Editor of Knowledge, *74, Great Queen-street, W.C.*

All Cheques and Post-Office Orders to be made payable to Messrs. Wyman & Sons.

∴ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of Knowledge, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

THE INVISIBILITY OF LIGHT—INCLINATION OF THE EARTH'S AXIS—THE ZOETROPE.

[49]—Without entering—at all events for the present—into the discussion of the question "Is the Sun hot?" I should like to suggest to "Tyro" (letter 6, p. 35) a simple experiment which will give him ocular demonstration that light is invisible. Let your correspondent, then, make a pasteboard tube, ten or twelve inches long, and three inches in diameter. Close the bottom with a disc of card, and line the whole with black velvet. This done, let him cut two holes, say half an inch in diameter, opposite to each other, two-thirds of the way towards the closed end of the tube; and between these a third hole. If he will hold this simple piece of apparatus so that the sun shall shine across the tube, *i.e.*, so that sunlight shall enter in at one of the side holes and pass out at the other, and will look into the tube through its open end, he will see —nothing; the interior being totally dark. Now, let him introduce a strip of writing paper through the hole between the two others (which should be at the lower side of the tube), and push this paper up until it enters the beam of sunlight. Instantly the interior of the tube will become illuminated, because the previously invisible light will be reflected from the paper, and so become perceptible. "Tyro" has presumably noticed that a beam of sunlight entering a darkened room through a hole or chink in the shutter is traceable as it crosses the apartment. This, however, arises from the reflection of the light by the particles of dust which fill the atmosphere of the apartment. Were it practicable to eliminate these by burning, or otherwise, the path of the ray would be quite invisible, and the round spot of light on the floor or opposite wall, would be the only indication we should receive of the entry of sunlight into the darkened chamber at all.

I do not know whether the "Tyro" of letter 9 (p. 36) is the same "Tyro" as he to whom I have just been essaying a reply. At any rate, I will suggest another experiment as a means of clearing up this second difficulty. It is this. Let your querist obtain a lamp, an apple, and a knitting-needle. Furnished with these, he must thrust the knitting-needle diametrically through the apple, and place the lamp in the middle of the table. The lamp will stand for the sun, the apple for the earth, and the knitting-needle for its axis. Now, he must incline the needle 23°, and we will suppose that, in doing so, he causes the top of it to point to the north wall of his room. Then he must carefully preserve the direction of the needle constant in this position, and, doing so, carry it round the lamp. An instant's reflection will show him that, should he start from the north side of the lamp, the upper or northern end of his needle (and obviously the northern half of his apple-earth) will be inclined from the lamp; and that when he brings it round to the south side of the lamp, the top of the axis, still pointing to the north wall of the room, must be inclined towards it. The end of "Tyro's" query is not quite so intelligible as might be desired; but he seems to conceive in some occult way that the earth's rotation must affect the position of her axis. If, while studiously keeping his knitting-needle axis parallel to itself during its revolutions round the lamp, he twists it so as to make the apple rotate on it, he will at once see how the two movements may be independent of each other.

As "Moonstruck" (query 1, p. 38) has a question on a cognate subject, I may say that perpetual spring, rather than perpetual summer, would reign at the poles of the earth, were its axis perpendicular to the plane of the ecliptic. Summer would, of course, be continuous at the Equator, where the sun would be always vertically overhead.

If "Zulu" (query 10, p. 38) will reflect, *imprimis*, how much what we call seeing is a matter of inference, and, in the next place, remember that the image of any object is retained by the retina for something like 0·1 second after such object has disappeared, he will get some idea of the way in which the images in the Zoetrope are caused, as it were, to shade into each other, the mind unconsciously supplying the intermediate steps. The real images, in the case of an actually moving object, must, so to speak, overlap in a way which must render it impossible to predicate definitely that any one given instantaneous attitude of the body in motion has been actually observed.

A Fellow of the Royal Astronomical Society.

THE MISSING LINK.

[50]—Dr. Andrew Wilson does good service in making known to your readers the erroneousness of the widespread notion that man is descended from monkey. Concerning the question to which he makes excellent reply, I think the following remarks in Professor Huxley's Preface to Hæckel's "Freedom of Science" (p. xiii.) will be serviceable.

"All the real knowledge which we possess of the fossil remains of man goes no further back than the quaternary epoch, and none of these remains present us with more marked pithecoid* characters than such as are to be found among the existing races of mankind. But then the equine quadrupeds of the quaternary period do not differ from existing *Equidæ* in any more important respect than these last differ. Yet it is a well-established fact that in the course of the tertiary period, the equine quadrupeds have undergone a series of changes exactly such as the doctrine of evolution requires. Hence sound analogical reasoning justifies the expectation that when we obtain the remains of pliocene, miocene, and eocene *anthropidæ*, they will present us with the like series of gradations." —Edward Clodd.

THE 1-INCH ORDNANCE MAPS.

[51]—In the first numbers of Knowledge, attention has been called to the fact that the 1-inch to the mile Ordnance maps are not trustworthy. A very good case in point has come to my knowledge. From Handcross, in Sussex, three roads run to Brighton, one through Crabtree and Henfield, one through Cuckfield, and the other through Hicksted and Bolney. The one through Crabtree leaves the other roads about a mile south of Handcross Gate, and is shown in the right place on the map. The one through Cuckfield leaves the one through Bolney about a furlong lower down; but on the map it is a good mile and a quarter, and, consequently, for about three miles run is shown entirely in the wrong place.—I am, &c.,

G. W. Buckwell.

PALIZSCH AND HALLEY'S COMET.

[52]—Allow me to point out that, in an article on Comets in the first number of Knowledge (p. 10), you have inadvertently adopted an oft-repeated error, that when Palizsch re-discovered Halley's comet on Christmas Day, 1758, he found it "without telescopic aid." A complete account of his discovery, in his own words, will be found in the "Berliner Jahrbuch" for 1828, by which it appears that it was made with a telescope of 8 ft. focal length, and was the result of a search for the comet in the part of the sky where he expected it to appear. With this he noticed, about six o'clock on the evening in question, a nebulous-looking object, between ε and δ Piscium, which he had not seen there before; and subsequent observations, on Dec. 26 and 27, proved that it was indeed a comet. Thus did Palizsch (who, though certainly a farmer, was not a peasant, for he was a man of education, and an amateur in botany and other sciences, besides astronomy) first observe the predicted return of a comet nearly a month before anyone else; Messier being the next, and observing it at Paris, with a 4½ ft. Newtonian, on Jan. 21, 1759. I presume the mistake that Palizsch found it casually, and without telescopic aid, was founded on a misunderstanding of a note in Herschel's "Outlines," which certainly conveys that impression, but does not actually state it, so that it is difficult to be sure whether Sir John really thought so. But at any rate, it has been repeated in many books on astronomy, and Madler thought it

* Ape-like.

necessary to contradict it in his "Geschichte der Himmelskunde" (vol. II., p. 460). Palitsch was less fortunate in 1780, when he thought he had discovered another comet in Cancer, which proved, however, to be a now well-known nebula. He died at Lungraa, near Dresden, on Feb. 22, 1788, in the 65th year of his age; his memorable discovery on Christmas Day, 1758, was made at Prohlis, between Dresden and Pirna. Yours, &c.,

Blackheath, Nov. 11. W. T. Lynn.

DO COMETS OBEY GRAVITY?

[53]—As I am probably the victim of ill-written text books, such as you allude to in your introduction to the correspondence columns, perhaps you will kindly permit me to be set right in regard to a little matter which has occasionally troubled me, and which is again suggested by the article on comets.

It is stated in that article that comets obey the law of gravitation; and also that the matter of which they (or at least their tails) are composed is of inconceivable tenuity.

What puzzles me, then, is how these flimsy concerns can possibly be obeying the laws of gravitation, which I understand to mean that bodies attract each other in proportion to their mass. How is the sun's attraction, which fixes the *massive planets* to their present paths, to be reconciled with the fact that these *airy bodies* wander round orbits so gigantic?

If you cannot afford space for my difficulty, a reference to what you consider a reliable work will greatly oblige, yours, &c.,

Comet.

THE CRIMSON-CIRCLED STAR.

[54]—Will you kindly inform me to what star Tennyson refers in "In Memoriam," LXXXVIII., verse 12—

"And last, returning from afar,
Before the crimson-circled star
Had fallen into her father's grave."

The use of the feminine possessive pronoun would naturally suggest Venus. But why "crimson-circled"? Would this be effect of refraction on the horizon? If so, though only a dilettante astronomer, I do not remember having observed it.

I wish every success to your new Magazine, whose motives and virtues I diligently proclaim everywhere.

Quite apart from punning, I think you have taken as your motto, "Sublimi feriam *sidera* vertice."

Yours faithfully, M.R.C.S.

[I have always supposed crimson-circled here to mean surrounded by the crimson sunset glory. Is it not LXXXIX.?—Ed.]

TABLES OF MERIDIANAL PARTS.—THE FLAT EARTH.

[55]—Can you tell me how it is that the Table of Meridianal Parts in Riddle's Book of Tables differs so much in some parts from the corresponding table in Chambers' and Norie's books? The fact is the more strange, because the formula which Riddle gives for calculating that same table yields results identical with those tabulated in the two latter works. Which is likely to be the more trustworthy, Chambers' book or that of Riddle?

Have not you, and men of science in general, a right to ask your impassioned friend and determined enemy "Parallax" to prove that he has some clearly-defined, or, at all events, some intelligible theory of the motions of the heavenly bodies, and some conception of what that theory involves, by (1) constructing a set of tables which would enable us to find our way about on the earth; or (2) by forecasting for us such events as eclipses, planetary transits, &c.; or (3) by showing how it comes to pass that if the upholders of the Newtonian theory be the fools, or impostors, or empirics which he asserts them to be, their forecasts are so invariably justified by results?

And if he refused, or were unable to give an account of himself in some such way, to forbid him, on pain of a writ "*De lunatico inquirendo*," to open his mouth, or write, or ever send telegrams on this subject as long as he lived, to any living man, saving only Mr. Newton Crosland. Your obedient servant (and admirer and well-wisher),

Winter.

P.S. It would be interesting to discover what would be the result of the meeting and intermingling of chaos with chaos (in the way hinted at above)—whether it would be order or annihilation.

[It was a favourite idea of the late Professor De Morgan's to set paradoxer against paradoxer. It is singular that they only agree in attacking the theories which men of science agree in accepting. They never agree among themselves. Each may have a follower or two, or even ten or twenty; but they do not follow each other.—Ed.]

PYRAMID MEASURES.

[56]—With reference to your remark about the coincidences, I may remark that my mathematical knowledge does not enable me to prove that it is possible to produce the same coincidences by the use of any other values of the diameters and distances of the three bodies, and of the scale of reduction, than those I have given; if, however, it can be proved to be possible, then I admit my conclusions will not be entitled to the consideration which at present I claim for them. And further, if the next transit of Venus be observed, as it ought to be, and the resulting value of the sun's distance proves to be identical, or very nearly so, with the value I have derived from the pyramid measures, will it be quite satisfactory to a mind of average intelligence to say that the agreement is a mere coincidence? Of course, you may reply that this argument has no present value; nor am I inclined to attach much weight to it, because, looking at the results of past transits, it is scarcely to be expected that the next will finally settle the question of the sun's distance, and yield a result in which all astronomers will concur, and which will be more reliable than the one derived from the pyramid measures. Probably the results of Professor Winnecke's new method of determining the sun's distance from Venus observations will be more accurate than any of the results obtained by other methods.

I think a much greater interest is now being taken in the pyramid than you seem to be aware of. An active correspondence has been going on this week in one of the Manchester papers, in which, however, I have taken no part; and a lecture was delivered there on Wednesday evening. Lectures are also being given in other towns and districts, and the pyramid is apparently fast becoming a household word.

I notice printer's errors in four of my equations which render them unintelligible. I enclose a list of corrections of four of the formulæ in my paper.—Yours, &c., Joseph Baxendell.

INTELLIGENCE IN ANIMALS.

[57]—Some years ago my father, who was a medical practitioner in Somersetshire, had a valuable horse, which eventually he was obliged to part with, as it was vicious, and not always safe to drive. During the time my father drove it, he had occasion to visit daily for several weeks an old gentleman who had met with a serious accident. His patient lived at the bottom of a steep lane, which branched off at right angles from the main road, at about 3½ miles from the town where my father lived. This horse was always used for visiting this patient, and during the first two or three weeks, when there were dangerous symptoms, was frequently driven down the lane twice a day.

The farmer to whom my father sold this horse lived at a distance of several miles beyond this turning on the same road, and attended regularly the market in the town where my father lived, and necessarily passed this sharp turning both going and returning therefrom. Some three or four years after purchasing this horse, he had occasion to drive into the town to fetch my father to attend his wife. As the case was urgent, he got into the gig, and was driven by the farmer towards the farm where he lived. Suddenly, without the slightest warning, the horse turned down the lane he knew so well, nearly capsizing them.

As soon as they had recovered themselves, the farmer exclaimed that "he had never known the horse do such a thing before all the years he had had it." My father was surprised, and said, "Not when you have driven this way to and from the market?" The farmer replied, "that the horse never even so much as looked at the turning, whilst he had driven it, until now." "Well," said my father, "he must associate me, knowing that I am in this gig, with the many visits he used to pay with me down that lane, when I attended my poor old patient at the bottom, after his accident. I patted his nose before starting, and he knows by my voice that I am behind him. His memory has served him well, and he concluded that I must be going the same journey we performed together so many years ago." My father always considered this fact evidence of reasoning powers in the

horse, and although I incline to the same opinion, I will not comment upon it, but content myself with simply relating this anecdote. A. H.

Nov. 19, 1881.

---

[58]—A singular instance of *apparent* prescience in a dog occurs in an account given Nov. 21 of a father shot by his son. Here is the evidence of the wife and mother :—

"We heard nothing to disturb us after retiring to bed until about half-past two o'clock next morning. About that time a little dog which belonged to my husband, and was a great favourite, came upstairs, and jumped upon our bed. My husband tried to make the dog go away, but he could not do so, as the little thing seemed so 'fussy.' At last he thought the best thing to do would be to take the dog downstairs, and by shutting the door at the bottom, prevent it from returning. My husband got out of bed, and took the dog in his arms for the purpose of carrying it away. In about half-a-minute, and when he was on the stairs, I heard a loud report, as if a pistol or a revolver was being fired. This was repeated twice, and the deceased then shouted out at the top of his voice, 'I am shot!' "

The peculiarity here is that the coming danger, of which the animal appeared cognisant, could only have been imparted by the footsteps or other movements of *a member of the family;* this, under ordinary circumstances, could have given no such premonitions of danger to the dog. Has any similar case been observed?

Bark.

---

[59]—In the article on "Intelligence in Animals," in No. III. of Knowledge, p. 46, the writer speaks of animals possessing the power of practical reasoning, but not abstract. Does not the following anecdote show a power of more than merely practical reasoning? I do not know whether it has been quoted by anyone else in this relation to Darwin's theory.

Two students were in the habit of visiting each other at their respective rooms; each had a dog. On one occasion both dogs were left outside the room while their owners were inside. The dogs began to fight, which ended in their being admitted into the room and kept at a distance from each other. On a subsequent visit one dog was absent, and the other dog was put outside as before. The two students were soon after surprised by hearing what they thought was their two dogs outside fighting. On opening the door the dog walked into the room, which was the end he desired. He had remembered the reason why, on a previous occasion, both he and the other dog had been admitted into the room, and he had acted accordingly.—Yours, &c. Frederick G. Abbiss.

REASON IN ANIMALS.

[60]—In support of the view that animals possess a certain amount of reasoning power, I would contribute the following instance, which has not hitherto been published.

During my boyhood my father had the shooting over some property adjoining a deer-park, and we owned at this time a very intelligent setter, which used also to retrieve. One day my father shot and wounded a hare, which made its way through a hole in the park-paling. The dog leaped the paling, caught the hare, and brought it back to the fence in its mouth. It then tried several times to return by leaping the paling, but the weight of the hare prevented it from reaching the top. After resting awhile it bethought itself of the hole through which the hare had come, and, taking the hare to this hole, it pushed it through, then leaped the park paling, and brought the hare to my father.—I am, sir, your obedient servant, R. Clement Lucas, B.S., F.R.C.S.

Dec. 18, 1881.

ARE WOMEN INFERIOR TO MEN?

[61]—I read with much pleasure your remarks on the question, "Are women inferior to men?" It occurs to me that if we are inferior in brain capacity, the reason may be that sufficient care is not taken to develope the brain. We all know the size of the hand is increased by constant work—at least of a particular kind. And constant use of the other parts of the body usually leads to an altered and probably heavier formation. Now, in a girl's education the brain is but slightly exercised. Music and needlework, which occupy so much of her time, scarce exercise it at all. And even the part of her education which does require brain-work seldom calls it forth vigorously. She has fewer rewards to look forward to if she succeeds, and fewer punishments if she idles. Many idle boys require whipping—and get it. Many idle girls require whipping—and do not get it. Then, just when the boy is about entering on the most active part of his brain-work in a University, the girl is taken from school, and sets out on a new course of *flirting* and *husband-catching*. She is sometimes at this work, and perhaps even married at an age when the boy who idles would be whipped—as she ought to be. Again, in her after-life, she has but rarely much brain-work to do, and the development of the brain is probably not maintained. But I should be surprised to hear that the brain development of George Eliot, or George Sand, for instance, was inferior to that of the average male, and if it was, it would prove that the quality, not the quantity, of brain was the really important point. If girls were as well taught at schools as boys, got as much brain-work to do, and were then sent to universities, and did not begin to look for husbands until they were twenty-two or twenty-three years old, I have no doubt their brains would be much improved. I know my views on whipping will be unpopular, but if the sexes are equal, as I contend, why not treat them alike?—I remain, &c., Susan G.

EFFEMINACY OF APPEARANCE.

[62]—Can any of your readers give me a description of the characteristic difference between the physiognomy of the male and female of the human species? You may sometimes see men whose features might be called effeminate; now in what does this peculiarity consist?

The article on the question "Are women inferior to men?" brought this to my mind. Physiognomist.

OPTICAL ILLUSION.

[63]—In regard to the optical illusions, there may be added to the instances adduced in Mr. Foster's article, one of circles.

If, say, a 2-inch hole be cut in a piece of brown paper and an inch periphery left round it, and, again, another 2-inch hole be cut with a three inch periphery, the two holes, although exactly the same size, will appear not to be so.—I am, &c.,

Percival A. Fothegill, F.R.A.S.

A "LUNAR ILLUSION."

[64]—I have frequently noticed what your correspondent M. calls a "Lunar Illusion" (No. 23, p. 57), but I have always supposed a different reason for it, and I hardly think that M.'s arrow hits the mark.

Let us suppose a lighthouse on our horizon; we know that a straight line from it drawn through the moon would bisect it very differently from a line drawn from the setting sun (below, in fact), though the sun would appear in the same place as the lighthouse, and a line from it would, of course, seem as if it ought to bisect it in the same way. The *enormous comparative distance* of the sun seems to me the true reason; and I have sometimes thought that a rough idea of his distance might be made by taking the angle of M.'s sagitta when the moon is near the zenith, knowing, of course, the distance of our satellite from the earth.—I am, sir, yours, &c.,

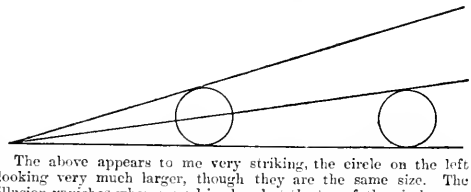
Cleveland Lodge, Sydenham. S. H. W.

TELESCOPES.—OPTICAL ILLUSION.

[65]—Would it be in accordance with your plan to give a popular description of the different kinds of telescopes, with the apparatus, giving a few hints to amateurs in obtaining them, explaining among other things the following :—

The Terrestrial Telescope.
„ Astronomical „
„ Newtonian „
„ Equatorial „
„ Huyghenian Eye-Piece.
„ Pancreatic „ „
„ Kitchener's Pancreatic Eye-Piece, &c., &c.
„ Different ways of mounting.
„ „ kind „ stands.
„ Power that object glasses will bear, &c.

As the circulation of Knowledge increases, as I am sure it will do, you may be able to spare a portion of space in each number to the above subject.



The above appears to me very striking, the circle on the left looking very much larger, though they are the same size. The illusion vanishes when a card is placed at the top of the circles.

F.H.S.

SOLAR HEAT.

[66]—Referring to Letter 2 (page 15), I am of opinion that whatever conditions apply to this earth apply also to the sun, only in a greater degree. The matter of which the earth (and all the planets and satellites) is composed, once formed part of the sun, which has gradually condensed and left each planet behind in its turn. Geologists tell us that at a period inconceivably remote our globe was in a state of intense heat. This is practical proof that the sun is in a similar state. Referring to Letter 28 (page 58), Mr. Newton Crosland endeavours, by one fell blow, to annihilate the great law of universal gravitation. In promulgating this great law, Newton cleared away heaps of the cumbrous rubbish with which the old schools of astronomy were hampered. Emerson says: "The tendency of all science is to simplify." Mr. Crosland endeavours to complicate. Yours, &c., John Thomson.

IS THE SUN HOT?

[67]—It may interest your readers to know that this subject was discussed in *Design and Work*, Vol. VII., under the question, "Does the Sun Warm the Earth?" The leader of that discussion endeavoured to prove that we receive our heat from the earth, and not from the sun! Under the title of "The Great Primordial Force," it has also received the attention of Henry Raymond Rogers, M.D., of Dunkirk, N.Y., in a paper published in the September number of *Progress of Science*. In this paper, Dr. Rogers propounds a similar opinion to that expressed by your correspondent, "Cogito," in letter 24. G. E. Bonney.

THE SUN'S HEAT AND THE EARTH'S RADIATION.

[68]—I have read the replies to Anti-Guebre's question (which, like yourself, I have frequently encountered before); but in all of them, including your own, one important factor is omitted—viz., the difference between the obstructive or absorbent power of atmospheric vapour to the rays of heat from different sources. The sun-rays, as several correspondents have stated, pass through our ordinary atmosphere with but little absorption; but this is not the case with "obscure rays," or rays from a less heated and non-luminous source. Hence the earth warmed by the sun does more to warm the air than the sun itself does, because the heat it radiates is absorbed by the air, and also because it warms the air by direct contact and the commingling of the portion of air thus heated with that above, or "convection." It appears to me that even our best treatises give too much credit to this latter action, and too little to the first. The following experiment which I tried many years ago on Mont Blanc, at an elevation of between fourteen and fifteen thousand feet, is instructive. My coat was wetted by falls on the sloppy surface of the glacier below, and at the elevation above-named, I noticed that the coat-tail opposite the sun was thawed, while that in the shade was frozen and stiff. By slowly turning round like a joint of meat before a roasting fire, I alternately thawed and refroze all sides of my coat-tails in about one minute, as nearly as I can remember. The direct rays of the sun were painfully scorching, and skinned my face and ears completely, but in the shade, the thin and highly-dried air permitted a far greater degree of radiation of obscure heat to take place than down below. Hence the freezing. I do not write this to controvert the other explanations given by yourself and correspondents, but merely to supply an additional factor.

Thus, the cooling effect of night radiation is far more effective above than below, seeing that the amount of resistance to the passage of the obscure rays is so greatly diminished there. This is strikingly shown by the sudden freezing of the rills and streamlets, which are such remarkable features of a glacier surface during the summer's day. They all stop as the sun sets, and the sloppy surface of ice is dried, as was the shady side of my wet coat.

W. Mattieu Williams.

LIGHTNING IN NOVEMBER.

[69]—Last night (Nov. 4) at 10.30 p.m., in a perfectly cloudless sky, the flashes of sheet lightning were vivid and incessant. Is not this very unusual at this time of the year? A strong gale was blowing in the Irish Channel at the time.—Yours, &c.,

Liverpool, *Nov.* 23, 1881. E. S.

LOGARITHMS.

[70]—Mr. Grundy asks for information on an important item in connection with Logarithmic work, viz., the tables. Many students give up in disgust this simple process of calculation because they have been unfortunate in their choice of books.

I have been in the habit of using Logarithm Books for many years, for work of every description, and with pleasure give him my experience.

In a long series of logarithmic calculations, the book to use will depend on the number of figures we require in the desired result. For instance, in doing 4-figure work, it would be a loss of labour and time to use a 7-figure table.

The following are the tables I have used with great comfort:—

For 4-figure Work:—

Table of Logs and Anti-Logs, published by Layton, price 1s. (Very useful.) This requires simple interpolation.

Table of Logs and Anti-Logs (Hannyngton), published by Layton, price 5s. A comfortable table, but rather dear.

For 5-figure Work:—

Table of Logs, published by Smith, Elder, & Co., price 1s. 6d. A good book, and well worth the money.

Table of Logs by Gauss. Better than the above, but requires a little more practice. It contains many other useful tables. Can be had of Trübner, price about 1s. 6d.

For 7-figure Work:—

Table of Logs by Bruhns. The best book published; I strongly recommend it. Can be had of Trübner, price about 4s. or less.

Table of Anti-Logs by Filipowski. This is a useful book when many Anti-Logs are required. Published by Bell & Daldy.

Abacus.

THE PRIMARY COLOURS.

[71]—In the little Treatise on Optics, forming part of the course of "Natural Philosophy," published in 1862, by the Commissioners of National Education in Ireland, a statement is put forward with respect to the constitution of the solar spectrum, which differs from that set forth in other similar works upon chromatics.

The correctness of that statement is borne out by what I myself conceive to be the appearance of the character of the colour of violet light, yet I confess I am puzzled to make out how, upon the explanation offered, the colour of the light in question is to be accounted for.

The commissioners, after describing in detail Newton's experiment of breaking up solar light into its seven coloured constituents, continue their statement as follows:—

"In reality, blue, red, and yellow are the only colours present, the rest being combinations of them. For the spectrum consists of a layer of each of these colours, superimposed on the other—the blue, the red, and the yellow appearing distinctly at those points at which they are most vivid in the superimposed and corresponding layers."

"The three colours of which the spectrum is really composed are thus divided among the seven which it contains, calling red rays R, yellow Y, and blue B.

White	Red.	Orange.	Green.	Blue.	Indigo.	Violet.
20R + 30Y + 50B	8R	7R + 7Y	40Y + 10B	7Y + 12B	12B	16B + 5R."

Thus far the commissioners.

As I have said, the impression produced on my eye bears out distinctly the statement as to the occurrence of *red* light in the violet exhibited by a really pure prism of dense flint glass. Yet if the spectrum consists simply of the layers of the three colours in question superimposed, it is difficult to conceive what appearance each of those spectra would present, could we manage to obtain it isolated. In what form, for instance, would the red spectrum present itself? From the above table we learn that no red exits in the yellow, green, blue, or indigo, while a considerable amount of red is met with again in the violet. Would the red spectrum exhibit a wide, blank interval, extending from the yellowish end of the orange up to the violet end of the blue?

An explanation of this matter, "plainly worded, exactly described," will doubtless be an easy task for you, and will probably prove a boon to others besides,

Yours, &c.,

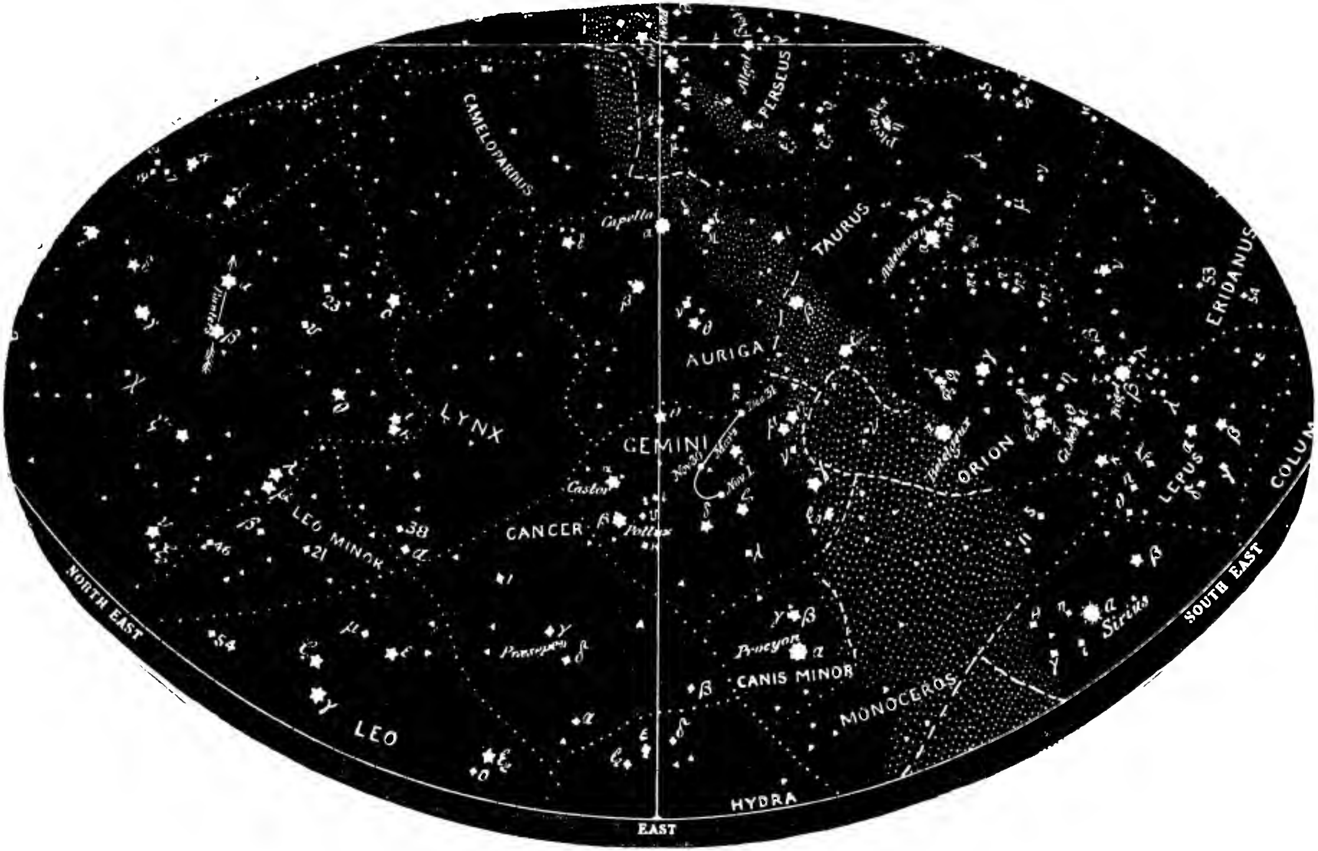
Mabel Winfred Lain.

PHRENOLOGY.

[72]—Will you allow me to make a few observations, in answer to the first query contained in letter 32, p. 59, entitled "Phrenology"? "G. P." says: "Assuming that phrenology is all wrong, what are the causes that determine the shape of the head?" I would observe at the outset that if we assume phrenology to be "all wrong," there can be no satisfactory explanation given of the diversities in the shapes of heads. A common answer to the query "Why are no two heads alike?" is, "Why are no two faces or hands alike?" The simplest answer to this last seems to be, that no two human natures are alike, and this will apply to the first also, when we consider that the varieties we discover in the

[Continued on page 99.

THE EASTERN SKIES IN DECEMBER.



This Map shows the position of the stars in the Eastern Skies. —

On November 30, at $10\frac{1}{2}$ o'clock.	On December 8, at 10 o'clock.	On December 16, at $9\frac{1}{2}$ o'clock.	On December 23, at 9 o'clock.	On December 30, at $8\frac{1}{2}$ o'clock.
On December 4, at $10\frac{1}{4}$ o'clock.	On December 12, at $9\frac{3}{4}$ o'clock.	On December 19, at $9\frac{1}{4}$ o'clock.	On December 27, at $8\frac{3}{4}$ o'clock.	On January 3, at $8\frac{1}{4}$ o'clock.

The movements of the planet Mars, which is travelling in this part of the stellar heavens at present, are indicated by the curved line marked with this planet's name. We show its path during the last month as well as December. He is now retrograding at his greatest rate. He passes his opposition, or is exactly opposite the sun, so as to come due south at midnight, on December 27. The stars in the Eastern skies are passing upwards from the horizon, moving aslant, from left to right.

⁂ Stars of the first magnitude are shown with eight points, those of the second with six, of the third with five, of the fourth with four, of the fifth with three.

Continued from page 96.]
shape of the head are the same varieties that exhibit themselves in the whole external form of man. Now, if these differences of bodily structure are marks of diversity of nature, the inequalities of the skull (which cannot be exempt from the process) will also indicate the same, or to come to the point, will indicate diversity of brain conformation, which is just the doctrine of phrenology. Assuming it to be established, then, that the "cause that determines the shape of the head" is peculiar conformation of brain, the pertinent remark of Professor Lawrence forms a fitting supplement :—"If the mental processes be not the function of the brain, what is its office? In animals, which possess only a small part of the human cerebral structure, sensation exists, and in many cases more acute than in man. What employment shall we find for all that man possesses over and above this portion—for the large and prodigiously developed human hemispheres? Are we to believe that these serve only to round off the figure of the organ, or to fill the cranium?"

With regard to the opinion of Mr. G. H. Lewes, that the brain acts as a whole, and that its functions are not localised, one merely requires to point to Dr. Ferrier's researches in cerebral physiology, by which it has been proved that the *individual convolutions are separate and distinct organs.* A. B.

POPULAR ELECTRICITY.

[73]—I write to suggest that now that electricity is becoming of such vast importance in the world, it is very desirable that a sound elementary knowledge of its principles should be widely disseminated, and that KNOWLEDGE might be an available medium for contributing to this result. Would it not be a good thing that a series of papers on this subject (including magnetism) should be published in KNOWLEDGE? The papers should be simple, and should suggest experiments which any person of intelligence might try for himself without elaborate or expensive apparatus. Something in the style of Tyndall's "Lessons on Electricity," but extending, of course, to current electricity. I venture to think that such a series, if produced by a competent hand, would be extremely popular with young people, whose desire for information in this direction is very great.—Yours, &c., DANIEL JONES.

COMETS' TAILS.

[74]—I have read with great interest your excellent paper on Comets, but am sorry to find no other theory can be introduced to account for the tails always pointing away from the sun, except that of solar repulsion. Such a theory, I am sure, should not be adopted without the most conclusive and perfect evidence of its existence; because, if we introduce a resisting medium into the solar and stellar system, we see in it the germs of its own destruction, which, although for a time making no effect upon the movements of the ponderous planets, must, in the end, make itself felt, even though that medium be of the rarest tenuity. I once heard a theory propounded, that comets were simply lenses, and the sun shining through them produced the appearance of a tail; that might apply to telescopic comets, without any indication of a nucleus, but not otherwise, for Sir John Herschell tells us the nucleus of a comet is opaque. The theory is, as far as I know, a novel one, and the readers of KNOWLEDGE must judge for themselves of its value.—Yours, &c., J. D.

THE SUN'S DISTANCE.

[75].—The latest determination of the velocity of light, by Michelson, gives 186,305 miles per sec. *in vacuo.* Supposing that the time interval for the passage of light across the major axis of the earth's orbit, which is given as 986·6 secs., may be relied on to the $\frac{1}{10}$ part of a second, as is likely, considering the numerous and accurate observations on Jupiter's satellites; may not the deduced semi-axis of the earth's orbit, which is 91,904,256 miles, be trusted as far as the first four figures? The corresponding parallax would be 8″·895, round which all the best determinations seem to centre, such as 8″·88 from transit of 1871, 8″·91 by Hansen's lunar method, 8″·894, and 8″·855 from observations on Mars. It appears that Michelson's method, which is based on an extension of Foucault's, gives a result which may be relied on almost down to the unit's place: for the interval to be measured was the passage of light over a distance of about 1,000 yards, and the direct deviation obtained was about 150 times that obtained by Foucault.—Yours, &c.

Marlborough College, Nov. 19, 1881. H. L. CALLENDAR.

[Considering the somewhat wide discrepancies between the observed time of appearance and disappearance of Jupiter's satellites, according to the telescope employed and the observer's eyesight, we should be disposed to doubt whether the method referred to can be trusted as likely to give results to the degree of accuracy you mention. Aberration is regarded as more trustworthy. ED.]

THE METRICAL SYSTEM.

76.—Sir W. Thompson, in his address at York, referring to the metrical system, says, "to it we are irresistibly drawn in all scientific and practical measurements, notwithstanding a dense barrier of insular prejudice most detrimental to the islander."

It would be superfluous to enlarge here upon the many advantages of the metrical system of weights and measures which are set forth and explained in so many elementary treatises; but if you could find space in your columns for two or three examples, illustrating the saving of labour that their adoption would introduce into the computations of every-day life, I cannot but think that you would make converts, and by facilitating calculation, promote accuracy, the stepping-stone to all knowledge.

Take an ordinary example from agriculture :—

A field of 6 hectares, 41 ares, 66 square mètres, sown with wheat, at 250 litres to the hectare, would require

$6·4166 \times 250 = 1,543·8500$ litres,
$= 15$ hectolitres, 44 litres of seed.

If the wheat is of specific gravity 0·80, the whole quantity would weigh $1544 \times ·80 = 1235·2$ kilogrammes.

Again, the seed required would be
2·5 litres for every are,
or 0·25 litres for every square mètre.

Let the same field be ploughed up to the depth of 2 decimètres (nearly eight inches), and suppose that the specific gravity of the soil is 2, every square mètre of the soil ploughed up will weigh $2 \times 2 \times 100 = 400$ kilogrammes, and the whole soil of the field ploughed to the depth of 2 decimètres will weigh

$64,166 \times 400 = 25666400$ kilogrammes,
$= 25666·4$ metrical tons.

It then becomes very easy to compute the proportion of any manure to the available soil.

Let the amount of manure applied be 1,000 kilogrammes per hectare :—

1000 kilogrammes per hectare
= 10 kilogrammes per are
= 100 grammes per square mètre
= 1 gram per square decimètre, or 2 cubic decimètres of soil.

$= \frac{1}{4000} = ·00025.$

If the amount be 600 kilogrammes per hectare
= 6 kilogrammes per are
= 60 grammes per square mètre
= ·6 gram per square decimètre

$= \frac{·6}{4000} = ·00015.$

When great accuracy is required, the use of logarithms will, of course, much facilitate the calculation, but they may be dispensed with for ordinary practical purposes. Now, let anyone try to work out such simple problems with a field of the same size expressed in English measures, viz., 15 acres, 3 roods, 17 poles, and the seed sown at 3 bushels per acre. He will see what an amount of labour they involve. Indeed, at the outstart, we are met with such an anomaly as this, that while the yard is our standard measure of length, few persons could give the length of the side of a square statute acre, such side being 69 yards and a long fraction (69·5701). Nor is the matter much facilitated when we find that $30\frac{1}{4}$ square yards go to one pole.

Should you think these remarks not too technical, I shall recur to the subject with some other examples in a future number, and beg to subscribe myself, yours, &c.,

MICROCRITH.

[We thank "Microcrith" for his excellent illustration of the value of the metrical system. It is actually easier in dealing with the second form of the above problem to convert the English measures into the metrical system, then to work the problems as "Microcrith" has done, and to turn the answers into English measures, than it is to work them throughout with the English measures.—ED.]

CAUSE OF GRAVITY.

[77]—In your note to letter No. 31 (page 59) on this subject, it is stated as a "demonstrated fact that the action of gravity is communicated far more rapidly than light travels." I beg to ask an explanation of this, as I was not aware that the action of gravity was "communicated" at all in the sense of "travelling" (or of crossing over a space during a greater or less lapse of time). As far as my present knowledge goes, the statement reminds me (I give

to illustrate my point, I may cite the remark of a friend who said he knew something which "travelled" quicker than light, and on being asked to explain, answered *sight*. I had some difficulty in explaining to him that sight was merely a mental interpretation of sensation produced on a *passive* organ by the light which had already "travelled" from the distant object to the organ in question.

Unless I have been misinformed, the present tendency of scientific thought is to do away with the idea of "attraction" altogether, as a figment of the intellect. What we call gravity, or any other form of so-called attraction, is merely the tendency to fall in the direction of least push. Thus, suppose a railway truck between two engines tending to push it in opposite directions. It cannot move both ways at once. It therefore moves in the direction of the weaker engine. Something analogous to this is the modern explanation of attraction so-called. A stone falls to the earth because the pressures exerted on it are least in the direction of the earth—no attraction at all in nature—all push and strife.—Yours, MUDDLERSBROUGH.

---

[78]—I was much gratified to find this question raised in the last number of KNOWLEDGE. It is an exceedingly interesting subject, and one I would like to see treated in a competent manner. In an article by yourself, entitled "The Mystery of Gravity," you intimated that you might at some future time describe a method by which gravity might be generated and propagated, founded on the views of Le Sage. I write from memory, and therefore cannot be certain of the exact words. Will you kindly say whether this promise has ever been fulfilled? If not, would you kindly favour the readers of KNOWLEDGE and myself by stating your views on this truly great question.—Yours, &c., T. J. HICKIN.

ELECTRICAL BELLS.

[79]—As a subscriber to your promising weekly, I have come across the extract from the *Times*, No. 1, page 14, wherein the writer recommends electric bells for private houses.

I beg to say from long experience, electric bells are very troublesome in private houses, however they may answer in hotels, where there is generally a *yearly charge* to keep them in order.

There is a better system in use in Government offices, and that system is the pneumatic, which is so simple and durable, that I wonder the *Times* should ignore "pneumatic" while writing up "electric."

I have pneumatic in my house, and the excellency of the whole arrangement is, beyond question, worth bringing to the front, certainly quite as much so as electric is by the *Times*. There is no battery nor anything whatever to attend to.—Yours truly,

M. TESTER.

THE FIFTEEN PUZZLE.

[80]—I enclose a *short* proof, which I gave in the *Brighton Herald* for May 22, 1880.

Take 15 tickets, numbered from 1 to 15, and arrange them in a row in any order. Let every instance in which a lower number is further on in the series than a higher number be called a disarrangement. Note whether the number of such disarrangements is even or odd. A cyclic interchange of any odd number of the tickets will make an even difference in the number of disarrangements, and, therefore, no combination of such interchanges can convert an order with an odd number of disarrangements into an order with an even number of disarrangements.

Now arrange the 15 tickets in a square, and bring the blank space to the place it is to occupy finally. Then after this, the game consists of the travels of this blank space over the board, finally ending where it started. The route pursued consists partly of tracks followed and again retraced, which make no ultimate difference to the number of disarrangements and partly of closed paths travelled round, which are cyclic interchanges of an odd number of tickets. No number of such operations can make the number of disarrangements zero if it happened originally to be odd.—Yours, &c., ARTHUR BLACK.

---

[81]—As you invite correspondence, I send you the enclosed very remarkable arrangement of figures. A year or two ago I sent them to the publisher of juvenile books. I believe it was not attended to. If so, I am of opinion that it is unknown.

At first sight it seems a confusion of figures; but, on examination, the arrangement will be found to be very simple.

You will perceive that the unit 1 is placed under the central square; if you follow the figures to the end, all confusion will vanish. To understand it is a very different thing.

West Brompton, Nov. 11, 1871. H. S.

The square of *all odd* numbers may be so arranged that the totals of all the columns—perpendicular, horizontal, and diagonal—shall be the same. And the totals will be the *larger** half of the square multiplied by the odd number. Thus the totals of

5 × 25 ÷ 2 = 13 × 5 = 65, the total.
7 × 49 ÷ 2 = 25 × 7 = 175 ,,
9 × 81 ÷ 2 = 41 × 9 = 369 ,,
11 × 121 ÷ 2 = 61 × 11 = 671 ,,

SQUARES OF "ODD" NUMBERS.

5 *totals* = 65.

11	24	7	20	3
4	12	25	8	16
17	5	13	21	9
10	18	1	14	22
23	6	19	2	15

Square 25 ÷ 2 = 13 × 5 = 65, the totals.

7 *totals* = 175.

22	47	16	41	10	35	4
5	23	48	17	42	11	29
30	6	24	49	18	36	12
13	31	7	25	43	19	37
38	14	32	1	26	44	20
21	39	8	33	2	27	45
46	15	40	9	34	3	28

Square $\frac{49}{2}$ = 25 × 7 = 175, the totals.

9 *totals* = 369.

37	78	29	70	21	62	13	54	5
6	38	79	30	71	22	63	14	46
47	7	39	80	31	72	23	55	15
16	48	8	40	81	32	64	24	56
57	17	49	9	41	73	33	65	25
26	58	18	50	1	42	74	34	66
67	27	59	10	51	2	43	75	35
36	68	19	60	11	52	3	44	76
77	28	69	20	61	12	53	4	45

Square of 9 × 81 ÷ 2 = 41 × 9 = 369, the totals.

This is a known method of making magic squares. We find in the magic square for the numbers 1 to 9; thus:—

4	9	2
3	5	7
8	1	6

in which also other methods of solution are indicated.—ED.

---

* The *larger* half means the actual half plus ½.

Queries.

[29]—Garden Tripod Stand for Telescope.—Could any of your readers tell me how to make a cheap garden tripod stand for a 3-in. glass, and where to get the several parts? The cheapest I can buy is £1. 1s., and that seems so dear for so simple a thing. Ignoramus.

[30]—Solar Heat.—With respect to the sun being hot, will you kindly explain to me why some countries are warmer than others? If it is because they are nearer the sun than the cold ones [but it is not—Ed.], why, then, should not the top of a mountain be warmer than the bottom? On a man going into a tropical country, he naturally gets brown-burnt by the sun (?). Does the sun act directly on the man, or does it first enter the earth, and the man, as it were gets the reflection?—Warmus.

[31]—Intensity Coils.—Can you inform me how to estimate the maximum battery-power which may be used with any given intensity coil, without incurring the risk of destroying the insulation? Can you afford me any practical hints as to the best way of restoring one so damaged without having recourse to a coil-maker? I presume it will be necessary to replace the secondary coil with a new one—but how?—Δ.

[32]—Engraving on Copper.—Want to know the usual method of engraving on copper, what the plate is covered with, and the materials used? Is it sulphate of copper and salt, or what? Engraver cannot get any cheap handbook bearing on the subject.—Engraver.

[33]—Astronomical Slides.—Can any of your readers give me a few hints how to prepare the above for a lecture on popular astronomy; also, how to make a good opaque black for same?—C. J. S.

[34]—Three-handed Chess.—Can any of your readers inform me of a way of playing chess with three players only? The four-handed game is well known to me.—Geo. H. Verney.

[35]—With reference to the calculations concerning the four asteroids and the magnitude of the third satellite of Jupiter, have there been found any great differences since 1846?—S. S. S. S.

[36]—Laplace's Theory.—Do you consider Laplace's conclusions with reference to the physical forces and evolution sound, as far as we now know?—S. S. S. S.

[37]—Vestiges of Creation.—Who is the author of "Vestiges of the Natural History of Creation," and do you consider it reliable?—S. S. S. S.

[38]—Density of Neptune.—What is the density of the planet Neptune, and how many of his satellites have been discovered?—S. S. S. S.

[39]—The Moon's Rotation.—The moon turns once on its axis in exactly the same time that it takes to revolve once round the earth. Is there any law or theory as to the cause of this, or is it a mere coincidence?—C. O. K.

[40]—Fine Drilling.—Professor Edward C. Pickering, of Harvard College, says that in undertaking to measure the intensity of the light of the satellites of Mars, he had occasion to need an extremely small hole. Among the artisans who essayed to furnish what was required was one who had succeeded in making a hole edgewise through an old-fashioned three-cent piece, and another who had pierced a needle through from end to end. A hole about the twenty-five-hundredth part of an inch in diameter was finally secured.—(*Public Opinion*, Nov. 19, 1881, p. 658.) Have you any knowledge of the above? Assuming that there is no mistake, an account of the mechanism employed, and of the boring instrument, would be of interest.—A. T. C.

[41]—The Planet Vulcan.—Is anything more known of the planet Vulcan; and is it believed to be certainly in existence?—S. S.

[42]—Magnetoscope.—Is there any instrument made for the purpose of measuring the amount of magnetism, and also electricity in the human body? I think I have heard of a "magnetoscope," but know no particulars.—S. S.

[43]—B.Sc. and D.Sc. Examinations, London University.—I am desirous of obtaining such a knowledge of science as would enable me to answer such questions as are set in the B.Sc., and even the D.Sc. examination papers of the University of London. What books would you recommend for this purpose? I shall be extremely obliged for an answer to this.—An Enthusiast.

[44]—Illumination of the Solar System.—May I, as a reader of Knowledge, request you to give me and my fellow readers some sound instruction on the subject of the new theory started by Mr. Collyns Simon, on the "Solar illumination of our system"? I have seen attention called to it by several foreign periodicals, but none by the English. Are we to accept it as possible, or reject it as impossible?—V. A. T.

[45]—Cause of Gravity.—What is the cause of gravity? There is an interesting article, if I recollect rightly, in the old "Encyclo. Lond.," giving the views of Sir Richard Philips on this matter. Philips believed that all the phenomena attributed to attraction might be accounted for by the laws of motion. Meter.

[46]—Planetary Rings. Are these not evidences of matter more or less plastic beyond the solid planetary nucleus, the phenomena presented by the denser and cloud portions of the atmospheres of planets, ranging themselves centrifugally, in belts? This globe, in my view, would appear belted in other planets. This explanation might be illustrated experimentally. Meter.

[47]—Optical Illusions. Are these not all due to the simple law of contrast?—Meter.

[48]—Trisection of an Angle.—I shall be glad if any of your readers can inform me how to trisect *any* angle. A small diagram will greatly assist.—Euclid.

[49]—Lifting Man's Weight.—Could you kindly inform me how it is that four men appear to lift a fifth so easily when they all inspire their breaths together? Is it simply a trick, or is there some scientific explanation of it? I should esteem it as a favour to have an answer in your next issue.—D. H. B.

[50]—Wasted Energy?—A certain amount of energy is supplied to an electric lamp in the form of current electricity. A small part reappears as heat, the rest as light. What form does the energy radiated as light vibrations take as the light is constantly absorbed by surrounding objects?—A. H. H.

[51]—Botany Lectures.—Can the Editor or a reader of Knowledge tell me of any first-class lectures on Botany, embracing such subjects as are not included in the ordinary lectures given at the various science schools, but are required for the S. and A. Honours Exam.? Do not any of the masters of the subject teach, either by lecture or correspondence?—Nemo.

[52]—Microscope.—Can anyone oblige by recommending what they consider from experience to be the best microscope for botanical and biological work; cost, with all necessary appliances, not to exceed £10.?—Nemo.

[53]—Suggestion.—Botanical Papers.—If the Editor of Knowledge should see fit to introduce into his useful and interesting paper a series of articles on botanical subjects, I think many readers would welcome them with pleasure, as the subject is one that is now so widely studied, and the new discoveries and theories of the learned do not appear in the text-books till long after date. A column devoted to this subject would surely be as approprioté to Knowledge as a chess or whist column. Nemo.

[54]—Chemical Questions.—1. In testing a solution of ferrocyanide of potassium with chloride of ammonia, ammonia in excess, and hydrosulphuric acid, no precipitate was obtained. Could you explain why no precipitate was thrown down, since iron is one of the third group of metals? 2. Strong solutions of bisulphate of potassium and potassic iodide were separately treated with tartaric acid. No effect, even when stirred on a glass surface. Why was there not a white precipitate following the course of the stirring-rod?—Castor and Pollux.

[55]—Future of Greek Verbs.—Is there any rule for the lengthening or otherwise of the vowel when forming the future of a pure verb in Greek. For instance:

φιλεω	makes	φιλησω
καλεω	,,	καλεσω
τιμαω	,,	τιμησω
ἐραω	,,	ἐρασω

Why should the ε be lengthened to η in φιλεω and not in καλεω?—Castor and Pollux.

[56]—Can you kindly recommend a book covering the chemistry for the South Kensington Honours Syllabus?—Castor and Pollux.

[57]—The Great Bear.—In what latitude would this constellation become invisible for three months of the year, by dipping below the northern horizon? Is the upper pointer (Dubhe) the most western star of the constellation, and the tail star (Benetnasch) the most eastern? What is the difference of celestial longitude between the most eastern and most western stars of the constellation—*i.e.*, how many hours and minutes of longitude does the Great Bear spread itself over? The Súrya Siddhánta, a textbook of Hindu astronomy, which seems to teach a modification of the Ptolemean system, attributes to this constellation a cycle of 2,700 years. The translator (Rev. Ebenezer Burgess) is at a loss to know what this refers to. Can you solve the difficulty?

Has the Great Bear been made use of by any people for measuring time, in connection with the Dog-star or any other? Bentley, in his Hindu Astronomy, says that the Hindus had the following method of measuring the amount of *precession*: They assumed an imaginary line, or great circle, passing through the poles of the ecliptic and the beginning of one of their lunar asterisms called *Maha* (instead of twelve solar signs, they had twenty-seven lunar asterisms). This great circle, which was called the line of the Rishis, was supposed to cut some of the stars of the Great Bear, and the precession was noted by stating the degree, &c., of any *movable* lunar asterism cut by that fixed line or circle as an index. That is to say, their asterisms shifted, precessionally, just as our "Aries" has got into Pisces, and they measured the amount of precession by the passage of the asterisms over the assumed fixed line. This fact suggests to me to ask whether the Egyptians made out any similar connection between the Great Bear and Sirius, or between the Pole-star and Sirius. I know that a line drawn through "the pointers" would not pass through Sirius, because the Right Ascension is so different; but is any sort of connection known to have existed? GEORGE ST. CLAIR.

[58]—SIRIUS AND ORION.—I have met with a statement that Sirius is in the shoulder of Orion. Knowing that Sirius was in the Great Dog constellation, I was puzzled. Did the Orion constellation at any time include Sirius? GEO. ST. CLAIR.

[59]—MERCURY'S REVOLUTION.—The "Science Primer on Astronomy" (by J. Norman Lockyer, F.R.S.), p. 62, says that Mercury is 84 days in traversing its orbit. Most books which I have looked into give Mercury's sidereal revolution as 87 days 23 hours 15 minutes 43 seconds. Is the sidereal revolution something different from the "traversing of the orbit?"—GEORGE ST. CLAIR.

[60]—SOUND.—How does sound penetrate through a brick wall?—S.

[61]—Will the Editor, or anyone else, inform me the name of the great comet that appeared in our northern sky this last midsummer; also, how long it takes to make one journey round the sun?—S. C. H.

[62]—ALGOL.—Where abouts in Persius is the variable star Algol? If this is the same star as in the head of Medusa, I suppose the latter constellation is a part of the former. Is it so?—F. H. S.

[63]—ALGOL AND MIRA.—When are Algol and Mira at their brightest?—F. H. S.

[64]—STAR LETTERS AND NUMBERS.—Not having examined a stellar map before those that appear in KNOWLEDGE, will you kindly explain the following? I have been under the impression that the stars of all constellations are named after the Greek letters, and when these are exhausted, the numerals are then resorted to, beginning, of course, at 1? I find this is not the case, *e.g.*, take Lynx, as marked in the map on No. 1. The brightest star is of the fourth magnitude, and is α; there are only two others marked in this constellation, but instead of their being β, γ, or 1, 2, they are called 31 and 38. F. H. S.

[65]—NEW STAR IN CASSIOPEIA.—I am told that a periodical star in Cassiopeia will shortly appear, and it will be so bright as to be seen at noonday. Is that so? F. H. S.

[66]—Has Venus ever been seen in the daytime?—F. H. S.

Replies to Queries.

[11]—LOGARITHMS.—Without knowing the extent of accuracy desired by Mr. Grundy (query 11, p. 60) in his computations, it is difficult to advise him as to the class of tables he requires. Copies of the ordinary "Seven-place" tables of Hutton, Babbage, Sang, and others are easily procured second-hand (the first for preference); German tables to six places, by Ursinus and Bremiker, can be purchased at Nutt's; and the best of several five-place logs. will be found in Galbraith & Haughton's series, now published by Cassell. This includes a table of "Sum and difference" logs. by Gauss. The last table is made specially applicable to Life contingencies and the general formation of tables by a continuous method, by P. Gray, who inserts it in his "tables and formulæ," tabulating for each log. that of the function $1+x$. An error in Babbage may here be noted. In the eight-figure series attached to his larger table, the log. of 103 (an important figure, as being the initial 1, plus its interest at 3 per cent.) should be 01283722, not 01283723. The most complete table of Anti-logarithms is the old folio of Dodson, frequently to be picked up at the stalls; see also Shortrede's tables to seven places in the usual form. Yours faithfully,

H. S. A.

[19]—COMPARATIVE ANATOMY OF BIRDS AND ANIMALS. Charles Sherborn asks, What are the corresponding bones in man and other mammals to the "furcula" (*furculum*) of birds? I am surprised Mr. Sherborn has not discovered the answer to his query in any good manual of *zoology*. The "furculum" of a bird (*anglicè*, the "merry-thought") is composed of the two collar-bones or clavicles of the bird, which are, in most cases, firmly united to form one bone. This bone, in turn, is joined to the breast-bone, and forms a strong arch, or, rather, keystone, of the shoulder. It should be remembered that in a bird's shoulder there are three typical bones—scapula, or shoulder-blade; clavicle, or collar-bone; and coracoid bone—on each side. The coracoid bone, developed as a distinct bone in birds, reptiles, and lower vertebrata, is represented in all mammals, except the lowest, as a mere process (coracoid process) of the shoulder-blade. In the lowest mammals (*e.g.*, *Ornithorhynchus* and *Echidna* of Australia) the coracoid, as in the bird, is articulated with the breast-bone. In this respect, as well as in the absence of sutures or distinct lines of union between the skull-bones, and in other joints of internal anatomy, the lowest quadrupeds present a striking affinity to birds. ANDREW WILSON.

[25]—FORMS OF FOOD. As explanatory of the terms relating to food in Dr. Carpenter's paper, which puzzle "Desdichado," I would advise him to read a simple elementary treatise wherein foods at large are treated. Such a book as Corfield's "Laws of Health," 1s. 6d. (Longmans), will assist him. Foods are divided into (1) Nitrogenous (containing carbon, hydrogen, oxygen, and nitrogen, and sometimes sulphur and phosphorus) and (2) non-nitrogenous. Of the latter, there are four chief varieties:—(1) Water (H_2O); (2) fats and oils (CHO); (3) sugars and starches (amyloids or hydro-carbons) (CHO, but differing from fats in the amount of O they contain); (4) minerals (*e.g.* lime, salt, iron, &c.) "Desdichado" will obtain all necessary information concerning foods from any primer of physiology, and such knowledge should form, indeed, part of every system of school training.—ANDREW WILSON.

TRAINING.

WE have before now spoken of the singular views which have prevailed with regard to the diet best suited for men who were desirous of developing their physical powers to the highest degree, and of the harm which has been done by the empirical, and in many cases ridiculous, rules which were laid down. Some of the most objectionable of these are now happily set aside, and the opinions of those intelligent persons who taught that mutton was better than beef for "wind," that all fluids should be avoided by men who wish to "get into condition," that meat was to be eaten without salt, and that pedestrians should drink sherry and boxers port, would be laughed at, even by the most ardent fanatic in an Eight; but, though a good deal of nonsense has been got rid of, a bad system still prevails, and there is no exaggeration in stating that harm is still done by the regulations respecting diet which, even in these days, are unhesitatingly obeyed. At one time, no doubt, some of these rules appeared to have a certain scientific sanction; but it has now been well established that the views on which this sanction was based were not only erroneous, but directly opposed to the truth. In so far, therefore, as rules which are in accordance with them have any effect, they must have a bad effect. It is true that they do not work so much ill as might be expected, but this is because the men who follow them are usually very young, very vigorous, and lead, apart from diet, a most healthy life. Still, unless modern physiological teaching is altogether wrong, even the modified system now followed must cause some evil, and the sooner it is swept away the better. If it be said that the men who train steadily often attain very "high condition," the answer is that this is due in no way to their food, but to constant and fitting exercise in the open air, to regular hours, to strict temperance with regard to alcohol, and to abstinence from, or great moderation in, smoking. Strength is attained not by diet, but in spite of diet.

That erroneous views should at one time have been held is not wonderful, for in support of them the great name of Liebig could be quoted by those who had sufficient energy and intelligence to attempt a scientific study of the question. It is now, however, well established that in some of his conclusions Liebig was wrong, and notably that he was wrong in thinking that muscular or mechanical effort was entirely supported by nitrogenous food, and that the heat-giving foods sustained the process of combustion which is constantly going on in the body, but did nothing more. If he was right, of course, the more muscular work a man did, the more nitrogenous food he would require; and trainers were therefore not mistaken in favouring meat, and in looking with great dislike on those foods which are commonly thought to produce fat; but then, unfortunately, Liebig has been shown to have been in error, and any system of diet which is in accordance with his views cannot be a good one, and is in all probability a very bad one. The

erroneous nature of views based on Liebig's doctrine is well known to physiologists; but, nevertheless, is hardly as yet so generally known as it ought to be, and very likely on the banks of Isis and Cam there is no suspicion of the truth. Possibly every year a certain number of men break down in training, with more or less injury to their constitutions, owing to a faulty diet. Instruction on this subject is therefore anything but superfluous, as a deeply-rooted error is not by any means eradicated; and all who are interested in athletic sports should welcome the appearance of two articles which a writer on physiology of the first eminence has contributed to Mr. Richard Proctor's new magazine, Knowledge—a periodical, we may observe, which promises to satisfy a want that has long been felt. In this magazine Dr. Carpenter has come forward to protest against the belief in Liebig's views which appears unfortunately still to exist. As need hardly be said, he does not write specially on training or diet, but generally respecting food material and physical effort, his articles being on "The Relation of Food to Muscular Work." They are written with all his accustomed clearness and powerful simplicity, and we hope to aid in calling attention to them, as they cannot fail to do much good if they reach those who habitually misfeed young men with a view to producing "high condition."

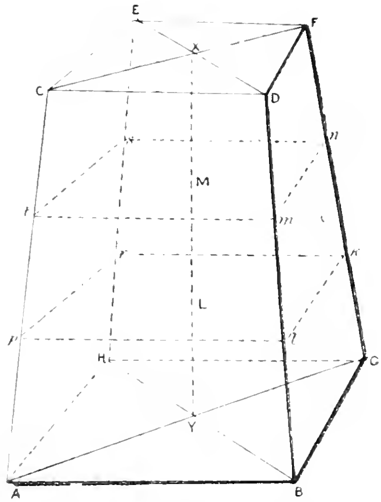
It is not necessary to reproduce here the careful and minute account which Dr. Carpenter gives of the process involved in muscular effort. Those who wish to understand this must seek the pages of Knowledge, and they will be very well repaid for their pains. His summing-up, however, which states briefly the views of modern physiologists, should be given in his own words, which are as follows:

"The *mechanical working* of the body of a living animal is as directly dependent as its *heating* upon the oxidation of the hydro-carbons of its food; and these may be most economically supplied by non-nitrogenous substances. On the other hand, the mechanism can only be kept in working order by the continual renovation of its substance (its very existence as a living whole involving the continual death and decay of its component parts); and for this renovation a supply of *proteids* is essential, with a certain admixture of *fat* to serve as a material for protoplasm."

Now it is scarcely necessary to point out how entirely these truths are opposed to the system followed in training, which did seem to receive some kind of sanction from Liebig. It is true, no doubt, that nitrogenous food is required for the renovation of the muscle, which wears out as all the tissues of the body wear out; but the consumption of muscle caused by effort which, as we have said, has been likened to the wear and tear of a machine—is small when compared with the consumption of the non-nitrogenous substances, which represent the fuel that is burnt to maintain the force developed. It is therefore clear that when there is severe and continuous physical effort, a large supply of the latter kind of food-material will be required to make good the loss occasioned by that effort, while of the former only a slight increase will be made necessary. The principle followed in training is exactly to reverse things. It is true that men are no longer encouraged to gorge themselves with underdone meat and to avoid sweets as if they were poison; but still, in the main, the trainer favours meat, and watches with some jealousy and restricts the other kinds of food. He ought to do just the opposite. We do not, of course, mean to say that the resources of the French *cuisine* should be placed at the disposal of young men in training, as it is sufficiently obvious that those who desire to attain a high state of health must confine themselves to simple and digestible food; but of simple food it is the non-nitrogenous kind that is the most needful, and it is about as reasonable to fear a large proportion of nutriment of this class as it would be to fear the oxygen of the air. Nay, more harm may be done by abstaining from the food indicated. Natural laws cannot be disobeyed with impunity; and when nature points distinctly to one kind of diet, and men choose to adhere to a diet of precisely the opposite kind, evil of some sort is not unlikely to follow. The argument that the diet is right because men who adopt it do get into "high condition" we have already answered, and there can be little doubt that the ailments which assail men in training and the occasionally serious results of training are in part due to a vicious system of diet which, in so far as it has any scientific basis, is founded on a doctrine which is now thoroughly exploded. Much, therefore, do we hope that Dr. Carpenter's valuable contributions to Knowledge will be read at the Universities and other places where there is devotion to the severer kind of athletics. If these and some other writings are studied, we doubt not that, before long, the foolish rules which still remain will be swept away, and that the happy young athletes who are able to enjoy good and wholesome dinners, which tend to produce, not to retard, the much-desired "condition," will fervently revere the name of the man of science who released the victims of training from an odious thraldom.—From the *Saturday Review*.

Our Mathematical Column.

Mathematical Query 1[?].—A mason has a block of stone as in figure, square at top and bottom. Perpendicular height, XY = 10 feet; AB, side of base, = 8 feet; CD, side of top, = 6 feet. He desires to cut it in three parts of equal solidity. Will one of your mathematical readers kindly tell him an easy way of doing it?—Cymro.



The practical answer to this question is simply to mark off Bq, Gk, Hr, Ap each equal to 2·783 ft., or to about 2 ft. 9⅜ in.; and qm, kn, rs, pt, each equal to 3·269 ft., or about 3 ft. 3¼ in., and cut off by planes parallel to $ABGH$, the pyramidal frustra pG and tF.

Presumably the block is to be cut by planes parallel to the top and bottom.

The best way of treating this question is, perhaps, the following:

The block EB may be regarded as part of a pyramid, having $ABGH$ as base. The height of this pyramid would be 40 ft., for its linear dimensions narrow one-fourth in 10 ft. of ascent, and reduce, therefore, to nought (or the vertex is reached) at four times this height.

Of this pyramid, the part or frustum EB has a volume bearing to the volume of the pyramid the ratio $(40)^3-(30)^3 : (40)^3$

$$=64-27 : 64 = 37 : 64$$

In other words, putting V for volume of pyramid, volume of block $EB=\frac{37}{64}\cdot V$. Now we require to determine two points L and M in YX, so that planes through L and M parallel to $AHGB$ may cut off from the lower part of the pyramid one-third and two-thirds respectively of the volume EB. The volumes thus cut off will, therefore, be respectively

$$\frac{1}{3}\cdot\frac{37}{64}V \text{ and } \frac{2}{3}\cdot\frac{37}{64}V, \text{ or}$$

$$\frac{37}{192}V \text{ and } \frac{74}{192}V$$

Now, if L and M be respectively distant x and y feet from the vertex of the pyramid, we have the volumes cut off from the lower part of the pyramid by the planes through L and M, respectively equal to—

$$\frac{(40)^3-x^3}{(40)^3}V \quad \text{and} \quad \frac{(40)^3-y^3}{(40)^3}V$$

$$\text{Hence } \frac{(40)^3-x^3}{(40)^3}=\frac{37}{192}; \quad \text{and} \quad \frac{(40)^3-y^3}{(40)^3}=\frac{74}{192}$$

$$\text{or } x^3=\frac{64000\times 155}{192}=\frac{155000}{3}=51666\cdot\dot{6}$$

$$\text{and } y^3=\frac{64000\times 118}{192}=\frac{118000}{3}=39333\cdot\dot{3}$$

We can [illegible] approximate solutions by logarithms, thus For [illegible], we have

$$[illegible]\ 51466\cdot67 = 4\cdot7132101$$
$$\text{cube root of which} = 1\cdot5710701 = \log.\ 37\cdot245$$
$$\text{whence } x = 37\cdot245 \text{ feet,}$$
$$\text{and } YL = 40 - x = 2\cdot755 \text{ feet.}$$

For [illegible], we have

$$[illegible] = 39333\cdot33 = 4\cdot5947608$$
$$\text{cube root of which} = 1\cdot5315869 = \log.\ 34\cdot008$$
$$\text{whence } y = 34\cdot008 \text{ feet,}$$
$$\text{and } YM = 40 - y = 5\cdot992 \text{ feet.}$$

Thus

$$YL = 2\cdot755 \text{ ft.};\quad LM = 3\cdot237 \text{ ft.};\quad \text{and } MX = 4\cdot008 \text{ ft.}$$

In practice, I suppose it would be more convenient to know whereabouts the planes of section respectively cut the lines *DB*, *FG*, *EH*, *CA*. For this purpose all we have to do is to divide each of these four lines in the same proportion as the line *XY*. This, whether it is done by construction or by computation, is too simple to need further explanation. I may just note, however, that

$$BD^2 : YX^2 :: (40)^2 + (YB)^2 : (40)^2$$
$$:: 1632 \qquad : 1600$$
$$:: 51 \qquad : 50$$

so that, for the divisions along *DB*, *FG*, *EH*, and *CA*, the above values for *YL*, *LM*, and *MX* have all to be increased in the ratio $\sqrt{51} : \sqrt{50}$ or approximating as 101 to 100. Increasing them by one-hundredth, we get, supposing *lm*, the required points of division along $DB - Bl = 2\cdot783$ ft.; $lm = 3\cdot269$ ft.; and $mD = 4\cdot048$ ft.

Our Chess Column.

The Two Knights' Defence.

We take next a sounder form of this opening, where Black, instead of retaking the Pawn at his fifth move, plays away his Queen's Knight to Queen's Rook's fourth. The game opens thus:—

1. P. to K.4 / P. to K.4
2. Kt. to K.B.3 / Kt. to Q.B.3.
3. B. to Q.B.4 / Kt. to K.B.3.
4. Kt. to K.B.5. / P. to Q.4.
5. P. takes P. / Kt. to Q.R.4.

White has now two lines of play; he may either check with the Bishop or play P. to Q.3, defending the Bishop while leaving it to protect the forward Queen's Pawn. The first, which is the better play, will now occupy our attention. Note, that whatever play is adopted, White's attack is, for the moment, over. He has to provide for the safety of his King's Knight, in attacking which Black can develope his game. The opening proceeds thus:—

6. B.Q.Kt.5ch. / P. to Q.B.3.
7. P. takes P. / P. takes P.
8. B. to K.2 / P. to K.R.3; or 8. B. to Q.R.4 / — (A)
9. Kt. to K.B.3 / P. to K.5; or 8. Q. to K.B.3 / — (B)
10. Kt. to K.5 / Q. to Q.5; or 10. — / B. to Q.3.
11. P. to K.B.4 / B. to Q.B.4. — 11. P. to Q.4 / Q. to B.2.
12. R. to K.B.sq. / Q. to Q.3. (Pos. 1.) — 12. P. to K.B.4 / Castles. (Pos. 2.)

Position 1.

Black.

White.

Position 2.

Black.

White.

In position 1 White seems to be the better off. Black has his game more open, and in fact, the attack rests for the moment with him. But the attack does not seem sufficient to compensate for the Pawn which Black has lost. It will be observed that at move 12 Black had to provide against the move P. to Q.B.3, attacking Queen, followed by P. to Q.Kt.4 attacking both Knight and Bishop. He might have done this by playing Bishop instead of Q. to Q.'s third. In this case White would still push Q.B. Pawn, attacking Q., and on her retreating to Q.'s fourth, her best move, would play P. to Q.Kt.'s fourth, with decided advantage. Or Black might have played away his Q.Kt. to Q.Kt.'s second, leaving, however, his Q.B.P. undefended, and on White taking it, Black Queen has to retreat to Q.'s third.

On the other hand, in position 2, Black's game seems as good as White's. He is a Pawn short, but his forces are better situated.

Next week we shall carry on the variations A and B, arising from White's playing 8. B. to Q.R.4, or 8. Q. to K.B.3, instead of B. to Q.2.

Young players will find it a useful exercise to play several games from each of the positions 1 and 2, taking the attack and defence alternately, and, in every case, playing through the opening moves till either position 1 or position 2 is reached.

Instead of 11. P. to K.B.4, by which position 1 is reached at twelfth move, White may play 11. Kt. to K.Kt.4. On this Black takes the Kt. with his Q.'s Bishop, White retakes with Bishop, and Black plays Kt. to Q.B.5. This leads to an even game.

Several of our readers appear to find considerable difficulty with Mr. Healey's little problem at p. 41, two declaring flatly that there must be some mistake. The solution is simply

White.	Black
1. R. to Q.Kt.7 (ch.)	1. K. to B.sq. (If K. to R. sq., there follows perpetual check, unless K. goes to B. sq.
2. R. to Q.Kt.5.	2. P. Queens.
3. R. to Q.B.5 (ch.)	3. Q. takes R., stalemate.

The other position, and Ponziani's position in our last number, are easy enough. Black's choice is divided between perpetual check and stalemate.

We give, in conclusion, a little problem of our own invention. It presents no difficulty whatever for those who are at all proficient in problem-solving; but may amuse, for ten minutes or so, those who have not given much attention to that department of Chess. (The very feature which makes the problem interesting for these directs the former at once to the solution.)

No. 3.—Problem by the Editor.

Black.

White.

White to play and mate in two moves.

Our Whist Column.

By "Five of Clubs."

Again we give a simple whist game, taken from actual play. It is borrowed from the "Westminster Papers" for 1877. The first player, *A*, was our correspondent (and friendly critic), Mr. Lewis, whose Double Dummy problems long formed so marked a feature of the "Westminster Papers." We give this time *B*'s inferences, with notes on the play as before. The game is interesting as showing how a good player may be led by the fall of the cards in the first two or three rounds to lead out trumps even when short in them, and when one of the adversaries probably holds four.

We show also how two tricks might have been saved by correct play of the weaker hands, Y and Z.

THE HANDS.

Spades—Kn. 10, 3.
Hearts—6, 2.
Clubs—Q. 7. 5, 2.
Diamonds—A. 8. 4. 3.

Spades—Q, 6, 5, 2.
Hearts—A. Kn, 8.
Clubs—10, 9, 8.
Diamonds—10, 6, 2.

B

Y — Z Dealer

Trump Card, Spades 4.

A

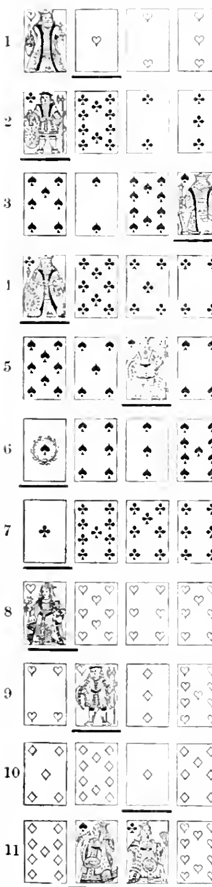
Spades—K, 9, 4.
Hearts—10, 9, 7, 3,
Clubs—6, 4, 3.
Diamonds—Q. Kn. 7.

Spades—A, 8, 7.
Hearts—K, Q, 5, 4.
Clubs—A, K, Kn.
Diamonds—K. 9, 5.

Score.—A B = 0; Y Z = 0.

NOTE.—The underlined card wins trick, and card below it leads next.

A *Y* *B* *Z*



B's INFERENCES.

1. *A* has Queen of Hearts and probably two other Hearts; neither *A* nor *Z* (who has not signalled) is very strong in trumps.

2. *Y* has led from 10 C and two small ones, probably from 10, 9, 8; *Y's* hand must be very weak, but in all probability he has four trumps. *A* has Ace of Clubs and King of Clubs.

NOTE TO TRICK 2.—With such a hand *Y* should have led a trump.

3. *A* has strength enough in trumps, with command in other suits, to justify a trump lead. (This is *B's* inference, and also our comment.)

4. *Z*, if he has played rightly, has no more Clubs. 4 C was the lowest Club in hand, and *Z* cannot have two more, for *B* can place four of the remaining five, viz., 9 C with *Y*, Ace with *A*, and two in his own hand. But *B* knows that 6 C cannot be with *Y*, and if with *A*, then *A* would have originally led Clubs unless holding at least three Hearts besides Ace and King. *B* is for the moment liable to be misled by *Z's* false card.

NOTE TO TRICK 4.—*Z* plays badly in returning his partner's lead when Honours in the suit are declared against them. If leading Clubs at all he should have led 6 C, if only for the sake of uniformity.

5. The Ace of trumps lies with *A*, the Queen with *Y*.

NOTE TO TRICK 5.—*Y* might well have played his Queen of Spades. The Ace certainly does not lie with *B*, and is far more probably with *A* than with *Z*. Even if with *Z* there is the chance of *Z* having also a small trump.

6. The long trump is with *Y*.

7. *Z* played a false card, or at least incorrectly, in trick 4.

8. *A* holds 4 and 5 of Hearts, see Trick 1.

9. 10 H is probably with *Z*.

10. *B* knows that *Y* has led from a weak suit, not from King, Knave, 10, for otherwise *Y* would not originally have led a Club. He knows also that *Z* cannot be strong in Diamonds, or he would not have returned Clubs in which his partner showed weakness. The King of Diamonds probably lies with *A*, as *A* led trumps from so weak a suit as Ace to three. *B* therefore boldly plays his Ace of Diamonds, and with the long Club forces out the long trump.

11. It matters not how *Z* discards. If he discards a Diamond *A* discards 5 H, and wins the remaining tricks, as in the actual game.

A B make three by cards. Had *Y* led trumps at trick 2, or played his Queen of Spades at trick 5, *A B* could have made but two tricks. But the game might have gone better yet for *Y* and *Z* if, *Y* having led as he actually did, *Z* had led 7 H (bad as returning an opponent's lead usually is) at trick 4. This would have fallen to *A's* Queen; and *Y*, knowing *Z* with two more (for he never would have returned opponent's lead unless with four, at least, of the suit originally), would place 9 H and 10 H at once in *Z's* hand (having the 8 himself). *Y* would therefore play away his Knave of Hearts. *A* would have followed with a trump lead as in the actual game, *Y* taking the trick with his Queen. *Y* would not then lead 8 H, because, though his partner could win with 9 H, and then lead the winning Heart, *B* would ruff, lead a Club for his partner to take, who would then lead trumps, &c. But, leading a Club, *Y* would throw the lead again into *A's* hand, who would then have taken out another round of trumps, and playing then Ace of Clubs, as in trick 7 of actual game. If next *A* played a small Heart, *Z* would take the trick with 9 H and another with 10 H. If *A* led a small Diamond, *B*, winning with the Ace, would force the long trump with Queen of Clubs, and on *Y* leading 8 H, *Z* would make both his hearts as before. Or if *B* returned a Diamond instead of leading his Queen of Clubs, then, whether *A* led a Diamond or a Heart after taking the trick with his King, the remaining tricks would be with *Y Z*. The last five tricks would run in one or other of the following ways, *A* leading in trick 9:—

	A	*Y*	*B*	*Z*	*A*	*Y*	*B*	*Z*	*A*	*Y*	*B*	*Z*
9.	4 H	8 H	3 D	9 H	5 D	10 D	A D	7 D	5 D	10 D	A D	7 D
10.	5 H	2 D	4 D	10 H	4 H	Q S	Q C	Kn D	K D	2 D	3 D	Kn D
11.	5 D	10 D	A D	7 D	5 H	8 H	3 D	9 H	9 D	6 D	4 D	Q D
12.	9 D	Q S	Q C	Kn D	9 D	2 D	4 D	10 H	4 H	8 H	8 D	10 H
13.	K D	6 D	8 D	Q D	K D	6 D	8 D	Q D	5 H	Q S	Q C	9 H

The other eight tricks would be the same respectively as 1, 2, 3, 8, 5, 4, 6, and 7 of the annual game, except that at trick 4, corresponding to trick 8 of the actual game, *Y* would play Knave of Hearts instead of 8 H, while at trick 5 (of both games) he would play Queen of Spades, and *B* 3 S, the 6 S and Knave of Spades falling at trick 7 (corresponding to 6 of actual game). *Y* and *Z* would have lost only the odd trick, which, with such wretched hands, would have been getting off easily.

THE TELEPHONE AS AFFECTED BY SOME METEOROLOGICAL PHENOMENA.—Several Continental observers appear to have been lately studying the sounds which may often be heard in a telephone that is connected with a wire stretched, say, between the roofs of two houses, and connected with the water or gas pipes. On the occurrence of lightning, more especially, sounds are heard, and at the same instant (according to M. René Thury, of Geneva) as the flash is seen, whatever the distance of the latter. Even when no thunder was heard, and the discharge must have been at least 35 kilomètres off, M. Thury observed these induction effects. M. Lalagade, who has experimented similarly for some time past, thought to amplify the sounds, and did so by placing two microphones on the plate of the receiving telephone. The arrangement is set up in a quiet room, where all foreign vibrations are guarded against, and the author is able to hear the least sound at a distance of one mètre or more from the second telephone. Again, M. Landerer, at Tortosa, finds currents produced in his telephone-circuit by atmospheric electricity in three different ways. First, the condensation of aqueous vapour results in a sound recalling the cry of tin. A sensitive galvanometer in the circuit is not, or hardly, affected. These sounds are strongest at night. Next, there are the sounds which occur during lightning (and the currents producing which affect a galvanometer considerably). Thirdly, the wind generates currents which do not act on the telephone, but act on the galvanometer strongly. At Tortosa the very dry west winds produce the greatest oscillations. Telluric or earth currents set both on the galvanometer and on the telephone; they are distinguished from atmospheric currents by the regularity and continuity of their action during pretty long intervals.—*The Times.*

Answers to Correspondents.

*** *Communications for the Editor requiring early attention should be addressed to the Editor of* Knowledge, *74 and 75, Great Queen-street, London, W.C.*

Hints to Correspondents. *1. No questions asking for scientific information can be answered through the post. 2. Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries. 3. No queries or replies savouring of the nature of advertisements can be inserted. 4. Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge. 5. Correspondents should write on one side only of the paper, and put drawings on a separate leaf. 6. Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

John Hampden. Let us take it for granted that I am the "coward and sneak" you consider me; "my friend" the eminent naturalist you name (whom I have never met in my life), "a cheat, a swindler, and a shuffling cur," and our learned societies "selfish, dishonourable, and mischievous conspirators." Oblige, also, by noting outside your letters an address to which they can be returned.—Editor of British Chess Magazine. Many thanks.—J. Baxendell. In saying that the coincidences appear to me to disprove instead of proving your position, I refer to the circumstance that several of them are obviously mere coincidences, existing as such apart from the pyramid or its measures. They show that coincidences of the most remarkable kind can be found in this case, and presumably, therefore, in other cases, by those who look for them, and yet be, to all intents and purposes, meaningless, because accidental. Coincidences, therefore, do not supply that convincing evidence which the believers in what may be called the Great Pyramid religion finds in them.—W. Probyn Nevins. You are right; the comet is that of 1680. The comet of 1861, referred to at p. 28, was not seen by so many as the comet of 1858, being conspicuous only for a few days, and in the early morning, whereas the comet of 1858 was for months a brilliant object in the skies. But the comet of 1861 was in some respects even more remarkable.—A Fellow of the Royal Astronomical Society. You might regard me as "the kettle objecting to the pot its sordid superficies," for, like you, ... but my zeal is tempered now by the consideration that the world is censorious, and easily led to misinterpret warmth as necessarily implying personal feeling. Have we not both found it so? Moreover, most people are more easily pained than I should have thought possible when I first took part in controversy.—S. Biddle. It would save me a good deal of trouble to exclude the fifth magnitude stars; but many who use the maps want to have these stars in. It is very easy for those who want them excluded to take pen and ink and put them out.—J. I. Leighton. Occasional papers on quantitative chemical analysis might be admissible, if popular in tone; but at present we certainly have not room for a series of papers on the subject.—J. Norman Lockyer. We regret that you cannot at present spare time. Prof. Young has promised to write on the subject, and your treatment of it from another point of view would doubtless have been interesting to our readers. Perhaps at some future time you can oblige us.—W. Simons. The quotation was sent in a letter from an eminent physician. Did not notice the inaccuracy. The lines run, as you say—

Ignorance is the curse of God,
Knowledge the wing wherewith we fly to Heaven.

Thanks for encouraging words in reference to Knowledge.—J. W. C., Averillo. Thanks; corrected in Number 4. We began with the idea of a fortnightly map of the whole heavens, which would have made the pictures too small in scale. In changing our plan the mistake you notice arose, the first, third, fifth, &c., maps being taken with dates and hours, for the second, fourth, and sixth, instead of the true dates and hours.—Mar. S. Ridley. Book received, and forwarded to an enthusiast on the subject, for notice.—G. E. Bonney. Many thanks. The bookseller who thought the public likely to be interested in Knowledge would be less than we expected has certainly not thus far been confirmed by the event. The sale we hoped to attain in perhaps half-a-year or a year has already been exceeded twofold. Booksellers have a theory that nine-tenths of the journals started from time to time perish at the critical sixth number; possibly when we have reached the seventh your bookseller may have faith in our existence thereafter. We shall see.—J. B., *Norwich Advertiser.* Thanks.—F. C. Armstrong. Your query is not suited to our columns, though legal matters may be regarded as included in knowledge taken in its wider aspect.—P. A. Fothergill, F.R.A.S. Thanks.—Euclid. We have inserted your query; but though you may be readily shown how to trisect an angle by aid of a hyperbola, or the cycloidal curve called the *trisectrix*, you may depend no one will ever show you how to trisect an angle by use only of the straight line and circle, as in Euclid.—A Student. We are not free to comment on instruments advertised in our columns, but in this case the names of the advertisers stand very high indeed. We feel satisfied that you could rely entirely on any statement their house might make as to the qualities of their instruments.—J. H. Hodd. Many thanks. Mr. Foster has some kindred illusions already in hand, and finds the explanation in a peculiarity of Fig. 4 in No. 1. Your illusory picture shall be added to his collection, drawn as you suggest.—H. Griffith. Thanks for encouraging letter.—Henry Norton. You are severe, so far as we can make out your letter. Possibly you consider that readable writing and ordinary spelling would have been thrown away on persons so "binevolint" as to cater for "circle squairers, petty schoolmasters, and enquiring schoolboys." Your letter is absolutely alone thus far, and alone among so many, that we venture to conclude you are as exceptional in your views about Knowledge as in your system of orthography.—Jas. O. Jackson. On consideration, does it not appear to you that your request is a little unfair? To oblige many readers, we printed the map on a separate leaf. It is thus better printed, our number is enlarged by a full page of matter, and the map is made more convenient for study. As a reward for thus considering our readers' wants, you ask us to go to the expense of having each map separately pasted in. Apart from the consideration that most of our readers prefer to have the map loose, do you not think that your Society could pin or paste the map in? We printed 20,000 copies of each of the last two numbers, and these 20,000 extra leaves added considerably to the cost of those numbers; to have had them pasted in or an extra fold made for each would have involved additional expense, and have been unsatisfactory to many of our readers.—G. W. Niven. Your long article on "Clairvoyance" (seventeen very large and closely-written pages of M.S.) would occupy much more space than we can afford even for objects otherwise perfectly suitable for our pages; your subject can scarcely be so described.
F. C. We shall be delighted to receive your paper on "The Place of Dreams in the Growth of Primitive Beliefs."—Andrew Aitken. Thanks for the constructions of parabola, which shall appear if we can make space. First and fourth are scarcely suitable for "Geometricus," being so obviously deducible, one from the definition of a parabola, the other from the fundamental relation between the ordinate and the abscissa, that he could not have failed to recognise them. He wants an easier construction. The two others are in reality one, depending on the proposition that a series of equidistant concentric circles cut a series of equidistant parallels in a series of parabolas, having the centre of the circles as focus, and a line through that point perpendicular to the parallels as axis. There is a similar property for the ellipse, and the hyperbola, equidistant concentric circles replacing the parallels. Diagrams illustrating these relations have already been drawn for Knowledge, in accordance with promise made at foot of "Geometricus's" letter. There are simpler and better methods than these, however.—M. E. Pendred. Your first letter does not appeared, because unsuitable. If you are so fearful of science you had better leave it alone. We cannot strengthen your faith; we can only wonder why you are troubled.—John Steele. Many thanks for proffered M.S. (15 pp. closely written foolscap) in favour of the sun's being rigidly cold, and showing that we are chiefly indebted to water for both light and heat. But please don't.—Henry Grimshaw. Your illusions next week, if possible. We know nothing ourselves about the Extract referred to; the advertising and editing are distinct departments.—A Lover of Knowledge. Declining and inclining are different matters. The lines of the address, which are really horizontal, appear to decline—that is to be lower down—on the left. As to the other point, we labour under great difficulties with regard to correspondence. We should require twice the space we have, to find room for all. We will do our best to make room early for all that needs early publication, and in the long run for all that is worth preserving.—Ignoramus. You misinterpret my remark in "Half-hours with the Telescope." I do not say Mars shows a larger disc or more striking features, but the reverse. What I say is, that we see him on a larger scale; as, of course we do, seeing that he is much nearer the earth. No doubt you were looking at Mars. He is a disappointing object in the telescope.—B. H. Thwaite. Your letter is too long for what, after all, is an exposition of a very unsound doctrine. Take such a sentence as this:—"May not the rings of the planet Saturn be produced owing to that planet having two atmospheres capable of absorbing light from the solar rays?" Without wishing to discourage your efforts at original theorising, or to quote authorities against you, we must yet point out that a study of the facts known about Saturn's rings will enable you at once to decide that your explanation "may *not*" be accepted. Again we find a great pressure on our correspondence columns. Our own letter, promised in Number 4, was the first sacrificed.

Synchronizing Electric Clocks.—At the first ordinary meeting of the Society of Telegraph Engineers and of Electricians for the autumnal session, Professor G. C. Foster, president, in the chair, a paper was read by Mr. John A. Lund, on "The System of Synchronizing Clocks adopted in London and elsewhere." Mr. Lund said his paper was an attempt to demonstrate the results to be obtained by even a limited acquaintance with the science of electricity when patiently and perseveringly brought to bear upon some of the practical demands of daily life. The attention of electricians in the early days of their science was, he stated, as much devoted to synchronizing clocks as to message telegraphy, but the repeated failures in the former field, as contrasted with the triumphant successes of the latter, caused the application of electricity to telegraphy to become the favourite path of the electrician. Electric clocks were capable of being divided into six kinds. None of the old forms of electric clocks obtained a general public acceptance, the most successful, the Wheatstone, having only worked some five or six clocks from one motor. Their failure was due to the desire to make the clock subservient to the system, instead of *vice versa*. The criteria of a successful system of synchronizing, to obtain the approbation of the public while receiving the sanction of science, were that each clock should have a vitality distinctly independent of the time signal, and not stop through a failure of the regulating electric current to reach it; universal application to all kinds of existing clocks; lastly, due provision for the correction of errors. The system exhibited satisfied these conditions. Mr. Lund proceeded to say that, however perfect the mode of synchronising might be, it could not be successful without a complete "system." The system consisted of a correct standard clock, which, assisted by a well-erected and well-maintained system of telegraph wires, should send out the needed signals to the synchronisers. Two "standards" were used (one to fall in automatically should the other fail) for transmitting the currents of electricity, and those standards received their motion from a standard clock. The applicability of time current wires for telephone purposes was instanced by telephones being placed at each end of a circuit between the lecture-room (Institution of Civil Engineers) and Messrs. Barraud & Lund's establishment, Pall Mall, upon which wire there were also twelve electric clock synchronisers, through which conversation was carried on.

DREAMS.

By Edward Clodd.

The remarks which follow some questions concerning the attitude of science towards dreams, asked in Knowledge of Nov. 25,* indicate how belief in their quasi-supernatural character lurks in the minds of intelligent persons who would resent being called superstitious.

Certainly, the antiquity and persistence of that belief are small matter of wonder when we reflect that the phenomena of dreaming are precisely of a character to sustain that feeling of mystery which man's surroundings awaken within him; but an inquiry into its origin and growth may best dispel it, while such an inquiry will add its witness to that of the "great cloud of witnesses" concerning the survival, often in least suspected form, of rude primitive philosophies among the elaborated beliefs of civilised races.

The youngest and most vigorous of the sciences, Anthropology, has already made us familiar with the nature of a vast body of evidence, uniform in character, unearthed from old river-valleys, caverns, mounds, and tombs, witnessing to the primitive savagery of man and his slow uprising therefrom; but such evidence touches us only on the intellectual side. Even should desired skeletons of veritable men of miocene times—still better, of the "missing" *homo simius*—turn up, we should yet be within the limits of palæontology and zoology. Such relics of our remote ancestry would remain specimens only—"a little less than kin." It is not until the evidence from the Drift and from surface remains (about which Knowledge may hereafter tell its readers more in detail) gives place to that supplied by immaterial relics—articulate speech, myths which were for the time real, and sufficing explanations to him—that man touches us as *fellow*-man, as *thinker*,† striving to read "the riddle of the painful earth," and to peer into the mysteries of being.

* "Query 21," p. 80.

† "Man, a derivative root, means to think. From this we have the Sanskrit manu, originally thinker, then man."—Max Müller's *Lect. Lang.* I., 437.

Now, for the purpose of this inquiry, it is needful to have understanding of the mental condition of races in low stages of culture, and, generally, it may be said that the modern savage is, as the primitive savage was, in a state of "fog" concerning the nature and relation of what is in the mind to what is outside it. In this he may perchance command the sympathy of the modern philosopher, there being this important difference between the two, that while the philosopher speculates upon the nature of the connection between his mind and the external world, and confesses that "his knowledge of matter is restricted to those feelings of which he assumes it to be the cause," the savage has no capacity for such thought at all. He has nothing in his slender stock of words corresponding to the terms "objective" and "subjective;" that stock has no substantive verb "to be"—as, indeed, few of the languages of the world have ever had. He cannot distinguish between an idea and an object, an illusion and a reality, a substance and its image or shadow; and under bodily ailment, indigestion born of gorging, or delirium caused by starving, gives shape and substance, a "local habitation and a name," to "airy nothings," spectres of diseased or morbid imagination. Misled by superficial resemblances, he jumps at the most absurd conclusions; ignorant of the necessary relation between cause and effect, he is "carried about with every wind of" fancy; nor has he the capacity, which is the measure of intellectual growth, to strip the special of its accidents, and sink it in the general.

For example, he gives a different name to the tails of various animals, but has no name for "tail" in general; he can speak of sunshine, candle, fire-flame, etc., but "light" is an abstract term which he is unable to grasp. Such is his confusion between a thing and its symbol, that the name of a man is held to be an integral part of himself; he shrinks from revealing his own, lest the man to whom he imparts it injures him through it; still more does he recoil from naming the dead, or powers credited with baleful influence. He dreads having his portrait taken, feeling that some part of himself has gone in the process; the better the likeness, the more has "virtue gone out of him." Catlin relates that he caused great commotion among the Sioux by drawing one of their chiefs in profile. "Why was half his face left out?" they asked; "Mahtoochega was never ashamed to look a white man in the face." The chief himself did not take offence, but Shonka, the Dog, taunted him, saying, "The Englishman knows that you are but half a man; he has painted but one-half of your face, and knows that the rest is good for nothing." Which led to a quarrel, and in the end Mahtoochega was shot, the bullet tearing away just that part of the face which Catlin had not drawn.

We may now more clearly understand how the savage will interpret phenomena of a more complex order, and why he can interpret these only in one way. The phantasies which have flitted across the brain in coherent order or unrelated succession when complete sleep was lacking, leave the traces of their passage on the memory, and they are strong of head and heart, "true pepties who have no system," as Carlyle says, whose awakened consciousness is not affected by the harmonious or discordant, the painful or pleasant, illusions which have composed their dreams. But while for us they fill an empty moment in the telling, albeit now and again causing "eerie" feelings, and quickening such remains of superstition as slumber in the majority of us, they are to the untrained intelligence of the savage as solid as the experiences of his waking moments, true not only "while they last," but for ever afterwards. And the limits of his language only deepen the confusion within him when he tells what he has seen, and heard, and felt, and

whither he has been. For the speech cannot transcend the thought, and, therefore, can represent neither to himself nor to his hearers the difference between the illusions of the night and the realities of the day. The dead relations and friends who appear in dreams and live their old life; with whom he joins in the battle or the chase; with whom, the toils over, he sits down to feast, not, like the Psalmist, in the presence of his enemies, but upon succulent slices of the enemies themselves; the foes with whom he struggles, the wild beasts from which he flees, or in whose grip he feels himself, and, shrieking, awakens his squaw; the long distances he travels to dreamlands beyond and above—are all real, and no "baseless fabric of a vision." The belief is strengthened by that intensified form of dreaming called "nightmare,"* when gaping, grinning, spectre-monsters sit upon the breast, stopping breath and paralysing motion, which has helped to create the vast army of nocturnal demons that fill the folk-lore of the world, and that under infinite variety of hideousness have had lodgment for centuries in the beliefs of higher races.

What Schoolcraft says of the Indian mind, that "a dream or a fact is alike patent to it," applies throughout the whole range of the lower culture, a marked and widespread form of the confusion being in the belief that the soul leaves the body during sleep. Among the Zulus, when dead relatives appear to a man in his sleep, he concludes that their spirits still live, and the savage notion, that a sleeper should not be wakened, because of the possible absence of his soul, finds some continuity in the belief of mediaeval times, that trance and catalepsy were proofs of the temporary departure of the soul from the body. Hence, as Mr. Fiske has remarked, "it was no easy matter for a person accused of witchcraft to prove an *alibi*: for to any amount of evidence showing that the body was innocently reposing at home and in bed, the answer was obvious, that the soul may, nevertheless, have been in attendance at the witches' Sabbath, or busied in maiming a neighbour's cattle!"

(To be continued.)

INTELLIGENCE IN ANIMALS.

WIGAN, in his "Duality of the Mind," says that he once offered an apple to an elephant, letting the apple drop at the moment the elephant was about to seize it, so that it rolled out of its reach. The elephant waited a moment to see if Wigan would pick it up, and being disappointed in this expectation, set himself to blow violently against the opposite wall, and the recoil forced the apple to his feet. This may be regarded as a case of practical, rather than of abstract reasoning. Yet, as Wigan remarks, it was a trick which no one could have taught the animal, and "it must have arisen from a process of reflection perfectly similar to that which takes place in the human mind" under similar conditions. We have, indeed, he justly remarks, "examples of human minds not even capable of the degree of thought possessed in this instance by the elephant, yet performing, by a sort of automacy (*sic*) all the ordinary functions necessary to their occupation. In some of the mechanical processes in our great manufactories, where the minute subdivision of labour reduces the art of each individual almost to the very ultimate elements of muscular motion, I think that I have seen individuals incapable of a similar process."

In the following instance, from the same work, we have ingenuity combined with, and suggested by, indignation: "A large grey spider established himself in a recess formed by a shed and a projection of the house, and taking his long line diagonally from the corner of the house to the eaves of a small building which was at the bottom of the recess, he then filled up the triangular space with a well-defined circular web. I had noticed with admiration during the day his wonderful skill, the accuracy of his lines, and the equality of the spaces, and observed how carefully he pushed down his line, and fastened it securely with his two hind feet to each radius in succession. When he had finished about two-thirds of his concentric circles, or rather of his helix, he went to the centre and swallowed a quantity of white tenacious mucus, which he had deposited there at the commencement, having apparently spun himself out; he then proceeded to complete his work, which having accomplished, and thus reduced himself to very small dimensions, he hung himself up by the hind legs, and I presume went to sleep. The slightest touch of a fly was, however, sufficient to make him start out, and having wrapped up a few of them in his toils and well stocked his larder, he again betook himself to repose. In the meantime, one of the smaller spiders, considering that the diagonal line of his neighbour was strong enough to bear two webs, began to attach his lines to it, and having so done in four or five places, proceeded to spin his own web. My older friend tolerated the intrusion very patiently, and acquiesced in the use his neighbour was making of the "party wall," though against *spider law*. By-and-by the newcomer, having partly fitted up his own trap, and finding that no flies came into it, observing, I presume, the ample supply of food in his neighbour's premises, advanced along one of his own lines, seemingly for the purpose of open burglary. My old friend had tolerated much, but this was a degree of impudence for which he was not prepared, and which he determined to punish forthwith. He proceeded to the centre of his web, and giving the whole framework a violent shake, hoped to shake the intruder down upon the ground. He did no more, however, than turn him round on the line, where he hung very patiently till the shaking ceased, and then resumed his march towards his neighbour's territory. Again and again, and with increasing violence, did the large spider shake his web—it was all in vain; there was the enemy advancing, and though so small as to be easily overpowered, should he reach the mainland, the insult of the attempt was intolerable. On looking round, my elder friend saw that, during the violent shakes, he had broken two or three of his own short lines, and he left his opponent and set himself to work to mend them. Having completed the task to his perfect satisfaction, he returned to the burglar. The latter, when he came near, saw at once that he had been rash in provoking such an enemy, and hurried back to his own web. When his opponent saw him on his thin line in his retreat, he again set himself to his shaking fit, and made the most violent efforts to throw him down; it was all in vain, however, and he got safe home. After a moment's consideration, the other seemed to think that so audacious an attempt ought to be condignly punished, and he determined to retort the invasion. The thin lines of his diminutive antagonist, however, did not afford a sufficient support for his heavy bulk, and as he advanced, he carefully spun a strengthener upon the other's tenuous cord. It was now the little one's turn to shake off the intruder, and twice did he break the thin part of the line, and leave his enemy dangling. At last, the latter gave up the attempt, and went back to the centre of his own web, *after carefully detaching every one of the lines* which his neighbour had had the impudence to fasten to his long diagonal."

* ... Night-spirit. A.S. mare, nymph.

In this case we seem to recognise on both sides reasoning which approaches at times the abstract. In the calculation of means to an end, and change of plan in consequence of unexpected obstacles, there is practical reasoning. As Wigan well says, "Had the human race spun webs, and dared one another to single combat, they could not well have shown more judgment and skill in the attack and defence. The strengthening of the lines to bear the shaking, and doubling the smaller spider's lines while using them as lines of advance, belonged also to the order of practical reasoning, though of a rather advanced kind. But there was abstract reasoning, it seems to us, or a near approach to it, in the conduct of the smaller spider, first of all, in considering, as it were, how far he might trespass on the patience of an enemy whom he recognised as his superior, and again in the conduct of the larger in deciding when the time had come to give his small enemy a lesson, and in retreating finally without persisting, as if reflecting that his purpose was as well achieved as though he had actually driven the smaller spider from his web. His removing the lines which had supported the smaller web, though he had previously allowed them to remain, looks very much like a result of abstract reasoning.

We find illustrated by such instances the remark of Dr. Prichard, that among insects, if we take the different tribes collectively, manifestations of all the psychical qualities which we observe in mammifers and birds (regarding as a whole the properties divided among different departments), may be recognised in the most strict analogy. Attention, memory, the faculty of combining means to attain ends, cunning, the desire of revenge, care of offspring, and all the other psychical qualities which have been traced in the former class of animals (mammifers) are likewise to be observed in the latter as typical or characteristic phenomena—sometimes in one combination, sometimes in another; or, in different groups, sometimes strongly, sometimes more feebly expressed.

SOLIDS, LIQUIDS, AND GASES.

By W. Mattieu Williams.

PART IV.

As already explained, all gases are now proved to be analogous to steam; they are matter expanded and rendered self-repulsive by heat. All *elementary* matter may exist in either the three forms—solid, liquid, or gas, according to the amount of heat and pressure to which it is subjected. I limit this wide generalisation to *elementary* substances for the following reasons.

Many compounds are made up of elements so feebly held together that they become "dissociated" when heated to a temperature below their boiling-point. Or their condition may be otherwise defined by stating that the bonds of chemical energy, which hold their elements together, are weaker than the cohesion which binds and holds them in the condition of solid or liquid, and are more easily broken by the expansive energy of heat. To illustrate this, let us take two common and well-known oils, olive oil and turpentine. The first belongs to the class of "fixed oils," the second to the "volatile oils." If we apply heat to liquid turpentine, it boils, passes into the state of gaseous turpentine, which is easily condensible by cooling it. If the liquid result of this condensation is examined, we find it to be turpentine as before. Not so with the olive oil. Just as this reaches its boiling point, the heat, which would otherwise convert it into olive-oil vapour, begins to dissociate its constituents, and if the temperature be raised a little higher, we obtain some gases, but these are the products of decomposition, not gaseous olive oil. This is called "destructive" distillation.

In olive oil, the boiling-point and dissociation point are near to each other. In the case of glycerine, these points so nearly approximate that, although we cannot distil it unbroken under ordinary atmospheric pressure, we may do so if some of this pressure is removed. Under such diminished pressure, the boiling-point is brought down below the dissociation point, and condensible glycerine gas comes over without decomposition.

Sugar affords a very interesting example of dissociation, commencing far below the boiling point, and going on gradually and visibly, with increasing rapidity as the temperature is raised. Put some white sugar into a spoon, and heat the spoon gradually over a smokeless gas-flame or spirit-lamp. At first the sugar melts, then becomes yellow (barley sugar); this colour deepens to orange, then red, then chestnut-brown, then dark brown, then nearly black (caramel), then quite black, and finally it becomes a mere cinder. Sugar is composed of carbon and water; the heat dissociates this compound, separates the water, which passes off as vapour, and leaves the carbon behind. The gradual deepening of the colour indicates the gradual carbonisation, which is completed when only the dry insoluble cinder remains. An appearance of boiling is seen, but this is the boiling of the dissociated water, not of the sugar.

The dissociation temperature of water is far above its boiling-point. It is 5,072° Fah., under conditions corresponding to those which make its boiling-point 212°. If we examine the variations of the boiling-point of water, as the atmospheric pressure on its surface varies, some curious results follow. To do this the reader must endure some figures. They are extremely simple, and perfectly intelligible, but demand just a little attention. Below are three columns of figures. The first represents atmospheres of pressure—*i.e.*, taking our atmospheric pressure when it supports 30 inches of mercury in the barometer tube as a unit, that pressure is doubled, trebled, &c., up to twenty times in the first column. The second column states the temperature at which water boils when under the different pressures thus indicated. The third column, which is the subject for special study just now, shows how much we must raise the temperature of the water in order to make it boil as we go on adding atmospheres of pressure, or the increase of temperature due to each increase of one atmosphere of pressure. The figures are founded on the experiments of Regnault.

Pressure in Atmosphere.	Temperature F. °	Rise of Temperature for each additional Atmosphere.
1	212	37·5
2	249·5	23·8
3	273·3	17·9
4	291·2	14·8
5	306·0	12·2
6	318·2	11·4
7	329·6	9·9
8	339·5	8·9
9	348·4	8·2
10	356·6	7·6
11	364·2	6·9
12	371·1	6·7
13	377·8	6·2
14	384·0	6·0
15	390·0	5·4
16	395·4	5·4
17	400·8	5·1
18	405·9	4·9
19	410·8	4·6
20	415·4	—

It may be seen from the above that, with the exception of one irregularity, there is a continual diminution of the

additional temperature which is required to overcome an additional atmosphere of pressure, and if this goes on as the pressure and temperatures advance, we may ultimately reach a curious condition—a temperature at which additional pressure will demand no additional temperature to maintain the gaseous state; or, in other words, a temperature may be reached at which no amount of pressure can condense steam into water, or where the gaseous and liquid states merge or become indifferent.

But we must not push this mere numerical reasoning too far, seeing that it is quite possible to be continually approaching a given point, without ever reaching it, as when we go on continually halving the remaining distance. The figures in the above do not appear to follow according to such a law—nor, indeed, any other regularity. This probably arises from experimental error, as there are discrepancies in the results of different investigators. They all agree, however, in the broad fact of the gradation above stated. Dulong and Arago, who directed the experiments of the French Government Commission for investigating this subject, state the pressure at 20 atmospheres to be 418·4 at 21=422·9, at 23=427·3, at 23=431·4, and at 24 atmospheres, their highest *experimental*, limit 435·5, thus reducing the rise of temperature between the 23rd and 24th atmosphere to 4·1.

If we could go on heating water in a transparent vessel until this difference became a vanishing quantity, we should probably recognise a visible physical change coincident with this cessation of condensibility by pressure; but this is not possible, as glass would become red-hot and softened, and thus incapable of bearing the great pressure demanded. Besides this, glass is soluble in water at these high temperatures.

If, however, we can find some liquid with a lower boiling-point, we may go on piling atmosphere upon atmosphere of elastic expansive pressure, as the temperature is raised, without reaching an unmanageable degree of heat. Liquid carbonic acid, which, under a single atmosphere of pressure, boils at 112° below the zero of our thermometer, may thus be raised to a temperature having the same relation to its boiling-point that a red heat has to that of water, and may be still confined within a glass vessel, provided the walls of the vessel are sufficiently thick to bear the strain of the elastic outstriving pressure. In spite of its brittleness, glass is capable of bearing an enormous strain *steadily applied*, as may be proved by trying to break even a mere thread of glass by direct pull.

Dr. Andrews thus treated carbonic acid, and the experiment, as I have witnessed its repetition, is very curious. A liquid occupies the lower part of a very strong glass tube, which appears empty above. But this apparent void is occupied by invisible carbonic acid gas, evolved by the previous boiling of the liquid carbonic acid below. We start at a low temperature—say 40° Fahr. Then the temperature is raised; the liquid boils until it has given off sufficient gas or vapour to exert the full expansive pressure or tension due to that temperature. This pressure stops the boiling, and again the surface of the liquid is becalmed. This is continued until we approach nearly to 88° Fahr., when the surface of the liquid loses some of its sharp outline. Then 88° is reached, and the boundary between liquid and gas vanishes; liquid and gas have blended into one mysterious intermediate fluid; an indefinite fluctuating something is there filling the whole of the tube—an etherealised liquid or a visible gas. Hold a red-hot poker between your eye and the light; you will see an upflowing wavy movement of what appears like liquid air. The appearance of the hybrid fluid in the tube resembles this, but is sensibly denser, and evidently stands between the liquid and gaseous states of matter, as pitch or treacle stands between solid and liquid.

The temperature at which this occurs has been named by Dr. Andrews the "*critical temperature;*" here the gaseous and liquid states are "*continuous*," and it is probable that all other substances capable of existing in both states have their own particular critical temperatures.

Having thus stated the facts in popular outline, I shall conclude the subject in my next paper by indulging in some speculations of my own on the philosophy of these general facts or natural laws, and on some of their possible consequences.

PERSPECTIVE ILLUSIONS.

By H. J. Slack, F.G.S., &c.

Some persons have very little perception of perspective, and whole nations, as the Chinese, whether or not impressed by its effects, are not offended by drawings made in defiance of its rules. If experiments are made with English folk of different ages and degrees of education, a large proportion will be found obtuse in perceiving, and inaccurate in observing, the optical aspects of buildings, pieces of furniture, crockery, &c., as seen from different positions. On the other hand, the more artistically-cultivated or more naturally-endowed persons are extremely sensitive to all such effects; and, in some cases, most easily deceived. Etchings in simple lines, without shading, such as Flaxman's illustrations of Dante, show how easily the eye is led, by slight thickenings, curves, and angular approximations, to conceptions of distance or superposition, and it is probable that the illusions thus produced are strongest in the sharpest observers. Persons are sometimes met with who see nothing of the kind, and to whom all drawings look flat. Illusion figures are most deceptive when they give no hint of the real facts. Thus, your Fig. 8, p. 70, deceives an observer who finds no illusion in Fig. 9 on the opposite page. I see the illusions in both, but strongest in Fig. 8. Fig. 9 is more like a mosaic pavement, in regard to which the knowledge that the surface is flat makes it seem so, in spite of the lines. In looking at pictures and engravings, the mind willingly accepts their perspective indications. In Fig. 8 the illusion is produced by the series of diminishing arcs from the edge of the outer circle inwards. These correspond sufficiently with the representation in perspective of a series of curved objects of the same size, but looking smaller and smaller as the distance increases. This makes the centre of the line AB appear to bend inwards.

Compound vibration curves described in fine lines on paper are very deceptive. Mr. Washington Teasdale, who has great skill in these matters, has supplied me with many beautiful illustrations of this fact. He has also enabled me to make a variety of experiments with similar patterns, minutely ruled on glass as microscopic objects. The optical illusions are strongest when the lines correspond with those used in perspective drawing; and high magnification (say 1,000 ×) does not dissipate the impression, if enough of the pattern remains visible in the diminished field. When bands of lines of the same thickness cross each other, it is extremely difficult to illustrate them so as to make them look on one plane. Of two such series, either may be made to look uppermost. With large angle of operation and high powers, I believe it is quite impossible to obtain certain information of the structure of many objects, unless there are good reasons, independent of vision, for supposing one optical appearance more correspondent with fact than another.

Mr. Teasdale obliged me with a number of the compound vibration and curve slides, done in testing his apparatus, more or less imperfect. These are highly instructive. One especially, a spiral, with the initial part roughly scratched, and the subsequent parts wholly clear and fine, appears as a deep hollow under the microscope with minocular vision. A well known physiologist and microscopist, to whom it was shown, saw this perspective effect strongly when using one eye, but lost the illusion the moment both eyes were employed with the prism. This observer has both eyes better matched than usual, and trials with various persons show that the illusion is only partially dissipated when the binocular apparatus is used by persons whose eyes differ in focus, as is very common.

Reviews.

BRITISH FERNS.*

MANY find the study of ferns a difficult task, on account of the difficulty of recognising the distinguishing characteristics of each genus or class. The book before us is intended to remove this obstacle. At the beginning, a careful explanation is given of the general divisions of flowerless plants; of the different parts of ferns; of terms applicable to the shapes, etc., of their fronds; the grouping of ferns; and the genera of British ferns. Tables are given of each species separately, and according to the following plan, the technical terms used in which will be found fully explained in Miss Ridley's work.

1. First the scientific title is given, with the abridged or full name of the botanist who first gave this name, and after that the common name by which the fern is known.
2. In each instance the special points of the genus are indicated under the heading of generic characters.
3. Under distinctive specific characters are noted the special peculiarities and the points of difference by which the fern is known from all others of the genus to which it belongs.
4. Whether the fern has a rhizome or caudex.
5. The characters of the stipes and rachis.
6. The scales of the stipes.
7. The shape of the frond; its average size, the length and width being ascertained.
8. The texture of the frond, some ferns being hard and leathery, others very soft, thin, and transparent.
9. Whether deciduous (that is, shedding its fronds in autumn) or not.
10. The arrangement of the veins in the fronds.
11. Position of the receptacle.
12. Sori, shape of, and usual quantity.
13. Whether the sori are dorsal or marginal.
14. If there is an indusium or involucre, or neither; when present, shape and character of such.
15. Locality, or where found.
16. Lastly come the general remarks to each species.

At the end of the book is an index containing a list of technical terms used in the book, by which easy reference can be made to the page on which the meaning has been given. With such a help as this little pocket guide, many difficulties will be removed, and the study of ferns will be made both easy and interesting.

* "A Pocket Guide to British Ferns," by Marian S. Ridley. (London: D. Bogue.)

HIEROGLYPHIC INSCRIPTIONS OF THE SAKARA PYRAMIDS.

By a Member of the Society of Biblical Archæology.

THE recent magnificent discovery of royal mummies, papyri, and numerous other relics at Egyptian Thebes has been so surprising, as to throw unduly into the shade the almost equally important results attending the opening of pyramids at Sakara earlier in the year; doubly interesting, because their chambers and passages, contrary to those of pyramids previously explored, were found, except where mutilated, to be covered with hieroglyphics. The literature thus so marvellously preserved was soon seen to be of a very similar character to the most archaic chapters of the "Ritual," or "Book of the Dead," and of great mythological and theological value. They are, however, owing to their extreme antiquity, notwithstanding the distinctness and delicacy of the carved and painted pictorial hieroglyphics (which are equal to that of almost any other epoch), very difficult to translate, because many signs and ideas are used, or expressed differently from those of more recent texts with which scholars have hitherto chiefly been acquainted. Some of the inscriptions have now been published by Lepsius, in his "Egyptian Review," and a tentative translation of a portion of them made by Brusegh Bey.

The most valuable fact brought to light by a careful study of this decipherment of the texts is the decisive manner in which it enforces an immediate reconsideration of what were previously considered as axioms in Egyptology. Most, if not all, the myths and legends supposed to have been engrafted into the Egyptian religion at long subsequent dates are here found to be fully rife; not so much because some either appear in part or even amplified in the texts themselves, especially the Myth of Nut, but on account of the numerous allusions to, and short quotations from, legends which, to the initiated, at once called up, by a long train of associations, the story thus frequently only indicated by a sort of *double entendre*.

The whole history of Osiris, with his consequent belief in one supreme ever-existent deity, and account of a future judgment, with subsequent states of reward or punishment, is in full sway. It is distinctly and emphatically asserted of one deceased King, Pepi, that he is not really dead or annihilated, but that he has "received his spirit," or become spiritualised in the abode of the blessed. The legend of the struggle and triumph of Horus over Set, or of good over evil, is seen fully developed, as are many others. Ra, Sele, Harmachis, Tum, Tefunt, Harpocrates, Buto—in fact, nearly all the pantheon, hitherto considered to be a gradual accumulation of centuries after by many authorities—here burst into view in full splendour, and especially even Amen has his place.

The dog-star Sirius is mentioned in respect to its chronological importance, proving a careful observance of the constellations for at least two periods of fourteen and a half centuries previous to the writing of the inscriptions, or perhaps still older copies from which they were taken, and the objects depicted in the hieroglyphs indicate fully as advanced a culture and high civilisation as that of any epoch prior to the shepherd kings. The Elysian fields of heaven, besides many other places and events described in the ritual of the dead, are prominent, showing that this Bible of Egypt had long before been compiled and reverenced.

From this short *résumé* it will be gathered that these preeminently ancient texts afford no ground for arguments based on a theory of gradual development of Egyptian religion, from gross fetichism or anthropomorphic ideas; on the contrary, the theology exemplified is more spiritual, and diverges less into pantheism and animal worship by far than that of subsequent times. What are now believed to be divine truths, whether evolved out of necessity from man's spiritual nature, or imparted by primæval revelation, are, in fact, less buried beneath a *débris* of idolatry and ignorant superstition, than in the era when Egyptian religion (because misunderstood) became a jest to the writers of Greece and Rome.

A fortunate result of these explorations is also to terminate for ever the apparently endless controversy as to the original purport of the pyramids. These newly-opened pyramids are certainly the mausoleums of the monarchs whose names, creeds, and coffins they contain, and there can be no doubt but that such was the Great Pyramid which formed the basis for the wonderful conjectures of Prof. Piazzi Smyth and his school.*

These discoveries are almost certainly but the commencement of others equally interesting, for there are in the Nile Valley quite a number of pyramids yet unopened, and it is M. Maspero's announced intention to inaugurate his accession to the post of Marriette Pasha by completely exploring every one that is known.

[* I do not accept the wonderful conjectures of the Astronomer-Royal for Scotland; but no astronomer can doubt the astronomical significance of the structural details of the Great Pyramid. Whether intended as a tomb or not, it was certainly erected by men exceedingly well skilled in astronomy and mathematics, and as certainly astronomical observations, of considerable difficulty and requiring great exactitude, were carried on during its erection. Whether the Great Pyramid was erected with so much precision in order that astronomical observations might be made from it with great exactitude, or whether astronomical observations were made from it with great exactitude in order that it might be erected with great precision, may be a moot point. I have scarcely any doubt myself that both purposes were in view, the former as the primary one. —Ed.]

Letters to the Editor.

The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. He requests that all communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of Knowledge; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

*** *All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.*

All Letters or Queries to the Editor which require attention in the current issue of Knowledge, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

TO OUR READERS.

82.—Last week we had to add two leaves, including three pages of matter, to what we had intended to be our full weekly supply for at least the first half-year, and, probably, for the first year of our issue, and yet no less than 14 pp. of matter remained over. Our readers will see, therefore, that we lie under a considerable difficulty. We wish to find room for the better part of all the correspondence which reaches us. But we cannot do so without condensing most of the letters; and even so, we run over the limits which prudence dictates to us as suitable for a journal at the low price we have adopted. On the other hand, we have much to encourage us, even in the very circumstance which occasions our difficulty. Before we reached our fifth number we were receiving more correspondence than we expected to receive after we had been a year before the public; and the amount of this correspondence really measures the kindness of the welcome extended to us. That the friends we have already made are finding for us a welcome elsewhere, we know by the rate at which our circulation grows. We have had to reprint both our first and second numbers (every line having to be recomposed); and the indications are, that large though the second edition of No. 1 was, a third will before long be required. All this is very gratifying, and it leads us to hope that, long before we had expected, we shall be able to enlarge our weekly number. It may, perhaps, be said, that there are journals larger than ours at the same price, and that therefore we might at once enlarge our issue. There may be such journals, but if there is one giving anything like the same amount of original matter on *scientific* subjects at the same price, we have yet to hear of it. With the size we already have, and the amount of original (and costly) matter we give our readers, a very large sale is required to enable us permanently to enlarge each number. We shall not wait till such a sale is attained, but shall increase our weekly number in anticipation—probably long before. But our readers will understand that their co-operation is still needed. In the first place, each reader who contributes to our correspondence columns is earnestly requested to limit his remarks to subjects suitable to Knowledge, and to condense them to the utmost of his power. Then, each who approves our purpose can greatly help by making us known to others, noting to them in turn that they also, if content with us, can help to extend our sphere. We may point to the last four weeks' issue in evidence that we are anxious to meet our readers' wants by enlarging our numbers—without, however, engaging that such enlargement shall be permanent yet awhile. We may, indeed, note this, that if we had so kept down our correspondence and original matter as not to exceed what was given in our first number, our present issue, though the growth of only five weeks, would be remunerative. We have preferred, however, to increase our number, even at the risk of loss, and we shall continue to follow that policy so long as we receive such encouragement as heretofore from our readers and correspondents.

The Editor and Proprietors of "Knowledge."

"J. P. S." suggests that we should do as other papers dealing with popular science have done, in having reports of the meetings of scientific societies. We would gladly, if we could afford the space to do it properly. But let our friendly adviser consider how the matter stands. We already find it difficult to find space for what is absolutely essential as regards the purpose set before us. Now, the reports of scientific societies in the *Athenæum* for Nov. 26, which devotes only a section to science, and therefore condenses such reports as much as possible, occupy a page and a third, which, in the larger type of our correspondence columns, would be about a page and three-quarters. Now, let us ask how the readers for whom we specially cater, would care for so much space being occupied with reports like those in the *Athenæum*, excellent as those reports are in their proper place there. For instance, under the head "Chemical Society," we find this. "The following papers were read:—'Aluminium Alcohols, Part II. Their Products of Decomposition by Heat,' by Messrs. J. H. Gladstone and A. Tribe,—'On the Chemical Action of Decomposing Vegetable Matter on the Rock-forming Sediment of the Carboniferous Period,' by Mr. E. Wethered,—'On a and β Amylam,' by Mr. C. O'Sullivan,—'On the Action of Oxides on Salts, Part IV. Potassic Chlorate and Ferric Oxide,' by Messrs. E. J. Mills and G. Donald,—and 'On the Steeping of Barley,' by Messrs. E. J. Mills and J. Pettigrew."

Or take the following report of the Royal Society (Mr. W. Spottiswoode, President, in the chair):—"The following papers were read: 'Preliminary Note on the Photographic Spectrum of Comet *b*, 1881,' by Mr. W. Huggins,—'Note on the Reversal of the Spectrum of Cyanogen,' by Profs. Liveing and Dewar,—'The Sum of the Series of the Reciprocals of the Prime Numbers and of their Powers,' by Mr. C. W. Merrifield,—'Further Note on the Minute Anatomy of the Thymus,' by Mr. H. Watney,—'On the Production of Transient Electric Currents in Iron and Steel Conductors,' by Prof. Ewing,—'Experimental Researches on the Propagation of Heat by Conduction in Bone, Brain-tissue, and Skin,' by Dr. Lombard,—'On Allotropic or Active Nitrogen, and on the Complete Synthesis of Ammonia,' by Mr. G. S. Johnson,—'On the Comparative Structure of the Brain in Rodents,' by Mr. W. B. Lewis,—'The Prehensores of Male Butterflies of the Genera Papilio and Ornithoptera,' by Mr. P. H. Gosse,—'On the Propagation of Inhibitory Excitations in the Medulla Oblongata,' by Dr. H. Kronecker and Mr. S. Meltzer,—'Researches on Chemical Equivalence,' Parts IV. and V., by Mr. E. J. Mills,—and 'On the Refraction of Plane Polarised Light at the Surface of a Uniaxal Crystal,' by Mr. R. T. Glazebrook."

Or let us turn to a paper more especially devoted to science—*Nature*. Here the reports, as might be expected, are fuller; but they would scarcely correspond with our special purposes. Here is the report of the Entomological Society:—

H. T. Stainton, F.R.S., President, in the chair.—Exhibitions: An aberration of *Urapteryx sambucaria*, L., Mr. C. O. Waterhouse.—A new species of *Antheræa* from the Gold Coast; and some microscopic preparations of the saws, &c., of various *Hymenoptera*, prepared by Mr. P. Cameron of Glasgow, Mr. W. F. Kirby.—Pieces of honeycomb constructed on a bare wall, without any protection; and specimens and figures of new varities of *Armadillium vulgare*, L., and *Porcellio scaber*, Latr. Rev. A. E. Eaton.—A specimen of *Lycæna icarus*, Rott., var. *Icarinus*, Scriba, Dr. H. G. Lang.—An undescribed species of *Cicadidæ* from Borneo, with unusually developed opercula, Mr. W. L. Distant.—A female specimen of *Dufourea Minuta*, Lep., Mr. T. R. Billaps.—A specimen of *Scleroderma domestica*, Westw.; the larva was found parasitic on that of a Longicorn beetle in a pine-tree at Lyons; and some *Diptera* which attack figs in Turkey and Egypt, Sir S. S. Saunders (this led to an interesting discussion on fig-parasites and caprification).—Some remarkable tubes formed by Lepidopterous larvæ at Aden; and a specimen of *Cerura vinula*, L., which it was thought at first might belong to *C. erminea*, Esp., the President.—Papers read: Descriptions of new genera and species of Heterocerous *Lepidoptera* from Japan (concluded), by Mr. A. G. Butler; and a memoir on the various Dipterous insects (*Muscidæ* and *Tipulidæ*) destructive to cereals in Britain, by Professor Westwood."

The report of the Geological Society runs thus:—"R. Etheridge, F.R.S., President, in the chair. The following communications were read:—'On the genus *Stoliczkaria*, Dunc., and its distinctness from *Parkeria*, Carp. and Brady,' by Prof. P. Martin Duncan, M.B. Lond., F.R.S., F.G.S., Pres. R.M.S. 'On the elasticity and strength-constants of Japanese rocks,' by Thomas Gray, B.Sc., F.R.S.E., and

John Milne, F.G.S. 'The glacial deposits of West Cumberland,' by J. D. Kendall, C.E., F.C.S.'"

It would be the easiest thing in the world to fill four or five pages weekly with such reports. Indeed, it is easier to use them than to decline them; but however excellent such things may be in their place, we must point out that they would not at all correspond with the promises held forth in our prospectus. When we increase our space, it will be to find room for matter more likely to be widely and generally interesting. Of course, the papers read before our learned societies are full of interest for experts in the respective branches of science to which they belong; and their subject matter may be made very interesting by suitable treatment; but their mere names, or abstracts of their contents, could have no interest for the great majority of our readers. Even our scientific readers would only be interested, each, perhaps, in one or two out of a dozen such titles or abstracts. Richard A. Proctor.

PROFESSOR CLERK MAXWELL AND THE REVERSIBILITY OF THE GRAMME MACHINE.

[83]—Listening to Professor Sylvanus Thompson's paper on "Storage of Electricity," at the Society of Arts, last Wednesday, I heard to my surprise the following story (as an introduction to his subject):—"Not many months before he was seized with the mortal illness which robbed us too soon of his rare and unique genius, Professor Clerk Maxwell was asked by a distinguished living man of science what was the greatest scientific discovery of the last twenty-five years. His reply was, 'That the Gramme machine is reversible.'"

Now I fully subscribe to Professor Thompson's statement about the loss we have sustained by Professor Maxwell's death, of his rare and unique genius; but the latter part of the above citation I listened to as to a story told of great men; one of those stories which often have their origin in insignificant incidents or expressions, and are used for the purpose of raising the subject of which the great man speaks in the estimation of the listeners, or are intended to give a certain halo to his fame, and show his abstracted, simple mind. A story of this latter category I heard told of Arago. To enable a favourite cat to enter his study, he had a hole cut in his door; and when this cat had a kitten, he had a small hole cut at the side of the big one, to give facility to the kitten also to enter. We may look upon such stories as the spice with which sometimes scientific subjects are dished up; and in that light I accepted the account of Professor Clerk Maxwell's opinion about the greatest discovery within the last twenty-five years.

But I was astonished to find this story printed in the paper as given in *extenso* in the *Society of Arts Journal*, and hence offered to the reader as an undeniable fact.

Professor Thompson's paper itself contains the reason, why one may doubt, that Professor Maxwell should have made such a reply seriously; and the reason is, that ever since Ritter built up his first secondary pile, or Jacoby his first electro-magnetic engine, or Pacinotti his electro-magnetic engine with the first ring armature—nay, since Newton's law, as given by Professor Thompson himself in his paper ("to every action there is an equal and contrary reaction"), was enunciated, there could be no doubt whatever that the Gramme machine was reversible. But, principally, it follows directly out of Lenz's law of magneto-electric induction, published in 1834, and could have been foretold from all practical experience made with the electro-magnetic power engine which was intended and expected, some thirty to forty years ago, to supplant the steam-engine.

We will set aside for a moment Newton's "immortal" law *per se*, and its application to the secondary battery; and take the phenomena of the electro-magnetic motor, and of magneto-electric induction alone, into consideration.

Clerk Maxwell, in his "Electricity and Magnetism," 2nd edition, section 530 (Vol. II., p. 167), gives the latter phenomenon in the following words (under the heading Magneto-Electric Induction):—

"In all cases the direction of the secondary current is such that the *mechanical action* between the two conductors is *opposite* to the *direction of motion*, being a repulsion when the wires are approaching, and an attraction when they are receding. This very important fact was established by Lenz." (Pogg. Ann XXI., 483.—1834.)

Surely no great logical powers are required to interpret this law, as, in fact, years ago it has been interpreted—viz., the same arrangement of conductors and magnets which, by motion in relation to each other will produce a current in the conductor, will produce motion when from some electric source a current is sent through the conductor.

This "reaction" was applied in some of the earlier forms of magneto-electric "induction machines," which were used for illustrating the application of electricity as a "moving power"; and Pacinotti, when describing his electric motor, in which the ring armature was for the first time applied (1860-61), stated already that, when rotating the armature, his machine could be used as a generator of electricity.

Lastly, Jacobi showed nearly fifty years ago (about 1835 or 1836) that the efficiency of electro-magnetic motors was seriously interfered with by the electric currents induced in the machine. Hence, ever since the production of electric currents by means of magneto-electric induction was understood, and since the application of electricity for the production of motion has been studied, there could not have been any doubt about the reversibility of a magneto-electric or dynamo-electric generator into an electro-magnetic motor. And this story of Professor Clerk Maxwell declaring this "discovery" as the greatest scientific discovery of the last twenty-five years loses, to say the least of it, its point.

Perhaps some of your readers can bring some further light to bear upon this question, and witnesses will be forthcoming to prove either *pro* or *con*.

I may incidentally remark here that Professor Thompson's paper was the most complete account which it is possible to give of the important question of the storage of electricity, as he has thoroughly exhausted the subject in its scientific and practical bearing, for which he deserves the thanks of every electrician and engineer interested in this latest phase of the development of the science of electricity.

Nov. 26, 1881. C. G. G

SUNDAY ART EXHIBITION.

[84]—The exhibition of works executed by students of the City School of Art, which was opened on two Sundays in December last, having proved very interesting to a large number of people at the East-end of London, we have great satisfaction in announcing that arrangements have been made for again opening the exhibition on Sundays.

The Exhibition, which is the twenty-fifth Sunday Art Exhibition opened under the auspices of the Sunday Society, will be held in the Skinner-street Hall, Bishopsgate, and will be open from three to six o'clock p.m. on Sundays, Dec. 4 and 11. Admission will be free (without ticket), and we are pleased to be able to state that, in addition to the work of the students, some valuable pictures from the collection at South Kensington Museum will be exhibited.

In order that the widest publicity may be secured for this effort to provide innocent recreation on the leisure day of the week, we ask you to insert this letter in your columns, seeing that the facilities in London for visiting collections of art are far too limited, and that the want of open museums and art galleries on Sundays is especially felt by the inhabitants of crowded districts at this season of the year, when our climate so often practically closes the parks and gardens to them.—We are, &c.,

William Rogers, M.A., *Chairman*. } City School
R. H. Hadden, B.A., *Hon. Sec.* } of Art.
Thomas Burt, M.P., *President*. } Sunday
Mark H. Judge, *Hon. Sec.* } Society.

THE PYRAMID AND PARADOXERS.

[85]—If I were called upon to classify paradoxers, according to the good or evil effects they have had upon the community, I should give the Pyramid craze a very honourable place, for it has served to carry a knowledge of certain elementary facts connected with astronomy and geometry into dark regions where attention to such matters would probably never have been aroused by other means. There are thousands, possibly I should be nearer the truth if I said hundreds of thousands, who would never have known that the pole of the earth's axis is moving amongst the stars if it had not been for the Pyramid paradox, and the literature which has sprung up around it. There seems to be something connected with such speculations which has a fascination for a large class who would be wearied by a more cautious search after truth. We have only to notice how a statement, that three of the major planets will be in perihelion next year, and, consequently, something extraordinary may be expected to happen on the earth, goes the round of English and Colonial papers, to see that such speculations are fitted to do a sort of missionary work for science.

I wish to enquire what attitude those who would like to see the scientific spirit spread, should take with regard to such speculations. There are some who think that this tendency of human nature may be utilised to obtain money for science; and they have not thought it unworthy of them, as seekers after truth, to pose before the uninstructed, as weather prophets or alchemists. Give us money to study the sun, they say, and we will tell your fortune by sun-spots. We will show that the elements are not elementary, and, perhaps,

In this, we may then note them. I expect that there are a good many besides myself who feel that such a method of trading upon the paradoxical proclivities of our neighbours is not honest, and must not for a moment be indulged in. How, then, can we utilise the interest stirred up by such paradoxes to spread a love of science, and to bring to our neighbours all the benefits which follow from a patient search after truth?

It seems obviously unwise to ignore the paradoxers, or even unnecessarily to hurt their feelings and snub them, as some able men seem inclined to do. Paradoxing is an approach towards science, and, at all events, is better, and more worthy of being spoken of with respect, than purely selfish or unintellectual forms of enjoyment. Most of us are, no doubt, pretty frequently thrown amongst paradoxers, or with those whom we believe to be paradoxers. I would suggest that when we have made up our mind that our friend is a paradoxer, we should endeavour to put our objections to his paradox in the form of questions which raise difficulties that he has probably not yet considered. We may thus lead him on, and at the same time exercise ourselves in the art of seizing the difficulties of others.

Let us take an example. Mr. Baxendell, in your number for Nov. 18, says that he has been led to believe "that the data which formed the basis for the design of the great pyramid were the diameters and distances of the sun, earth, and moon, combined with the ratio π of the circumference of a circle to its diameter." He proceeds, let $s =$ the diameter of the sun, e = the diameter of the earth, m = the diameter of the moon. Then we have

(1). $\dfrac{se}{m} = 1{,}000{,}000\pi.$

(2). $\sqrt{s}\,\pi^{2}$ = length of one side of the base of the Pyramid.

And then follow thirty-one more such relations. I will not occupy space by repeating them. We might commence by asking whether the relationships discovered refer to the solar system at its present temperature, or to the temperature which its various parts had at the time when the Pyramid was designed. Let us suppose our imaginary pyramid paradoxer to answer that the relationships must be true for the temperatures and magnitudes of the designer's epoch. We might then proceed to inquire whether the probable errors in the determinations of the quantities made use of in the equations are sufficiently small to enable one to determine whether there has been any change of magnitude in the various parts of the solar system since the Pyramid epoch. The answer to this question will give an excellent opportunity for inquiring into the amount of the probable errors in determining the height of the Pyramid—the length of its base—and other pyramid magnitudes, compared with the probable errors in determining astronomical magnitudes. If we succeed in convincing him that the moon's distance can be determined with greater accuracy than the height of the great Pyramid, the rest is easy. It follows that there can be no advantage in attempting to determine astronomical quantities from pyramid measures.

But let us suppose that our companion is not sufficiently acquainted with astronomical methods to understand such reasoning. We can point out to him that the relationships he has found are not homogeneous. His first equation is equivalent to the statement that a length multiplied by a length is equal to a length multiplied by a number. Such a relation between quantities can only be true when a particular unit is used; and we can point out that all relationships in nature can be expressed so as to be true, whatever unit is used. We may then show him that his different equations involve different units; for example, his second equation involves the use of Pyramid miles on the one side, and Pyramid inches on the other.

In such a conversation, do not on any account refer to authority or endeavour to crush your opponent with facts that he cannot verify for himself, but patiently plod on, using your ingenuity to utilise the interest in the study of nature which has been begotten in his mind by the paradox, and, if possible, stir up his enthusiasm for the further study of such things, and endeavour to leave him with a sense of your perfect fairness and an appreciation of the scientific method which you strive to apply in satisfying yourself as to truth,

A. C. Ranyard.

Nov. 28, 1881.

PYRAMID MEASURES.

[86]—I do not profess to be master of the whole theory of probabilities, and it is perhaps owing to this that I have failed in my attempts to apply it in proving that the coincidences given in my paper are merely accidental. So far as I understand the theory, and have been able to apply it, the results indicate in a marked manner that the coincidences are *not* accidental, and, therefore, till the contrary can be shown, I think I am justified in my conclusion "that so far, at least, as the values of the distances and diameters of the sun, earth, and moon are concerned, modern science has made no real advance upon the science known to the builder of the Great Pyramid four thousand years ago."

The subject is one of considerable interest and importance, and, whether I am right or wrong in my conclusions, I shall be glad to see it fully and impartially discussed in Knowledge, and leave it to be decided from the results of such discussion whether it is desirable to enter into the questions of inspiration and prophecy. At present the general feeling appears to be decidedly against the coincidence theory, and the very few who object to the inspiration theory argue that in remote ages a high degree of civilisation existed, and that knowledge had been acquired which, when men afterwards relapsed into a state of superstition and barbarism was almost entirely lost. But on this theory the question again rises, In what way did men in those early times acquire this knowledge, and what evidence have we of its existence except that shown in the Great Pyramid?

I am, dear sir, yours faithfully,

Joseph Baxendell.

[87]—I venture to offer an explanation of the remarkable numerical relations between different parts of the Great Pyramid, pointed out by Mr. Baxendell in your number of Nov. 18, more probable, I think, than the supposition that its ancient builders had anticipated the discoveries of modern astronomy as to the distance of the sun and moon and the size and shape of the earth, but buried their marvellous attainments in a mass of stone-work, with no explanation, till, thousands of years afterwards, they were brought to light by the indefatigable zeal and scientific skill of Professor Piazzi Smyth.

The measures are, I believe, founded on astronomical observations, but observations of the most primitive character—the length of the year, the length of the month, the length of the week, and, what appears to have symbolised the course of time, the number 60, which meets us in the 360° of the zodiac, the 60 hours in India, and, I believe, also in Egypt, of the day, 60 minutes of the hour, 60 seconds of the minute, &c.

It seems to me impossible to reason with any assurance on this matter unless we knew more certainly than we do what their calculations were. We cannot ascertain this positively from the actual measurements, unless we assume that the old builders measured as accurately as Professor Piazzi Smyth, which is very improbable. It is quite possible that if we had the plans of the architect before us, we should find relations simpler than those stated above.

There is no necessity for attributing to the Egyptian builders any preternatural knowledge of astronomical facts in order to account for the peculiar relations subsisting between the measures of the Great Pyramid.—Yours, &c., G. Vansittart Neale.

[We have been obliged to omit the numerical relations indicated by Mr. Neale. They correspond with the measurements as well as others which have been devised. One could explain the proportions of the Pyramid in a dozen different ways.—Ed.]

POSSIBLE DAILY VARIATION OF PENDULUM.

[88]—There is a question that I have long thought might be worth trying respecting the earth's motion. In round numbers, say, the centre of the earth travels round the sun at the rate of 1,000,000 miles per day, or say 40,000 miles per hour; and the earth revolves at the rate of 1,000 miles per hour. One side of the earth will be going at the rate of 40,000 miles + 1,000; the other side 40,000 miles − 1,000; difference of velocity to be imparted in 12 hours, 2,000 miles per hour.

If a heavy and steady pendulum of great length were properly suspended and protected, some daily motion might be discovered, due to this varying velocity being communicated through the suspending-rod. The direction of revolution round the sun and the earth's revolution are both known. Perhaps some indication of some other motion might be found. A long pendulum would be essential. This, I apprehend, would not be so much affected by minute, rapid tremors, but would more clearly show the action of long duration. My own experience has been only with transits and other instruments in engineering work.

No. 1 of Knowledge has been sent to me to-day, as a sample, I presume. I shall take it. Receiving this has led me to trouble you with these remarks.—I remain, yours truly,

Henry Carr.

DARWIN'S THEORY OF EVOLUTION

(*Abstract, much condensed.*)

[89]—Sir John Lubbock, in his able and luminous address delivered before the British Association at York, told us that we ought to believe "that the horse and the ass, the sheep and the cow proceeded from common ancestors." I cannot find a title of

satisfactory evidence to prove the conclusion advocated by Sir John Lubbock. Let us take a single instance of Mr. Darwin's "method" of treating facts and inferences. He tells us that the rattle of the rattlesnake was probaby evolved by the desire of the creature "to frighten its enemies." [Darwin says nothing about the rattle-snake's *desire*.—ED.] Now the "enemies" of any animal seek it out in order to attack and destroy it; and, therefore, the rattle, so far from being a source of alarm, would act rather as an invitation to the snake's "enemies" to pursue and overcome it. [How if they dislike the noise?—ED.] Further, if the desire to frighten an enemy is a creative cause of such an organ as a rattle, why does not the same desire develop the same product in other creatures? Asimilar cause ought to produce a similar effect under similar conditions.

Sir John also alluded to those known transformations which occur in a short time, and which have been observed in many objects of creation; and he cited them as collateral testimony of those greater and more profound transmatations which have been supposed to be wrought in higher organisations during remote ages. I submit that this argument is altogether illusory. Those obvious minor transformations, to which Sir John referred, take a certain course—pursue a certain round—in obedience to regular processes and laws of being, and then terminate their career under known conditions.

The attention of the audience was also invited to the circumstance that the stripes of the tiger correspond with the long grass in which he makes his habitat; and that the spots of the leopard resemble the speckled appearance of the light falling through the leaves of trees. Now, if this eminent teacher really means that we should believe that in these instances the long grass and the specks of light are in the remotest degree the *causes* of the stripes of the tiger and the spots of the leopard, then I must say that the impression he wished to create is the most astounding and intolerable tax upon our credulity ever levied by the greatest scientific fanatic.

London, *Nov.* 19, 1881. NEWTON CROSLAND.

[Mr. Crosland entirely misapprehends the Darwinian theory and Sir J. Lubbock's remarks on it. We feel justified in excluding objections based on mere misinterpretation of the theory attacked; though inquiries suggested by such misinterpretations will always find a place here.—ED.]

PROBLEMS GEOMETRICALLY INSOLUBLE.

[90]—Would the geometrical solution of one or two problems, hitherto unsolved by geometry, be suitable for the pages of KNOWLEDGE? One is to determine the centre of gravity of a semicircle, and a computation of its distance from the centre of the circle by trigonometry. This, of course, is analogous to what is called squaring the circle.

Another is to determine the diameter of a sphere equal in volume to a given parallelopipedon. I should esteem it a favour if you would let me know what you think about them.—Yours, &c.,

J. G. MOORE.

[The trigonometrical computation of the centre of gravity of a circular arc is well-known. If our correspondent knows of any simpler form of it, we shall, of course, be glad to have his demonstration. If, as a preliminary to either of his problems, he proposes to "square the circle" geometrically, we shall be content to wait awhile. If he *has* squared the circle geometrically, we shall never succeed in showing "where the error comes in."—ED.]

A REMARKABLE RAINBOW.—LOGIC *versus* MATHEMATICS.

[91]—About three o'clock in the afternoon, one day last week, I observed a very bright rainbow, accompanied by its secondary external arc. To my great surprise, I noticed that the primary bow consisted of a triple series of colours, the red of the second band being in close contact with the violet of the first, and so with the third. The colours of the third band were very faint, and it was only distinctly visible for a short time at the summit of the arc; but the second band was visible over almost the whole length of the bow for three or four minutes. I should be glad to know whether this phenomenon has been noticed before, and how it may be explained.

I am rather sorry to see that, notwithstanding the warning of "F.R.A.S.," in No. 1, your admirable paper is being seized upon by the crotchet-mongers to air their remarkable notions, and I trust you will not think that I wish to dispute accepted and infallible laws of mathematics or of logic because I send you a paradox in which they appear to confute one another. My paradox is as follows:—

For every whole number there is a square, which is also a whole number. No two whole numbers have the same square.

Therefore there are as many whole numbers which are squares as there are whole numbers.

But there are many whole numbers which are not squares to other whole numbers.

It follows that there are whole numbers which are not whole numbers.

I prefer, however, to infer that the series of numbers being infinite, and the series of their squares being therefore also infinite, the latter infinity includes the former. I should like, however, to see a more satisfactory explanation. Faithfully yours, THETA.

[We do not see how there can be a more satisfactory explanation than the one "Theta" has himself supplied. If we consider any corresponding parts of the two series, 1, 2, 3, 4, &c., 1, 4, 9, 16, &c.; we see that, taking them together towards infinity, the latter will run on to a higher infinity, as it were, the highest number in the latter series being always the square of the highest number in the former. Or, algebraically:—

$$\frac{1^2+2^2+3^2+\ \ldots\ +n^2}{1+2+3+\ \ldots\ldots+n}=\frac{\frac{1}{6}n(n+1)(2n+1)}{\frac{1}{2}n(+1)}=\frac{2n+1}{3}$$

or is infinite when n is infinite.—ED.]

STONE ON WHEELS.

[92]—The results obtained by "Queensland" and his mathematical friend (Query 28, p. 80), with regard to the stone rolled on wheels, probably differ through their not understanding each other. If "Queensland" means the wheels to be supported by and revolve on fixed axles, then the stone will move, as he supposes, through a distance of 75 in. If, however, he intends the wheels to rest on the ground, they will themselves move along a distance of 75 in. for each revolution, carrying the stone with them, and at the same time they project the stone forward (with regard to their own position) an equal distance; it will, therefore, move a total distance of 75 in. + 75 in. = 150 in. G. M.

POLARITY *versus* GRAVITATION (*Abstract*).

[93]—I AM too old a stager to take umbrage at any usage, however rough, which I may experience in the arena of debate; when, therefore, you tell your readers that I am "a paradoxer," who hardly knows what he is about, I accept the imputation in the parliamentary and controversial sense in which it is meant. I presume it is your mode of saying that you differ from me in opinion.

My ideas must naturally suffer some loss of cogency by the necessity which exists of compressing their exposition within the space which you have kindly allotted to me.

Permit me to submit a few words of reply to your remarks on my letters. With regard to my objections to the Newtonian theory of the tides, as you merely content yourself with reiterating that theory, and asserting its correctness, I can, of course, say nothing more on this subject. Discussion becomes profitless when one disputant sets up what the other knocks down.

Touching my criticism on the centrifugal and centripetal forces as regulators of the motions of the universe, I beg leave to say that "the ill-informed writers" who used the term "centrifugal force" in the sense which I condemned are Joyce, in "Scientific Dialogues;" Milner, in "The Gallery of Nature;" Ferguson, in his "Lectures edited by Brewster;" Dr. Lardner, in his "Astronomy;" and "Keith on the Globes"—all well-known expounders of the Newtonian system—and Sir Isaac Newton himself. When you say that "centrifugal force is only another way of viewing the centripetal force," I know what you mean, but I fancy that the general reader will require further explanation. The revolution of a planet round the sun is supposed to be effected by the attraction of gravitation or centripetal force of the sun drawing the planet out of the straight line on which it was first impelled by its Maker.

In one part of its orbit the sun draws the planet nearer to itself, and thereby accelerates its speed. This increase of speed is supposed to generate "a centrifugal force" which has a repellent effect, and thus sends the planet off again on its proper course. Now, here comes in the ticklish part of this theory. When once the attraction of gravitation overcomes a rival force, nothing can stay its career of conquest, except the intervention of a third power of equal potency and independent jurisdiction. As the accelerated speed above-mentioned has no such independent origin, but proceeds directly from the centripetal force which draws the planet towards the sun, the planet cannot, by any struggle of a centrifugal force, escape from the catastrophe of ultimately being precipitated upon the face of its ruler, and there terminating its blundering career. Fortunately for us, the planet knows better, and obeys the law of polarity, not that of gravitation. I submit that my theory of polarity—attraction and repulsion—gets rid of the difficulty here so patent, and enables us to arrive at a sounder idea of the laws of revolution.

I now leave my ideas to their fate. If they are good for any-

thing, they will flourish; if they are worthless, they will die. I should consider them of not much value if I thought they would generally be accepted without a hard battle.

It may perhaps be as well to inform the general reader that my views do not in any way affect the working of those mathematical problems which are based upon the facts and phenomena of Nature.

Newton Crosland.

THE FAURE ACCUMULATOR.

[94]—As one who has read and recommended several friends to get Knowledge, might I ask a favour?

Much mention has lately been made of the "Faure Accumulator," and the benefits likely to accrue by this addition to electrical appliances, but I, like a good many more, have no very clear or precise idea as to what this invention is.

Would you therefore give in a future (and let me hope near) number of Knowledge, an account and description of it?

A Scientific Smatterer.

FAURE ACCUMULATOR. GRAVITY.

[95]—Would you kindly furnish me with a short account of the construction and mode of action of the Faure Accumulator? also, if not asking too much, the proof, or where it is to be found, of your statement concerning gravity, on page 59, No. 3, of Knowledge?

G. T.

PRACTICAL WORK WITH THE TELESCOPE.

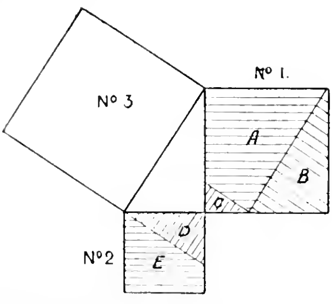
[96]—In reply to your correspondent "G. M.," letter 39, I would suggest for his use the Rev. T. W. Webb's "Celestial Objects for Common Telescopes," new edition, and R. A. Proctor's "Larger Star Atlas," 4th edition; and that he might do very useful work in carefully observing and recording the colours of stars, and the changes of brightness of some of the variables.

With best wishes for the success of Knowledge, I am, dear Sir, yours faithfully,

Joseph Baxendell.

THREE-SQUARE PUZZLE.

[97]—The enclosed has never been published in any book or periodical, but you are welcome to insert it in your paper, Knowledge, if you think well to do so. If a piece of cardboard is cut into the five pieces, A B C D and E, it is not easy to form the third large square with them. This makes a good puzzle for Christmas.



Arrange the five pieces A B C D E, which compose the two small squares Nos. 1 and 2 into a single square, No. 3. This, when done, is a mechanical proof of the above proposition.—Yours &c.,

Alf. A. Langley,
Engineer-in-Chief, Great Eastern Railway Co.

REPORTS OF SOCIETIES.

[98] Truly, as the "announcement" of Knowledge was originally gratifying to those who seek it, and equally as truly as the publication itself proves so, still, you will not wish the compliment of having got "one subscriber" to be often repeated to you. In my humble case I ordered three on "spec" of No. 1 before publication, and at once posted one off to the Australian up-country—the latitude somewhere where you did see what "Parallax" says not.

And after saying this, may I find a little fault? I will venture. It is in the omission of any chronicle of the proceedings of the learned societies, both home and foreign. For instance, the Meteorological met on the 16th, and discoursed on the big storm of Oct. 14. Now, sir, this feature is a great desideratum, and, therefore, let me urge it strongly; and also that the reports, however brief, be systematic and real. There surely would have been something most interesting to report concerning Professor Thompson on the "Storage of Electricity." And even the mental science societies should not be left out in the cold. The "Aristotelian," for instance, could tell the world briefly of its goings on in the "knowledge" of its mind-work. Yours, &c.,

J. F. S.

AQUEOUS VAPOUR.

[99]—In letter 20, on page 56 of your welcome paper, G. F. P. Dyer makes a statement about aqueous vapour, of which I venture to question the accuracy. He says "that aqueous vapour has the power to absorb rays of heat coming from the *earth*, but is incompetent to absorb rays from the *sun*." Now, in "Heat as a Mode of Motion," Professor Tyndall states (paragraph 684) that experiment proves that the aqueous vapour of the atmosphere absorbs about four-tenths of the heat radiated from the sun towards the earth. Has subsequent experiment disproved the Professor's conclusion, or has Mr. Dyer made a mistake? I think in this case Dr. Tyndall must be right.

H. P.

[H. P. will find, on more careful reading of paragraph 684, that Dr. Tyndall does not say exactly what H. P. has stated above. It is, however, true that aqueous vapour absorbs a portion of the sun's heat-rays, but in much smaller proportion than it absorbs the obscure heat-rays from the earth.—Ed.]

FLOWERS OF THE SKY.

[100]—May I take the liberty of calling your attention to certain passages in your work, "Flowers of the Sky?"

In page 2, the velocity of light, "at a rate exceeding more than ten million times the velocity of the swiftest express train."

In page 15, "that light carrying its message at a rate exceeding six thousand times the velocity of the swiftest express train, would be utterly unable to give a true account of the position and movements of the celestial bodies."

Again, in Figs. 17 and 18, the remarks that apply to 17 belong to 18, and *vice-versâ*.—Yours, &c.,

Wilhelmina K.

[I have not the book by me, but, unless I mistake the passage at page 15, it does not indicate what the velocity of light is, but a velocity which, though enormous, would utterly fail to do what light does. Figs. 17 and 18 got interchanged somehow after the book had been passed for press.—Ed.]

INTONATION IN SYNAGOGUES.

[101]—In answer to your correspondent "G. P." The accents in the Hebrew Bible supply the place of musical signs. Warschawski, in his "Progressive Hebrew Course and Music of the Bible," (London: Longmans, 1870), gives a series of equivalents for each of these accents in modern musical notation. For the accents themselves, see any large Hebrew Grammar. With regard to what may be called a cognate matter, the chanting of the Koran, Lane, in his "Modern Egyptians," gives the musical notes which would express the mode in which the first chapter is chanted. There are, of course, full treatises in Hebrew and Arabic on these subjects, from which deductions could be drawn: this, however, would require much patient research.

W. A. S.

A NEW COMPARISON OF POISONS.

[102]—In your last number (No. 4) you give an abstract from the *Times*, quoting the result of a number of experiments of the action of poisons in solution upon fish. Is there not some mistake in relation to the poisonous properties of lithium and barium. The paragraph runs thus:—Lithium (atomic weight 7, not 17), with an atomic weight only the twentieth of that of barium, is three times as poisonous. Now, it is generally known among chemists that barium (especially the chloride) is an exceedingly poisonous metal (or salt), whereas lithium, even in comparatively large quantities, is not poisonous, the citrate, for instance, being often prescribed for gout.

I think some mistake must have been made in copying the original, which, of course, is no omission on your part, it being merely an abstract. Wishing your valuable journal all success.—Yours, &c.,

Technical Chemist.

[The "copy" was the paragraph itself. Thanks for pointing out the inaccuracy. Newspaper science needs such correction, as we know from articles and paragraphs on subjects more especially our own than technical chemistry.—Ed.]

EVOLUTION—STAR-MAPS—BRITISH MUSEUM.

[103]—While defending, to the best of my ability, the theory of evolution, I have been asked the following question, which I have been unable to answer: "If man be an 'evolved' being, why has he not improved?"

I should like to be informed whether—(1) Since man has existed has the process of evolution effected any change in him? (2) If so, what change? (3) If not, why not?

With reference to your star-maps, you say in No. 4 of KNOWLEDGE that the times given in Nos. 1, 2, and 3 are one hour out, but that the error is corrected in No. 4. Yet taking the same dates, the times in No. 4 agree with the others. I would be glad if you would explain this.*

Could you, or any of your readers, inform me on what conditions and by what means admission can be gained to the British Museum library and reading-room?† G. M.

PROTECTING HOUSES FROM LIGHTNING.

[104]—I wish to protect a square house which has nine chimneys, all of equal height, from lightning, by means of two iron rods 3 ft. above two of the *centre* chimneys, connected with the iron water-pipe which supplies the cisterns from the main, by a galvanised iron wire conductor. Will you kindly tell me if this protection will be sufficient, and whether I have chosen the right chimneys. I prefer using the *centre* ones, as the conductors will be less conspicuous than if they were placed on chimneys *near the corners* of the house, the roof being nearly hidden from view by a parapet. I am delighted with KNOWLEDGE, but I wish you would print the names of the stars of the first and second magnitude on the map. B.

A QUESTION OF GRAMMAR.

[105]—Is "Nameless" (query 24) correct in writing "*would* the editor," &c.? Should not he have written "*will* the editor"? "Nameless's" mode of asking his question, I know, is frequently adopted, and my eye just now lights upon a letter in the *Guardian*, where the writer has "*might* I call your attention," &c. Would not *may* have been the proper word? Again, "I cannot but think" is an expression of every-day occurrence, and I presume right; but is "I can but think" wrong? "I can but think" seems only another way of saying "I can only think," which is also of common occurrence. If "I can but think" is not wrong, then we have both expressions, one with the negative, and the other without, meaning the same thing. We have the word "annul" and also "disannul," both meaning much the same thing, but "dis" is not used as negative, but as intensive. Would that be the case with the word "not," in the first instance? A. T. C.

THE MISSING LINK.

[106]—Mr. Wilson, in Letter 33, admits "where the links that connect man to his lower neighbours are to be found is a difficult question to answer," but until it is answered satisfactorily, I am afraid that common ignorance (?) will continue to ask the unfortunate question. One evolutionist to whom I put the question answered that he supposed the remains were all under the sea.

It seems to me that evolutionists would call every one that does not agree with their dogmatical statements an ignoramus.—I am, &c., ANOTHER IGNORAMUS.

THE MISSING LINK (*Abstract*).

[107]—I approach a criticism of Dr. Wilson's remarks (p. 74, No. 4) on the "Missing Link" with a nervousness that is only equalled by my desire to know and possess the truth respecting the circumstances surrounding the case.

Your correspondent, "Ignoramus," if not satisfied as to the foundation of evolution, has, I think, a right to ask for that which evolutionists declare exists, and is the only foundation upon which evolution is said to exist.

Professor Huxley ("Encyclopædia Britannica," 9th edition, vol. iii., p. 690) speaks thus: "The only perfectly safe foundation for the doctrine of evolution is in the historical, or rather archæological, evidence that particular organism, have arisen by the gradual modification of their predecessors (which is) furnished by fossil remains." Similarly Bastian, Darwin, Herbert Spencer, and others.

Now I ask for one species from the lowest to the highest strata in any of the geological periods that have been transformed into another?

Secondly, if the truth of evolution rests on fossil remains ("Missing Link"), where are those fossil remains? Where found? Who found by? Where are they now? Hæckel, Buchner, Darwin, &c., have failed to find or give any. Evolution's foundation does not rest on rudimentary organs, but on fossil remains.

I only plead for what evolutionists declare has led them to teach and hold the doctrine of evolution. To tell me that the fossil remains are gone down to the bottom of the sea—that where men first lived is all ocean—is to mock me in my earnest cry for more light.—Yours, &c., MITCHELL.

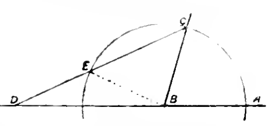
KNOWLEDGE FOR THE YOUNG.

[108]—I am very pleased with KNOWLEDGE, and am endeavouring to make my children like it. Parents do not sufficiently estimate the importance of watching boys' literature. I have great difficulties before me, but if, when my boys are young men, these difficulties right themselves, I may be satisfied, but not before. The penny weekly journals started within the last few years by the Religious Tract Society and others, professed to supply an improved literature, but I fail to see it in such brutal tales of adventure as "From Powder-monkey to Admiral," &c. Boys eagerly read them, and the principles they learn are carried into practice in their every-day life. The few chapters similar to those in KNOWLEDGE are not read at all. I find it much easier to read "The Land of the Midnight Sun," with the map before me, to my boy aged nine, than to get his elder brother to look at it—he is too busy over some tale of the "to be continued in our next" class. I was really astonished to watch the interest the younger boy took in Darwin's book on worms, which I read to him, and he has since studied their habits to a surprising degree. How, then, will it be possible to rectify the mischief already done by the penny journals? Can you offer a column of inducements to boys for short essays on scientific or natural history subjects suited to certain ages (with permission to consult a parent or guardian in the composition)? It seems to me this would bridge over the difficulty I am now experiencing with the two elder of my eight children. Wishing your magazine much success. R. GILL.

[We fear it would not be possible yet to give a column to short essays by boys; but possibly a column or two especially for boys would be a useful addition.—ED.]

KNOWLEDGE—ILLUSION—TRISECTING AN ANGLE.

[109]—In addressing you a few words of congratulation on your success in producing KNOWLEDGE, I beg to suggest that there are a great many questions which may be elucidated in it (such as the method used by the American meteorologists in predicting storms, the present theory of the spectrum colours as differing from that taught in ordinary text books, papers on biology, &c.) which are *caviare* to the general public, and, therefore, exactly fitted for its pages, even at the risk of crowding out chess and whist, which are very fairly dealt with in the ordinary magazines, and hardly come within the special scope of KNOWLEDGE, as it seems to me. However, the many must be studied, of course. I personally should like to see it exclusively devoted to the dissemination of sound natural science, hence this hint. Your interesting notes on illusions have recalled to me the following, wherein the oblique lines enclosed within the parallel straight line A and B cause the latter



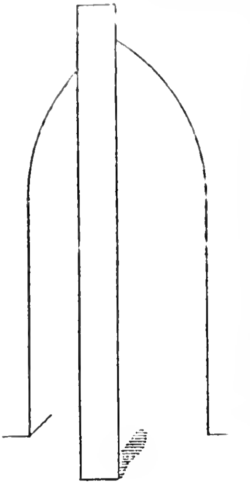
to appear zigzag instead of straight—which they really are. I send also a mechanical way of trisecting an angle, in reply to Query No. 48, thinking it cannot be done by pure geometry. It was got by me from "Wormell's Plane Geometry," and I find it quite correct for angles under 120°. ABC is the angle to be trisected. From B draw a semicircle, as in the figure. Then mark off the radius used for the semicircle on the straight edge of a piece of paper, which must then be placed so that the edge cuts through

* When we wrote as above, we supposed our correction was in time; but, as a matter of fact, the map, which, to ensure perfect blackness, was printed separately, had been for hours in the machine-room, and nearly half the impressions had been already struck off when the correction was made.

† By letter to chief Librarian, accompanied by a letter from a householder, certifying respectability, and stating objects of applicant: age must be over twenty-one.—ED.]

the point of intersection C, and so that one of the two marks on it lies in the semicircle, and the other in AB produced, as in E and D respectively. The point D thus obtained gives the angle CDA, which is the required third of ABC. The proof is interesting. For the exterior angle ABC is $= C + D$. But since BC is $=$ to BE and to ED, the angle BCE is $=$ to BEC, and this to $EBD + EDB$; that is, to twice the angle D. Therefore ABC is equal to 3 times D.—Yours, &c., James Warren.

SINGULAR ILLUSION.



[110]—A singular and practical illustration of the optical illusion, Fig. 2, of Mr. Foster's came under my notice a short time ago. The tower-arch of a church had been rebuilt, and during its construction a tall strut was set at an angle to the base, with its head fixed against the wall just above the apex of the arch. Whilst standing at the chancel steps, the arch presented a most singular appearance, and I called the contractor, who looked somewhat alarmed and astonished, and we both thought the arch must have dropped on one side. The accompanying drawing will explain what we saw. The pointed arch shows better than the semicircle the apparent illusion of the two lines belonging to different circles. F. Long.

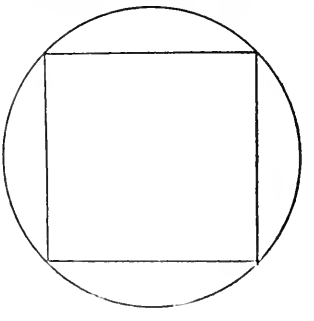
In order to make the illusion more plain, the strut is drawn out of proportion.

ILLUSIONS.

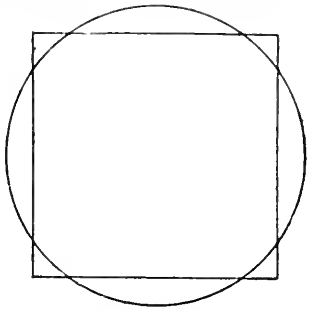
[111]—A few remarks upon the paper by Mr. Foster, on "Illusions," may be of some slight interest. The effects which angular, curved, and straight lines, in juxtaposition, have upon one another with respect to the eye are certainly very curious, and few eyes will fail to perceive the apparent distortions in the cases figured. I should like to remark, however, that in Figure 5, to my eyes, and to those of the one or two persons to whom I have presented the figure, the effect of the curves on the straight lines is just the reverse of that stated to be the case by Mr. Foster.

In Figure 6, to my eyes the straight lines AB and CD appear nearer in the middle, and EF and GH appear farther apart in the middle, thus agreeing with what is stated, and being the *reverse* of the two previous pairs of lines, which is what one would expect. I cannot by any method of gazing cause the straight lines in the last two pairs, Figure 7, to appear anything but parallel.

Below will be found a figure which shows the "flattened" appearance of a circle at the four corners of an inscribed square—a distortion of the same nature as that shown in Figure 3.



The figure beneath shows the same effect on the circle, and also gives the square the appearance of being drawn in at the middle of each side. Both these effects are shown much better



with larger figures. All these diagrams form pregnant comments on the oft-repeated adage: "Cannot I believe my own eyes?"—I am, yours, &c., Harry Grimshaw, F.C.S.

Clayton, Manchester, *Nov.* 21*st*, 1881.

CIRRUS CLOUDS.

[112]—In reply to "Anti-Guebre" (letter 2, p. 15), scientific men believe cirrus clouds to be composed of ice crystals because no other reasonable explanation is available. These clouds are found to produce certain optical effects upon light transmitted through them which can only be explained by the theory of their crystalline nature, ice being the only substance which will produce the observed phenomena under the conditions. This can be mathematically proved. In conclusion, I would ask your correspondent, Mr. G. F. P. Dyer (letter 20, p. 56), to refer to page 463-4 of Tyndall's "Heat," where it is stated that the aqueous vapour of our air does absorb a very considerable amount of direct solar heat, about four-tenths of the entire radiation; these being chiefly *dark* rays, which are the most effective as regards heating purposes.—I remain, sir, yours truly,

Birmingham. T. J. Hickin.

VIVISECTION. INJURIES TO THE BRAIN.

[113]—Most people think that of all cruel operations upon animals, that of cutting the brain is beyond all the most cruel. The first two extracts from recent numbers of the *Lancet* may modify their opinion. The third extract is from "Body and Mind," by Henry Maudsley, M.D., F.R.C.P., &c., &c.

G. A., aged 15 years, met with an accident by which one-half of the scalp was torn from the skull, which was itself fractured. From between the edges of the broken bone, brain substance was oozing, and this kept on for thirty-six hours. Recovery took place. The points to be noticed are:—

1. When the boy was found, he had already walked sixty yards without any assistance from the place in the coal mine where his head was crushed between a waggon and a rock, which forms the side of the "waggon way," and he afterwards walked home.

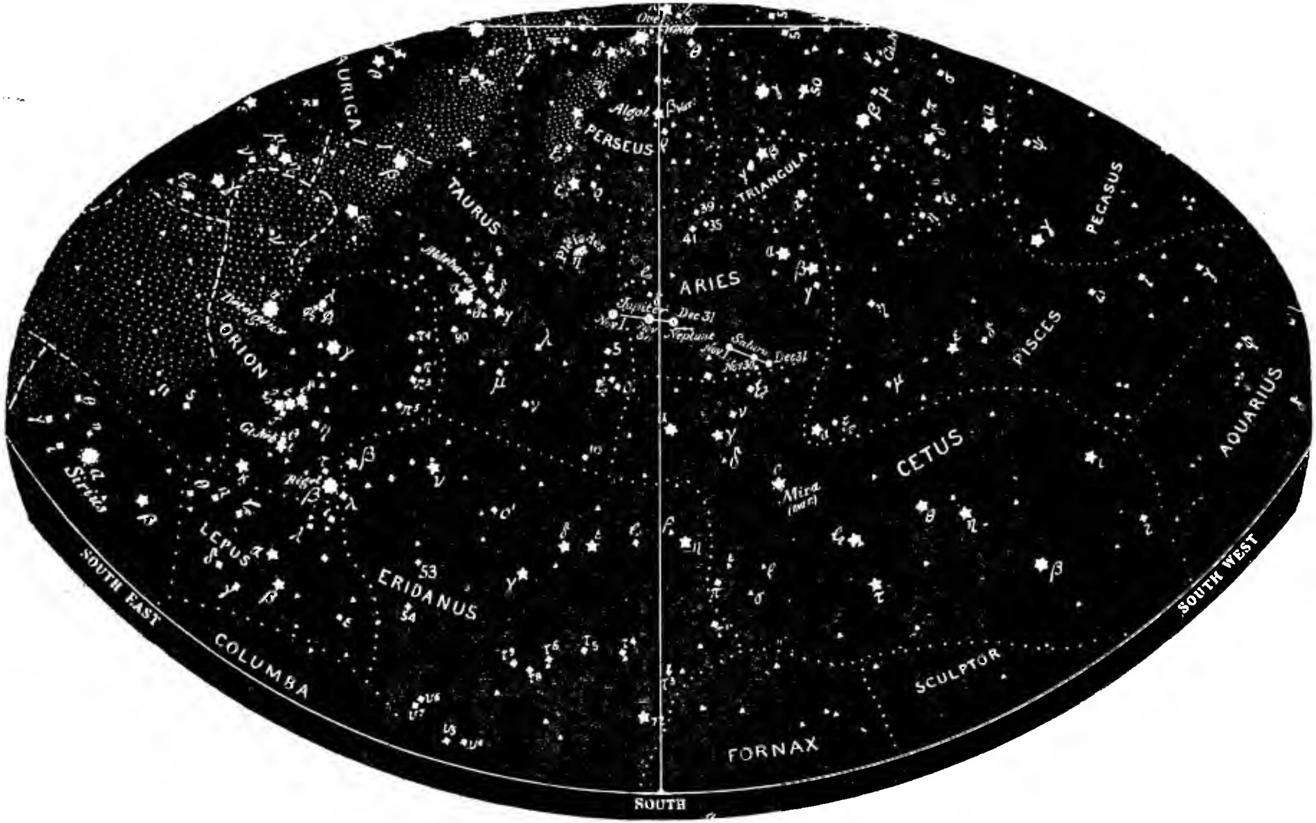
2. Although the injury was inflicted on March 6, 1880, the intellect is not impaired or mind affected in any way.

A man, aged 44, in an attempt at suicide, sent a small dagger through his skull into the brain. He had held the dagger in his left hand, and given it with the right several blows with a mallet, believing that he would fall dead at the first blow. To his profound surprise he felt no pain. He struck the dagger in all about a dozen times. When seen, about two hours after, the handle was projecting, 9 centimètres of the blade being sheathed in the head. For half-an-hour unsuccessful attempts were made to get the dagger out with a strong pair of pincers, the patient being held firm on the ground by two vigorous persons. The patient, who walked well and complained of no headache, was taken to a coppersmith's, and the dagger fixed to a chain passing over a cylinder turned by steam power. The man was fastened to rings in the ground. At the second turn of the cylinder the dagger came out; the patient, who had submitted to these manœuvres, suffered no pain or inconvenience. He walked to the hospital, remained there for ten days without fever or pain. He then returned to his work, and the wound healed.

R. E. Williams.

[*Continued on page* 121.

THE SOUTHERN SKIES IN DECEMBER.



This Map shows the position of the stars in the Southern Skies:—

On November 30, at 10½ o'clock. | On December 8, at 10 o'clock. | On December 16, at 9½ o'clock. | On December 23, at 9 o'clock. | On December 30, at 8½ o'clock.
On December 4, at 10¼ o'clock. | On December 12, at 9¾ o'clock. | On December 19, at 9¼ o'clock. | On December 27, at 8¾ o'clock. | On January 3, at 8¼ o'clock.

The movements of the planets Jupiter, Saturn, and Neptune, now travelling in this part of the stellar heavens, are indicated by the lines marked with these planets' names. All these planets are retrograding, but less swiftly than last month, when, as explained in No. 1, they passed their respective points of opposition. The stars in the southern skies move across ... to right.

... of the first magnitude are shown with eight points, those of the second with six, of the third with five, of the fourth with four, of the fifth with three

Continued from page 118.]

BRAIN AND BRAIN CASE.

[114]—In Letter 42, page 78, of Knowledge, Charles Hamilton asks three pertinent questions. Leaving you to answer the first two as you best can, allow me to make a few brief remarks on the last, viz., "Does the brain shape or mould the form of the cranium or skull?" Dr. Lawrence, late Professor of Anatomy and Surgery to the College of St. Bartholomew's Hospital, London, in his "Lectures on Man," says of the skull that "the general capacity and particular forms depend entirely on the size and partial development of the brain." While Dr. Mayo, late Professor of Anatomy and Surgery to Royal College of Surgeons, in his work on "Human Physiology," after considering the relation between mind and brain, says, "Then it is certain that the skull is formed after the brain, and moulded upon it; and that very moderate attention will enable an anatomist, for the most part, to distinguish those prominences which are caused by inequalities of bone from those which mark the proportions of brain." Dr. Turner, Professor of Anatomy in the University of Edinburgh, in a paper read before the Royal Society of that city, on Jan. 19, 1871, says, "The outer surface of the skull does not correspond in shape to the outside of the brain."

Now, sir, what is the meaning of all this? Out of mere curiosity I have consulted medical men with regard to the mutual relations of skull and brain, till I am tired, and, although they set out with the observation that the question is simply one of fact, no two of them give me the same answer. Indeed, they are completely at sixes and sevens. What I wish to point out as the moral of all this is, that for us there is nothing left but to fall back upon nature, which, as Dr. Gall said, is the only infallible testimony, and bring the inquiry to the test of observation and of fact, leaving medical men to dogmatise as they choose.

Glasgow, *Nov.* 25, 1881. A. B.

TECHNICAL TERMS—SCIENTIFIC NEWS—ILLUSION.

[115]—I take the liberty of sugggesting that you *request* corre spondents to place the technical terms they employ side by side with the popular modes of expression, for the reason given in letter 46, p. 78. In letter 46, p. 79, in the fourth line of the second paragraph, Mr. Allen, in alluding to the shape of the forehead, uses the term "orthomètopy," bracketing the meaning. So far so good, but only in the next line he makes use of the term "prognathism"; three lines further appears "orthognathism," and again five lines below the word "Sella." Writers must know that only specialists, or classical scholars, would understand the meaning of terms such as these. What, therefore, I take the liberty of suggesting would be your placing a standing notice to correspondents at the commencement of the correspondents' column. Also that, under the head of "Scientific News," you give weekly, or from time to time, the most recent inventions or discoveries in physical and mechanical science that would be of popular interest.

F. H. S.

In reference to the drawing I sent you last week illustrating an optical illusion (letter 65, p. 95), the effect is much more striking with the horizontal line uppermost.

[It seems to us more striking still when the angle is put uppermost or lowest.—Ed.]

THE DURATION OF A FLASH OF LIGHTNING.

[116]—Can you or any of your readers give me information on the following two points:—

1. Did Wheatstone or anyone else ever make an experiment on a flash of lightning to determine the time of its duration?

2. If so, what was the nature of the experiment, and where is it described?

I may state, to prevent misapprehension, that I am quite aware that Wheatstone made experiments to determine the duration of an electric spark produced under certain definite conditions, and that these experiments are fully described in the "Transactions of the Royal Society." But I find it explicitly stated by several writers of high authority—for example, Mascart,* Daguin,† Ganot,‡—that Wheatstone made experiments on the lightning flash itself. They say he employed a white disc with black rays, very close together, which he put in rapid rotation, and so placed that it was illuminated by each succeeding flash of lightning. The details of the experiment are fully given by Deschanel,§ who, however, does not ascribe it to Wheatstone. Now I have searched in vain for the authentic record of this experiment, and I should feel greatly obliged to anyone who can give me information about it in the pages of Knowledge.

I think you will agree with me that the subject is not without interest for your readers, when I mention the widely different statements that have been put before the public, quite recently, regarding the duration of a flash of lightning. According to Mascart,* it is less than $\frac{1}{1,000}$ of a second; according to Deschanel,† it is less than the $\frac{1}{10,000}$; and according to Tyndall,‡ less than $\frac{1}{100,000}$. "Wheatstone has shown that it certainly lasts less than a millionth part of a second."§ Of course, if this last statement be true all the others are, in a certain sense, true also; but they do not give us the whole truth.—Yours, &c. Gerald Molloy.

LUMINOUS PHENOMENON.

[117]—I find in the volume of the *Leisure Hour* for 1853, under the title of "Astral Wonders," a pamphlet on a lecture delivered by the Rev. J. Craig, M.A., a short time before.

I wish to call your attention to the following. He says:—"When I was a boy, from some cause or other I was put into a dark room and tried to escape out of it. I had a knife in my pocket, and I began to cut a hole in the door to try to get quietly away by coming at the latch. Still, something occurred which induced me to remain where I was. I heard a footstep, and I knew I was not doing quite right. When I pulled my hand back the sun happened to be shining very much and I saw little globules running off in all directions. I thought even then this was very remarkable. I again put out my hand, and on pulling it back I saw the little globules running off as before When I grew up to be a man I began to think of that childish thing. I felt certain then that light was a fluid and could run off our fingers like water; and if you feel any interest in light and will examine for yourselves you will see that light is truly a fluid; it has its waves, its currents, its ocean deeps, and our telescopes may yet tell us something of its tidal surroundings."

I shall be most happy to receive any information on the above subject, viz. (that of light being a fluid) which you or any of your correspondents may afford me.—Yours faithfully, W. M. M.

[Mr. Craig seems to have mistaken a physiological for a physical phenomenon. His experience showed, as many others do, that "seeing is not always believing." In a railway accident I have seen "astral wonders," as I have when I have been pitched on to my head by a galloping horse, but I do not infer that stars reside in my head.—Ed.]

A £5 TELESCOPE.

[118]—"Twenty" (letter 48, p. 79) cannot obtain an absolutely perfect instrument for £5, but for this sum he can obtain from numerous opticians a telescope which has all that is necessary for a beginner, and the other apparatus he can get from time to time (and at no considerable cost), as he becomes more experienced. The £5 telescopes advertised are refractors; that is, the usual sort with a lens (object glass, of 3 in. diameter) at the end of a tube. The other sort, termed reflectors, having a silvered mirror at the bottom of a tube reflecting the image to a focus at the top, are less costly (if a large instrument is wanted), but require very nice management, and should only be purchased after considerable experience is acquired. The £5 glasses are very good ones indeed, containing all the groundwork of a first-class instrument, and will be found all that "Twenty" wants to commence with. After a time, he will like a tall wooden tripod-stand (which can be made by a handy man), and will want to add a "finder;" that is, a miniature telescope fixed at the side, by looking through which a celestial object can be immediately brought into the field of view of the larger one. He will also want a couple of extra eyepieces of different powers to the one supplied with the instrument, as different objects require different powers to show them at their best. After this (if his taste for observation developes), he may like to replace the object glass with one by a celebrated maker. These things, however, only result from an increased passion for the study of the heavenly bodies. The instrument, as supplied for £5, contains all that is necessary for a beginner, and one who simply wishes to observe the stars for occasional pleasure will never want anything more. Such accessories

as the student wants can always be added, and the cheap instrument made as complete as the most expensive. It is a great mistake for a beginner to have too large and complex an instrument, and the difference in view through a very large glass compared with an ordinary one, such as is here referred to, is not so great as would be imagined. I may add, that the eye can be educated the same as the hand, and, after a time, "Twenty" will be able to see much more through his glass than when he started. A novice looking at Jupiter, for instance, will see but a small blank disc, but a practised observer, looking through the same telescope, will see a multitude of interesting details on the planet's surface quite invisible to the former. It is scarcely necessary to add to the foregoing that for £5 a very good second hand instrument can sometimes be got by advertising. There is no occasion, either, to reply to "Twenty's" other telescopic queries, as I see the Editor promises an article upon the subject. ALBERT P. HOLDEN.

107, Hoxton-street, N.

COMETS' TAILS.—RAINFALL AND FORESTS.—THE OLFACTORY TRACT.—INTELLIGENCE IN ANIMALS.

[119] 1. There is a question I should like to ask you with respect to comets' tails, viz.: Has the spectrum of the tail ever been obtained; if there has been one taken, was there any alteration or new band observed in the spectra? I look forward eagerly to the continuation of your articles on the subject, for, I am sorry to say, I am very ignorant on the subject.

2. With respect to your article on the Fiji Islands, I noticed the interesting circumstance of the rainfall diminishing simultaneously to the cutting down of timber. Was it not the same with the Island of Ascension, only in a still more remarkable degree; for had not the inhabitants to plant trees again, so that they might be again blessed with rain? I should be glad if you would inform me if I am correct in the above, for I do not know where to look to refresh my memory on the subject.

3. In reading "M. L.'s" article on "Vivisection," an idea occurred to me connected with the olfactory tract, on which I should like your opinion. It is this:—A good many years ago my cousin and self were working in the same "Lab.," and by accident he smashed a full Winchester of NH_4HO, with the natural result that he was half-suffocated; but the part I am curious about is, that from that day to this he has had neither taste nor smell. Do you think that the dose of NH_3 destroyed that part of the brain referred to by W. L.?

4. "Intelligence of Animals":—I am in a position to give rather a curious case of the intelligence of rats, proving—as does your article—the *practical*, but if we look at it in rather a favourable light, might prove even the abstract, which is wanting.

The rats in this case also "bored" through a lead pipe; so far there is no difference to the example in your paper, and you will think this is one of the "two and two equal four letters"; but this lead pipe, unfortunately for my father, was in the "hold" of one of his ships, and through their (the rats) craving for fresh water, and getting it, a great deal of damage was done; they actually did hit on the *fresh water* lead pipes in *preference* (may I say) to the other salt water ones (leading from the W.C.'s on deck, I mean, which, as you are aware, are cleaned by salt water.) This, I think, is a curious coincidence, for might it not be turned by scientists either way, either to accident or to sagacity on the part of the rats?—Yours, &c., F. C. S.

MEN'S HEADS.

[120]—I have read carefully the letters on the size of human heads. I am inclined to think that our heads, as a nation, are smaller. The size of the head corresponds to that of the body, so that large heads mean large bodies. This is seen amongst navvies, agricultural labourers, and Irishmen from country places. Now-a-days machines do a great deal of our mechanical work, and our muscles getting less exercise, are not so large. Again, living in towns, and having little bodily exercise or hard work, means small bones and smaller frames altogether. The size of the head increases with that of the body, so exercise ought to be part of the system at our public schools, and then we get a sound brain in a healthy body. T. R. ALLINSON, L.R.C.P., &c.

[*Owing to the extraordinary pressure of correspondence, our article on "Comets" (illustrated with views of the destroyed comet of Biela) is deferred till next week. We must earnestly entreat our correspondents to be concise, and only to write when they have something really interesting and new to communicate.*]

Queries.

[67]—RAINBOW.—I should very much like to know why it is that a rainbow is semicircular?—G. S. M.

[68]—SOLAR STORMS.—By what method is the velocity of wind, &c., in the sun ascertained?—G. S. M.

[69]—THE MOON'S INFLUENCE.—It has been stated by Dr. Ball that the result of the moon's action on the tides is to drive the moon further and further away, and that the consequence of this is that the day is getting longer and longer. He says that 50,000,000 years ago the moon must have been very close to the earth, at which time the day would be only three hours long. Will you kindly say if what Dr. Ball says is correct? and how the action of the tides drives the moon further and further away, and how the distance of the moon regulates the length of the day?—E. K. [Will shortly make the question the subject of an article. Dr. Ball's general conclusions are sound; the detailed results he would not, of course, regard as exact.—ED.]

[70]—SEISMOMETER.—A description of an approved form of seismometer would be much valued by M. A. F.

[71]—NAMES OF FLOWERS.—Can you let me know, by means of your valuable paper, of any botany which will give the Latin and English names to all flowers, &c., and thereby much oblige.—R. D.]

[72]—ANTIQUITY OF THE PYRAMIDS.—"Sir John Lubbock, speaking of the antiquity of man, in his address at the late meeting of the British Association, said that 'The researches in Egypt seem to have satisfactorily established the fact that the pyramids themselves are at least 6,000 years old,' and mentions Professor Rawlinson's researches in support of this." What is the evidence on which this alleged antiquity is based?—ACTINOLITE.

[73]—CLOUDS.—Is there any explanation of the peculiar forms of Cirri and other clouds, especially that known as a mackerel sky? If a large, flat vessel of water containing a little sediment is agitated slightly, the sediment is deposited on the bottom in forms resembling those of some clouds. Are the latter supposed to be formed in a similar way?—E. C. R.

[74]—EXPERIMENT ON SOLAR HEAT.—I have read somewhere that if one side be removed from a box (the interior of which is blackened), and in its place three panes of glass with spaces between them containing air are inserted, water placed in a vessel in it may be raised to boiling-point by the exposure of the box in its modified form to strong sunshine. How is it that the heat, when in company with the sun's light, can penetrate the successive layers of glass and air, yet when deprived of its luminous companion, is retained in the heat-trap?—E. C. R.

[75]—THE RADIOMETER.—Would it be asking too much of our Editor to request that a series of papers explaining and describing the little that is known as yet of the forces and phenomena connected with the high vacua and radiometers might be given before long in the very interesting pages of KNOWLEDGE?—E. C. R.

[76]—PLANETARY MOVEMENTS.—The earth moves round the sun because of the latter's attraction, *i.e.*, but for the sun's attraction, the earth would move forward in a straight line. The attractive force of the sun must, therefore, necessarily retard the forward motion of the earth. Is not this so? If yes, does the earth go more and more slowly round the sun, and will it not ultimately stop and be drawn into the sun, and when? If no, what is the force which causes the earth not to go more and more slowly?—E. F. B. HARSTON. [The answer to first question is "no"; and that, therefore, no force is required to prevent the earth from being retarded. Why should a force at right angles to her course retard the earth? Her path not being absolutely circular, the force of the sun sometimes slightly hastens and at others as slightly retards the earth; but in the whole year changes not her speed at all.—ED.]

[77]—TERRIBLE DREAMS.—What explanation can be given of the horrible dreams that sometimes occur to persons?—S. S. S. S.

[78]—ANTIPATHY AND SYMPATHY.—What is the explanation of the extraordinary antipathy felt by some persons against some tame animals and things; and the converse—extreme sympathy, almost amounting to infatuation, shown by other persons (innate, not acquired)?—S. S. S. S.

[79]—MENTAL PHYSIOLOGY.—Whose works are now the best authorities on the study of mental physiology?—S. S. S. S.

[80]—THE CHIN.—It has been said that man is the only animal having a chin. Long before recent attention was called to the deficiency of this feature in a certain homicidal criminal, observation had led me to note various cases of cruelty perpetrated by almost chinless people; once, indeed, by a very young creature of twelve years old, described truly, I think, as "a perfect brute." Where

cruelty has not been observed, gluttony has been the marked fail ng. I have seen a chinless man eat like a pig, and look exactly like a pig while eating. Does not the paucity of this characteristically-human feature point to the animal propensities being in excess of the moral, if not the intellectual, tendencies? The Papuans are said to have little chin, and to be very cruel. ETHNOLOGIST.

[81]—THE MOON'S ATMOSPHERE.—By whom and when was the discovery made that there is no atmosphere around the moon? Swedenborg claims the honour of having the fact communicated to him by angels, and that he was the first to know and publish it.

[82]—PROBABILITIES.—Has not the writer of the article on "Trusting to Luck" put "eight times running" and "nine times running" where he should have written "nine times running" and "ten times running" respectively, the chances being

$$\frac{1}{2^9} \text{ and } \frac{1}{2^{10}} \text{ equal to } \frac{1}{512} \text{ and } \frac{1}{1024}$$

respectively?—H. A. N.—[Yes.—ED.]

[83]—CHEMICAL QUERIES.—(*a*) Are there more than three allotropic modifications of sulphur? The two crystalline forms and the plastic modification I am acquainted with, but in Miller's "Inorganic Chemistry" ("Longman's Text-Books"), 1874, it is stated that "a fourth may be procured by placing in carbon disulphide the hard mass furnished by keeping the viscous sulphur till it becomes solid. The carbon disulphide discloses all that can be removed from the mass, and a *grey amorphous powder* is left" (p. 142). Roscoe, in his "Elementary Chemistry," simply says that "the tenacious" (*i.e.*, viscous) "form is insoluble in" carbon disulphide. Does the latter refer to the amorphous powder mentioned by Miller? (*b*) In Roscoe's "Elementary Chemistry," p. 62, edit. 1880, referring to nitrogen tetroxide, I find it stated that "this substance forms the greater part of the reddish brown fumes evolved when *nitrous* oxide gas escapes into the air." Should this not not be *nitric*? (I may say that at present I have not an opportunity of trying these for myself.)—THEION.

[84]—ANCIENT MAN.—In Darwin's "Origin of Species," I read, "Mr. Horner's researches have rendered it in some degree probable that man sufficiently civilised to have manufactured pottery existed in the valley of the Nile thirteen or fourteen thousand years ago." I should like some information about these researches, and their reliability.—CLIO.

[85]—A GRAVITY ILLUSION.—The Toricelli tube, or a long glass tube filled with mercury, and turned upside down, when full, into a cup of mercury again, is said by some acquaintance of mine to be unexplained, in so far that in theory, he says, the mercury glass-tube, when lifted up, should not weigh more than the weight of the glass, considering that the mercury is carried by the cup on the table in which it is. But, instead of this, it is found to weigh very much more. I was not many minutes in solving the mystery to myself, but do not yet know if it is really a mystery to professors of physics, as my acquaintance maintains. I can hardly think so, as I fancy to have read the law that gives the cause. However, I will give my version of it, after some one of your readers answers.—F. J. D. "SELBST." [There is no mystery in the matter, but the study of this question, as of others in our Query columns, may be a useful exercise to beginners in physics.—ED.]

[86]—THE COLOUR OF BIRDS' EGGS.—Are the different markings on birds' eggs considered to be merely accidental, or designed for special purposes?—ARACHNIDA.

[87]—TOADS.—What is the internal construction of the common toad, which permits of its existing for many years enclosed in blocks of solid matter?—ARACHNIDA.

[88]—BRAIN INJURIES.—How is it the brain can be cut and cauterised without exciting sensation? If true, this contradicts, apparently, the statement that the brain is the organ of feeling, made in W. L.'s letter (29, No. 3). Is electricity necessary to convey the least feeling or irritation to the brain?—BEE.

[89]—GELATINE PLATES.—I have just now a few gelatine plates, in which a red streak appears, either on the top or at the bottom, and seems to eat its way through the film, and so spoils them; also the silver from the paper coming on to the plate. A remedy for the above would oblige. Have any photographic readers of KNOWLEDGE tried to develope their gelatine plates by flowing over them a weak solution of silver, and developing afterwards the same as a wet plate? If so, kindly give me their experiences.—PERSEVERE.

[90]—THE MAGNETIC NEEDLE.—I should be glad if any reader can give me any information why the needle of the compass always points to the north, what is the attraction, &c.—W. H. PERTWEE.

[91]—MISSING LINK.—KNOWLEDGE for Nov. 25, p. 71, has an article, "The Missing Link," in which it refers to an article that has appeared on the same subject in a recent volume of the *Gentleman's Magazine*. Please say name of month in which this appeared.—TEASTLANT.

Replies to Queries.

[4]—THE EARTH'S INCLINATION. The motion of the earth is best shown by suspending a small globe by a piece of string, and carrying it round a candle (the candle being in the centre of its path). If the globe is carried on a level with the candle, it is seen that the poles will both just see the candle, *i.e.*, the poles and the whole earth will have perpetual spring. The true motion will be obtained by making the circular path *dip* half below and half above the level of the candle as it is carried round, so that at the lowest part the whole of the North Arctic zone may be in light, and at its highest point in shadow.—H. A. N.

[8]—VOLUME OF SPHERE.—Given that area of sphere = area of 4 great circles = $4\pi r^2$. Let the sphere be divided into pyramids, with the apex at the centre. If the number of pyramids is great, the base of each is nearly plane, and the pyramid

$$= \frac{1}{3} \times \text{height} \times \text{base}$$

$$= \frac{1}{3} \times r \times \text{base}.$$

The whole sphere is one of these pyramids multiplied by the number of times the area of the sphere contains the base, *i.e.*,

$$\frac{1}{3} r (\text{base}) \times \frac{4\pi r^2}{\text{base}} = \frac{4}{3} \pi r^3$$

$$= \frac{2}{3} \text{ of cylinder.}$$

This implies, however, the knowledge that the area = four great circles, which cannot be proved without the calculus.—H. A. N.

[10]—THE ZOETROPE.—The impression of any sight remains on the retina for the seventh part of a second; if a new impression is received before the first has faded, the two are seen simultaneously, and if the Zoetrope is turned too quickly, the images run into one another. If it is turned so that one-seventh of a second intervenes between two impressions, the motion will appear continuous; if it moves slower than this, it will seem jerky.—H. A. N.

[14]—VELOCITY OF SOUND.—"Sound's" difficulty arises, I think, from his not considering that the air is sensibly devoid of absorption and radiation, so that the heat generated in the condensation remains there to augment the velocity—or, rather, the elasticity upon which the velocity depends. In the rarefaction, the elasticity is lowered, both by the separation of the particles and the cold developed by such separation; and consequently "the cold developed augments the difference of elastic force upon which the propagation of the rarefaction depends." It is because the heat generated in the condensation augments the rapidity of the condensation, and the cold developed augments the rapidity of the rarefaction, that the heat and cold both help to augment the velocity of the sound wave. In gases possessing considerable absorptive and radiative power, "Sound's" objection would be perfectly valid.—T. J. H.

[16]—GERMAN AND ENGLISH.—In reply to "Eclecticus," Messrs. Macmillan & Co. publish a work which I think would suit him, entitled "A Comparative Grammar of the Teutonic Languages." By G. Helfenstein. Its price, I believe, is 18s.—W. G. ROLFE.

[18]—CHEMICAL TREATISES.—I have before me the ninth edition of "Fownes' Chemistry," on the old or equivalent notation, with an appendix epitome of the new system. Then I have Hoffmans' work on "Modern Chemistry;" also the little volume by Wurtz, "Chemical Philosophy according to Modern Theories," translated by Crookes; also "The New Chemistry," by Cooke (International Series); and, lastly, "Pilden's Chemical Philosophy." I would especially award the prize to the little work of Wurtz, which is exceedingly good and clever; but many years' study convinces me that "Modern Chemistry" is wholly based on very slender hypotheses, and that the consequent complexity and confusion must necessitate a change. An independent inquirer has little chance in England, but in France the Chemical Hierarchy is untainted with inconsiderate revolution; and M. Berthelot must be considered one of the greatest chemists of the age. If old or equivalent chemistry means *knowledge*, and new chemistry means hypothesis, it is especially *à propos* for this Paper to ventilate and make clear the difference.—ECLECTICUS.

[19]—COMPARATIVE ANATOMY OF BIRDS AND MAMMALS.—The furcula of birds are formed by the union of two bones called the clavicles. These are almost entirely absent in mammals. When present they are very rudimentary, and usually unossified; so that no trace of them is found in the dried skeleton. In man, the clavicles are more developed than in the other mammals, and constitute the so-called collar-bones. They are very rudimentary in dogs and rabbits. In the felidæ (lions, tigers, cats, &c.) they are more developed than in other carnivora, but have no particular

function. They are entirely absent in the ungulata. Clavicles are very characteristic of the lower vertebrata, being well developed in reptiles and fishes.—Geo.

[19]—Comparative Anatomy of Birds and Animals.—In answer to Query 19 p. 80, the furculum, or "merry-thought," of birds corresponds to the collar-bones, or clavicles, in man, which, instead of being separately joined to the sternum, or breast-bone, are joined together into a V-shaped arch of bone, the apex of which is commonly attached to the sternum by a ligament. The function of the furculum, according to Owen, is to oppose the force which tends to press the humeri or upper-wing bones towards the middle line during the downward stroke of the wing.—Medicus.

[23]—Faure's Accumulator. "Nameless" will find some information in regard to Faure's accumulator in *Nature*, vol. 21, p. 68, "Storing Electricity;" and p. 238 "Faure's Secondary Battery."—A. T. C.

[23]—Faure Accumulator.—A Faure accumulator may be made as follows: Take lead foil such as used for putting on damp walls; cut the plates, leaving a long tongue at one corner. I made the plates $1\frac{1}{4} \times 2\frac{1}{2}$ inches, with a tongue 2 inches long and about $\frac{3}{8}$ of an inch wide; next take some flannel—I used common, at 10d. a yard; cut it in strips one inch more in length than twice the length of the lead plates, and one inch wider than those plates; then take some blotting-paper and cut it into pieces, one inch each way larger than the lead plates; mix one pint of sulphuric acid, by measure, with ten pints of water, by measure, and with this and some red lead, make a paste; now, paint over one strip of flannel, on one side only, with the paste, leaving a half-inch margin of clean flannel all round, so that the painted part of the flannel will be exactly twice the size of the lead plate; paint over one of the lead plates on both sides, keeping the tongue clean; lay it on the painted flannel, and double the flannel over it; lay this covered plate down on any convenient board or piece of glass. On this covered plate lay one of the pieces of blotting-paper, or, if the blotting-paper is not thick and good, two pieces. Prepare another plate of lead with the flannel and red lead, as before; place this on the top of the blotting-paper, taking care that the tongue of this latter plate is on the opposite side to the tongue of the first plate. Lay another piece or pieces of blotting-paper, and so go on until you have a pile of as many plates as will go easily into the jar or cell you intend to use. See that the tongues of the alternate plates are on alternate sides of the pile of plates, then tie the pile round loosely in a couple of places with some paraffined twine; pinch the tongues on one side together, and those on the other side together, and attach terminal wires. Put the bundle of plates into the cell, fill up with the acid and water, and keep it full. I have tried this plan, and found it answer.—H. B. T. Strangeways.

[26]—Training.—There are some facts, if one could collect them, which seem to support "Oarsman's" question. Thus I know of two or three bicycle riders who ride a hundred miles a day, and yet who never taste animal food; and, again, a teacher of swimming who uses no animal food. The last few autumns a number of gentlemen have set out for walking tours, and they never use animal food, and yet get on very well indeed, saying they experience less thirst and less fatigue than if they eat meat, &c.—T. R. Allinson.

[27]—Marriage Death-rate.—With reference to "Benedict's" query respecting the marriage death-rate, I may say, for his information, that the result of an estimation made, showed that a number of married persons gave a mean death-rate of 66·76; and of unmarried a mean of 62·00.* I may also state that at the age of 15 to 20 the mortality is increased considerably, especially among women—the majority of deaths resulting from consumption and childbirth. A greater proportional number of deaths occur among those who marry at an early age.—Michael W. Reynolds.
[Rest of letter not strictly *ad rem.*—Ed.]

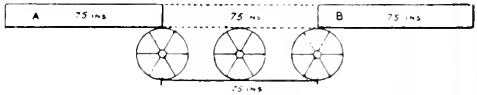
[27]—Marriage and the Death-rate.—I refer "Benedict" to the following extract from the *Times* (Weekly Edition), Febuary 14, 1879.

"It has been shown from statistics that in general, married people have a less mortality than the unmarried or widowed. Among facts indicating the relation between marriage and physical health, it has been proved by M. Janssens, of Brussels, that at all ages widowers are about twice as liable to phthisis as other men, but that married people are generally more liable to this disease than celibates. This law is constant for women; for men it holds good only before 25 years of age and after 45. Such facts and their meaning are discussed by M. Bertillon in a recent paper on the influence of the family state on morals. Not only do married people die less than others, but they show less tendency to suicide, to mental derangement, to assassination, to theft, and other like evils or crimes. . . ."

And the extract goes on to show that this is probably owing to the influence of children.—B. J.

[27]—Effects of Marriage on the Death-rate.—Dr. Bertillon, a French *savant*, some two or three years ago wrote an essay on "Nuptiality, or the Conjunctive Attraction of Human Couples." By comparing the mortality statistics of every country in Europe, he shows that, without exception, marriage is conducive to longevity. He arrives at the conclusion that a bachelor of 25 is not a better life than a married man of 45. French bills of mortality show that the annual death-rate among married men between 20 and 25 is rather under 10 per 1,000, and for bachelors of the same age, 16 per 1,000. For Paris itself the difference is still greater. Between 30 and 35 years of age the mortality is 69 per cent. greater among bachelors than among married men. Space will not permit further quotations from this interesting essay, but a more complete summary of Dr. Bertillon's conclusions "Benedict" may find in the *Lancet* for May 31, 1879.—Medicus.

[28]—Stone on Rolling Wheels.—If the stone was poised exactly in the *centre* of the wheels, it would then be carried forward 75 in. for each revolution, and the relative position of the stone and wheels is not altered. But, as the stone rests on the circumference of the wheels, it receives a motion from the revolution, and the part which rested on the wheels would be 75 in. beyond them for each revolution; and the forward motion of the wheel being 75 in., therefore the stone has advanced 150 in. It has travelled the same distance as a spot on the circumference of the wheels, which describes a cycloid for each revolution, and is equal in length to



double the circumference. I beg to inclose drawing, where A is commencement of a revolution, and B the end.—W. Stevens.

[28]—Stone on Rolling Wheels.—"Queensland's" "mathematical friend" is quite correct in saying the stone advances 150 in. for every 75 in. advance of the rollers. "Queensland," or any one else, may easily convince himself of the accuracy of the statement by a few minutes' experimenting with a two-foot-rule and an office ruler.—E. H. R.

[37]—"Vestiges of Creation."—I have seen it stated that the late Dr. David Page, the geologist, was the author of this book. It has also been attributed to Mr. Robert Chambers. Both may have been concerned in it, as Dr. Page was for a long time connected with *Chambers's Journal*. I think Lieut.-Col. W. A. Ross announced in the columns of the *English Mechanic*, some time ago, that he believed, and could prove, the author to be Sir Charles Lyell.—J. A. Westwood Oliver.

[37]—Vestiges of Creation.—This book was written by the late Dr. Robert Chambers, of Edinburgh. It foreshadowed, in some measure, the speculations of Darwin on the origin of new species through the modification of the old, as opposed to the doctrine of their "special creation." It advanced further than Lamarck; but Dr. Chambers' ideas were necessarily crude, for lack of the knowledge of later days, when compared with the certainties of modern evolution, which is founded on evidence derived from the development, structure, and distribution of animals and plants, as well as from their fossil history. "S. S. S. S." should read Darwin in preference to the "Vestiges," which possess, nowadays, more of a historical than a scientific interest.—Andrew Wilson.

[37]—Vestiges of Creation.—This work was published anonymously. Some—the majority—attribute it to Chambers, others to Sir C. Lyell. The subject was discussed recently in the columns of the *English Mechanic*. I should advise "S. S. S. S." to read it by all means, and mark, learn, and inwardly digest it.—W. G. Rolfe.

[38]—Neptune.—One satellite of Neptune has been discovered by Lassell, period 5 d. 21 h. 8 m., at a distance of 220,000 m. from the primary.—W. G. Rolfe.

[Let. 48]—Cheap Microscope and Telescope.—If your correspondent "Twenty" is not disposed to spend more than £5 on *each* of the above, he must restrict himself to a monocular microscope, and I should advise him to procure one of the so-called medical forms made by Swift, Beck, Baker, and several others. It is rather invidious making a selection from the several makers of low-priced microscopes, but I am bound to say that of the instruments which have come under my notice lately, Swift's are the best value for the money, taking into account the appearance and general qualities of

* There is some mistake about this statement.—Ed.

the stand and the quality of the lenses supplied. This is very much like an advertisement; but you, sir, may possibly know enough of me to tell you that I am not an advertising agent. Anyhow, whereever the instrument is purchased, let "Twenty" see to it that he is not misled by mere appearance. Get a solid stand—one that won't shake and twist about; and don't trouble about a lot of so-called accessory apparatus. You won't want it. Then see that you have a good inch and a good quarter-inch objective. You can do plenty of work with them: enough to make yourself a name in the world, and get plenty of recreation too. I am the possessor of a £5 telescope bought to let my bairns see the mountains in the moon, spots on the sun, and something of Jupiter, Saturn, &c.; but shall I say it, sir, and so shake your faith in my powers of replying to the query, that is all the "astronomy" I have done with it. What it does show it shows well, and enough for my purpose. That is all I can say.—H. P. H.

[48]—Trisection of Triangle.—There are three problems now given up as beyond the power of Geometry, namely, (i) to trisect any angle, (ii) to find a straight line equal to the circumference of a circle, and (iii) to find two mean proportionals between two given straight lines. Thus, "Euclid" is beyond the range of help. W. G. Rolfe.

[54]—Chemical Questions.—The explanation of (1) is that the iron of the ferrocyanide is not a base, but forms part of an acid, which, however, has never been isolated. Potassium ferricyanide acts in a similar way. A parallel case is chromate of potassium, or any metal which will not precipitate, as hydrate, unless reduced by zinc, or tin and acid. (2) To this part of "Castor and Pollux's" query, I cannot see an answer, unless the solution were alkaline; alkalies dissolving potassium tartrate.—C. T. B.

[54]—Chemical Questions.—In the first case given by "Castor and Pollux," the reason he has obtained no precipitate with ferrocyanide of potassium on adding the re-agents mentioned is this, that he has been inattentive, I might even say careless, enough to add hydrosulphuric acid instead of ammonium sulphide. He very correctly states that iron is one of the third group of metals, but the metals of that group are precipitated by Am Cl, Am HO and Am HS, and not by H_2S. And in the second case it is quite possible that the solution of tartaric acid was not sufficiently strong, although the salts under examination may have been so. This test is extremely delicate, and requires much more care than the questions of "Castor and Pollux" lead me to believe he has taken in his analysis.—Theophilus Pitt, A.K.C.

[55]—Greek Verbs.—Lengthening the vowel is the rule, deviation from it the exception. Those verbs which retain the short vowel take σ in pf. and ppf., med., or pass.; also in their verbal adjectives.—W. G. Rolfe.

[59]—Mercury's Revolution.—Undoubtedly 84 was a misprint; it should have been 88.—W. G. Rolfe.

[60]—Sound being the effect produced on the ear by any vibration, within limits of fastness and slowness, any substance that will vibrate can transmit it. Tyndall compares transmission of sound to a blow passed along a number of balls touching side by side; the last of the row only moves, so the last vibrated particle gives the sound, and can pass it on from one substance to another. The greater the elasticity—as steel, glass, ivory—and the lighter in weight, the better does a body transmit sound.—C. T. B.

[66]—Venus.—This planet is frequently visible in the day-time, and often casts a shadow at night.—W. G. Rolfe.

[66]—Venus by Daylight.—Taking the above query of F. H. S. to refer mainly to the planet's visibility *in England*, I may tell him that, owing to the unfavourable atmospheric condition that generally obtain here, she probably is not often visible during the daytime, although I saw her plainly several times this summer, on different days in (I expect) the month of July, when she had a considerable north declination, and was at her extreme westerly elongation from the sun (or thereabouts). I should mention that by visibility I mean visibility to the *naked eye*. If F. H. S. has sufficient knowledge of astronomy to understand the meaning of the terms "right ascension" and "declination," he will know how to find the position of Venus in the sky at any time by her bearing from the sun. Abroad, within and without the tropics, I have seen Venus day after day, for weeks at a stretch, and at sea have often determined the latitude daily for like periods, both in the mornings from about 9 to 10, and in the afternoons from 2 to 3, according as she was, respectively, to the west or to the east of the sun. In many of these cases, however, she would not be visible to the naked eye. If your correspondent has not that slight skill in astronomy with which I have credited him, I am afraid you would hardly allow me space to explain to him how and when to "spot" Venus.—Winter.

INFLUENCE OF MARRIAGE ON THE DEATH-RATE.

Note.—The enclosed is an answer to the query of "Benedict" upon the effects of marriage on the death-rate, if you should consider it worthy of insertion. W. H. Pertwee. *

For several years it has been noticed by statisticians that the death-rate of unmarried men is considerably higher than the death-rate of married men and widowers. I believe that Dr. Stark, Registrar-General for Scotland, was one of the first to call attention to this peculiarity, as evidenced by the results of two years' returns for Scotland.

But the law has since been confirmed by a far wider range of statistical inquiry. The relative proportion between the death-rates of the married and of the unmarried is not absolutely uniform in different countries, but it is fairly enough represented by the following table, which exhibits the mortality per thousand of married and unmarried men in Scotland:—

Ages.	Husbands and Widowers.	Unmarried.
20 to 25	6·26	12·31
25 „ 30	8·23	14·94
30 „ 35	8·65	15·94
35 „ 40	11·67	16·02
40 „ 45	14·07	18·35
45 „ 50	17·04	21·18
50 „ 55	19·51	26·34
55 „ 60	26·14	28·54
60 „ 65	35·63	44·54
65 „ 70	52·93	60·21
70 „ 75	81·56	102·71
75 „ 80	117·85	143·94
80 „ 85	173·88	195·40

From this table we are to understand that out of one hundred thousand married persons (including widowers), from 20 to 25 years old, 626 die in the course of each year; while, out of a similar number of unmarried persons between the same ages, no less than 1,231 die in each year. And in like manner all the other lines of the table are to be interpreted. Commenting on the evidence supplied by the above figures, Dr. Stark stated that "bachelorhood is more destructive to life than the most unwholesome trades, or than residence in an unwholesome house or district where there has never been the most distant attempt at sanitary improvement of any kind." And this view has been very generally accepted, not only by the public, but by professed statisticians; yet, as a matter of fact, I believe that no such inferences can legitimately be drawn from the above table. If death strikes down in five years only half as many of those who are unmarried between the age of 20 and 25 (as appears from the above table), and if the proportion of deaths between the two classes goes on continually diminishing in each successive lustre (as is also shown by the above table), it seems reasonable to infer that the death-rate would be even more strikingly disproportionate for persons between the ages of fifteen and twenty than for persons between the ages of twenty and twenty-five. I believe, indeed, that if Dr. Stark had extended his table to include the former ages, the result would have been such as I have indicated. Yet few will suppose that very youthful marriages can exercise so singularly beneficial an effect. It may appear at first sight that we are bound to accept the conclusion that matrimony is favourable to longevity. In the present instance we have simply to deal with the fact that the death-rate of unmarried men is higher than the death-rate of married men and widowers. All that we can can do is to show that one of three conclusions must be adopted. Either matrimony is favourable (directly or indirectly) to longevity, in a degree sufficient wholly to account for the observed peculiarity, on a principle of selection—the effect of which is such as, on the whole, to fill the ranks of married men from among the healthier and stronger portion of the community—operates in a sufficient degree to account wholly for the observed death-rates; or, lastly, the observed death-rates are due to the combination, in some unknown proportion, of the two causes just mentioned. No reasonable doubt can exist, as it seems to us, that the third is the true conclusion to be drawn from the evidence supplied by the mortality bills. Unfortunately, the conclusion thus deduced is almost valueless, because we are left wholly in doubt as to the proportion which subsists between the effects to be ascribed to the two causes thus shown to be in operation. It scarcely required the

* As I considered this article worth sending to the *Daily News*, I suppose I may accept Mr. Pertwee's suggestion. Passages from the article are quoted by Darwin, in his "Descent of Man," and his approval led me to include the article in my "Light Science for Leisure Hours." Mr. Portwee's quoting from the original suggests that the matter may be new to many of our readers.—R. A. Proctor.

evidence of statistics to prove that each cause must operate to some extent. It is perfectly obvious, on the one hand, that although hundreds of men who would be held by insurance companies to be "bad lives" may contract marriage, yet, on the whole, a principle of selection is in operation which must tend to bring the healthier portion of the male community into the ranks of the married, and to leave the unhealthier in the state of bachelorhood. A little consideration will show, also, that, on the whole, the members of the less healthy trades, very poor persons, habitual drunkards, and others whose prospects of long life are unfavourable, must (on the average of a large number) be more likely to remain unmarried than those more favourably situated. Improvident marriages are undoubtedly numerous, but prosperity and adversity have their influence, and that influence not unimportant, on the marriage returns. On the other hand, it is perfectly obvious that the life of a married man is likely to be more favourable to longevity than that of a bachelor. The mere fact that a man has a wife and family depending upon him will suffice to render him more careful of his health, less ready to undertake dangerous employments, and so on; and there are other reasons which will occur to everyone for considering the life of a married man better (in the sense of the insurance companies) than that of a bachelor. In fact, while we are compelled to reject Dr. Stark's statement, "bachelorhood is more destructive to life than the most unwholesome trades, or than residence in an unwholesome house or district, where there has never been the most distant attempt at sanitary improvement of any kind," we may safely accept his opinion that statistics "prove the truth of one of the first natural laws revealed to man, 'It is not good that man should live alone.'" Whether the law required any proof is a question into which we need not enter.

From the *Daily News*, *Oct.* 17, 1868. W. H. Pertwee.

Our Mathematical Column.

MATHEMATICAL QUERIES.

[2]—The Witch of Agnesi.—Will you kindly furnish a few particulars respecting the history, properties, and practical application (if any) of the above-named curve? If these are accompanied with a tracing of the curve all the better.—E. H. R.

[3] Apparent Paradox.—

$$\begin{aligned}
&\text{Let} & x &= y, & \\
&\text{then} & x^2 &= xy, & \\
&\therefore & x^2 - y^2 &= xy - y^2, & \\
&\therefore & (x + y)(x - y) &= y(x - y), & (A)\\
&\therefore & x + y &= y, & (B)\\
&\therefore & y + y &= y, \text{ since } x = y \text{ by Hyp.;} & \\
&\therefore & 2y &= y & \\
&\therefore & 2 &= 1. &
\end{aligned}$$

Anyone who kindly explains the fallacy in the reasoning which brings about this impossible result will much oblige—Puzzled.

[The fault lies in passing from A to B. Interpret them, and we see this at once. A really means that $(x + y)$ times nought is equal to y times nought, which is, of course, true; just as it is true that twenty times nothing is equal to ten times nothing. But we can no more infer that $x + y = y$ than that $20 = 10$. In fact, we cannot divide both sides of an equation by any common factor, unless we are sure that the factor is not equal to nought. In this case we know that it is.—Ed.]

[4]—I shall be very much obliged if you will kindly favour me with a solution of the following problem. Data. $R = 2$; $S = \sqrt{3}$; $r_b = 1$; r, r_a, r_b, r_c, being radii of inscribed and escribed circles: prove that $4 r r_a = a^2$, and $r_b = r_c =$ perp. from angle A on side BC of inscribed triangle.—Amicus.

Our Whist Column.

By "Five of Clubs."

A "YARBOROUGH" HAND AT WHIST.

Sir,—I was told the other day that a former Earl of Yarborough was always ready to wager £1,000 to £1 against the occurrence of a hand at Whist in which there should be no card better than a nine. Was the bet a fair one? Aletheus.

[The bet was decidedly unfair, and if made a great number of times must have resulted in large gains to the person who made it. It is easy to calculate the odds before the deal, (after the deal, or if the cards are cut and the lowest card is known, the odds are slightly altered). In each suit there are five cards, ace, king, queen, knave, ten, above a nine, or in the pack, 20 cards above a nine. From the remaining 32 cards a hand of 13 cards may be formed in

$$\frac{32 \cdot 31 \cdot 30 \cdot 29 \ldots 20}{1 \cdot 2 \cdot 3 \cdot 4 \ldots 13}$$

different ways. The whole pack, however, will form

$$\frac{52 \cdot 51 \cdot 50 \cdot 49 \ldots 40}{1 \cdot 2 \cdot 3 \cdot 4 \ldots 13}$$

different hands of thirteen cards. The chance, then, that any hand taken at random will have no card better than nine is represented by the ratio which the former of these amounts bears to the latter, or by the fraction

$$\frac{32 \cdot 31 \cdot 30 \cdot 29 \ldots 20}{52 \cdot 51 \cdot 50 \cdot 49 \ldots 40} = \frac{32 \cdot 31 \cdot 30 \cdot 29 \cdot 28 \cdot 27}{51 \cdot 49 \cdot 47 \cdot 45 \cdot 43 \cdot 41 \cdot 2^7}$$

$$= \frac{31 \cdot 15 \cdot 29 \cdot 14 \cdot 27}{51 \cdot 49 \cdot 47 \cdot 45 \cdot 43 \cdot 41} = \frac{31 \cdot 29 \cdot 2 \cdot 3}{17 \cdot 7 \cdot 47 \cdot 43 \cdot 41}$$

It will be found, on reducing, that this fraction is rather less than $\frac{1}{1828}$, so that Lord Yarborough, if he had been fair, (assuming always that he knew how to calculate probabilities) should have offered rather more than £1,828 to £1 against the occurrence of the hand in question. It must be understood, of course, that he wagered with one of the players against that player having a "Yarborough," not against the occurrence of a "Yarborough" among the four hands dealt. The chance of this latter event is, of course, considerably greater. It might seem at a first view that it was exactly four times as great, since there are four hands for each deal, but this is not the case, any more than the chance of the occurrence of a Yarborough in 1,828 hands amounts to 1,828 times $\frac{1}{1828}$, or to absolute certainty. The real chance that a Yarborough will not occur in four hands is thus obtained. The chance that a Yarborough will not occur in any given hand is $\frac{1827}{1828}$; that it will not occur in two hands is $\left(\frac{1827}{1828}\right)^2$ that it will not occur in three hands is $\left(\frac{1827}{1828}\right)^3$, and that it will not occur in four hands is $\left(\frac{1827}{1828}\right)^4$. This is very nearly, but not exactly, equal to $\frac{1828}{1832}$, or to $\frac{457}{458}$; so that the chance of a "Yarborough" occurring in any four hands, taken at random in different deals, is equal to about $\frac{1}{458}$; nor is the chance different when the four hands are in the same deal.

Supposing Lord Yarborough offered a wager of £1,000 to £1 to each member of a whist party, for ten deals, on each of 100 nights in each of ten years, he would have cleared about £18,000.]

"Mogul" writes to us that there are mistakes, some of them serious, in our Whist Column. It is very likely; but the principle on which this column, like the rest of Knowledge, is conducted, is that of free discussion, and the correction of errors as soon as detected and pointed out. "Mogul" only notes one, and there he misapprehends us entirely. He says we in effect say that the rules for leading are based on the principle of giving information to your partner. We have said nothing of the sort. We have said that the first great principle of the scientific game is to give your partner all the information in your power, consistently with the rules of the game. This is a very different thing. "Mogul" states rightly enough that the primary consideration in selecting what card to lead, especially what card to lead from any peculiar combination of cards in a suit, has been the best chance of trick-making. Of course, this is true; but, as an objection to our statement, "Mogul" might as reasonably have told us that the primary object in Whist was to make tricks. "Mogul" will find, as we proceed, that all questions of leading and play, second-hand or third-hand, are primarily weighed with reference to the chance of making tricks (which, by-the-way, has not yet been fully done, even the ablest Whist players being apt to shirk the mathematical problems involved). But that is not at all inconsistent with the statement respecting the distinction between scientific and unscientific Whist, or between what may be called the twenty-six card and the thirteen card games.

"Mogul" invites our attention to Hoyle and Cavendish. These, with Matthews (though Hoyle and Matthews are now a little out of date), Pole, Clay, Drayson, and others are our guides; to this degree, at any rate, that we should not depart from their teaching without assigning our reasons and speaking under correction from our readers. But vague corrections, like "Mogul's," are of little use to us.

Our Chess Column.

Great pressure of other matter compels us to limit our chess this week to a single game. It is, however, annotated fully, as promised in Number 1.

Game Played at Leamington Meeting, October, 1881.

Queen's Fianchetto.

WHITE. Mr. Walton.	BLACK. Mr. Bowley.
1. P. to Q.Kt.3.	P. to K.4. (a)

Resigns (j)	

NOTES BY MEPHISTO.

(Incorporating Mr. Bowley's comments.)

(a) In reply to 1. P. to Q.Kt.3., it is not advisable to advance P. to K.4. and Q.4. too hastily. P. to K.3. and Q.4. brings about a normal and safe development.

(b) Loss of time: White might have played P. to K.B.4. at once if that was his intention; but this attack was premature. P. to K.R.4. would have been better than Q. to K.2., to prevent the check with the Queen on R.5. Proper play was to develop the game by 4.P. to Q.B.4, Kt. to Q.B 3., &c., after the fashion of Queen's openings.

(c) Having missed the flood tide of the opening, fortune turns against White. P. to B.4. here is weak, as it opens up his game, of which Black at once takes advantage. In view of the good position of the Black Bishops, it would have been dangerous to castle on the King's side. 8. Kt. to Q.B.3. might have been played. Mr. Bowley points out that Black could not venture on

8. $\frac{\text{B. takes Kt.ch.}}{\text{P. takes B.}}$ followed by 9. B. takes P., because of

9. Q. to R.5. (ch.) 10. $\frac{\text{P. to K.Kt.3.}}{\text{Q. to K.5.}}$ winning.

(d) 10. Kt. to K.B.3. would have been better. If then Black played 10. Q. to B.7. 11. P. to Q.3. would have equalised the game; or, if B to Kt.5., in reply to 10. Kt. to K.B.3., then 11. Castles with a safer game than that obtained through the move in the text.

(e) Mr. Bowley thinks that 11. $\frac{\text{P. takes P.}}{\text{B. takes P.}}$ 12. $\frac{\text{Q. takes B.}}{\text{Kt. to K 2.}}$ 13. $\frac{\text{Q. to Q.3.}}{\text{Q. takes B.}}$ 14. Q. to B.3. would have been better. Should Black venture on 11. Q. takes B., White ought to win, as the following variation shows:— 11. $\frac{\text{P. takes P.}}{\text{Q. takes B.}}$ 12. $\frac{\text{P. takes B.}}{\text{Kt. to K.2.}}$ (to avoid the mate, and at the same time prevent B. takes Kt. (ch.), followed by Q. takes P. and Q. to Q.B.3.) 13. $\frac{\text{Q. to B.7. (ch.)}}{\text{K. to Q.sq.}}$ 14. $\frac{\text{Kt. to K.2}}{\text{Q. takes R.}}$ 15. $\frac{\text{Castles}}{\text{R. to K.sq.}}$; *best* to avoid the mate by Q. to Q.B.3.(ch.) 16. $\frac{\text{Q.Kt. to B.3.}}{\text{Q. to Kt.7.}}$ 17. Q. takes P. White now threatens to win by R. to B.8. If, to prevent this, Black plays 17. Q. to B.7., with the object of bringing her to K.Kt.3., then White plays 18. P. to K.4. first. The only move for Black would be 18. Kt. to Q.5.; then follows 19. $\frac{\text{R. to B.8.}}{\text{Kt.takes Kt.(ch.)}}$ 20. $\frac{\text{B. takes Kt.}}{\text{P. to B.3.}}$ to avoid the mate by R. takes R.(ch). 21. $\frac{\text{R. takes R (ch.)}}{\text{K. to B.2}}$ 22. $\frac{\text{R. takes Kt.(ch.)}}{\text{B takes R.}}$ 23. $\frac{\text{Q. takes B.(ch.)}}{\text{K. to Kt.3.}}$ 24. $\frac{\text{Kt. to R 4 (ch.)}}{\text{K. to R 4}}$ 25. Q. to B.5.(ch.) and wins. We give a diagram of the position

Position after Black's tenth move, Q. to B 7

Black.

WHITE.

(f) Played to make the Rook available for attack. White could not now play 12. P. takes P., as pointed out by Mr. Bowley, as Black would win by 12. $\frac{}{\text{R. to K.B.sq.}}$ 13. $\frac{\text{Q. to Kt.2.}}{\text{B. takes P.}}$ winning, as Queen cannot take the Bishop on pain of Mate in two by Q. to B.8.(ch.) and Q. to K.B.8 Mate.

(g) White's game is now seriously compromised. If he had tried to play 16. Kt. to B.4., instead of P. to B.5., then Mr. Bowley points out that he would have played the fine move of R. takes Kt., and after the subsequent exchanges Black would retain a slight superiority, *e.g.*, $\frac{\text{Kt. to B.4.}}{\text{R. takes Kt.}}$ $\frac{\text{K.P. takes R.}}{\text{Q. takes Q.}}$ $\frac{\text{K. takes Q.}}{\text{Kt. to K.6.(ch.)}}$ &c. Of course White could not play Q. takes Q. in reply to R. takes Kt., for then Black would win by R. takes R.(ch.) and Kt. to K.6.(ch.)

(h) If Black play Kt. takes K.P., White's reply would be 19. $\frac{\text{R. takes R.}}{\text{Kt. takes Q.}}$ 20. Kt. to R.3. forcing the Queen back, and retaining three pieces for the Queen.

(i) A slip, of course. Mr. Bowley tells us that Kt. to B.4., giving back the piece would have been White's best; but even then Black would retain a superiority.

(j) White must lose the Queen, or be Mated in very few moves.

In last week's Chess column position numbered 3 should have been 4. In the solution to Mr. Healey's Problem 2 it is unnecessary to consider the reply, 1. K. to Q.R.sq., for if Black so play White can win by 2. R. to Q.B.7.

In reply to numerous correspondents, we note that solutions of all problems we may give will appear a fortnight later. Names of any who, having correctly solved problems, care to forward their results will also appear.

While adhering to our plan of giving fully annotated games, and analysis of the openings, we shall be glad to publish problems and games, &c., of interest, which correspondents may send us.

Our friend "The Enemy" (need we say we refer to Mephisto) sends us a three-mover, recently published in the *Glasgow Herald*, by Mr. C. R. Baxter, Dundee, which we shall venture to publish next week. In this problem our two-mover of last week would seem to be embodied. Sometimes such coincidences are accidental (we may give a case in point presently). As our two-mover was published in the *Illustrated London News* more than twenty years ago (more exactly, on May 7, 1859), we presume Mr. Baxter will hardly claim priority.

Synchronised Electric Clocks.—It appears that an error has occurred in the *Times*, and most of the papers, including Knowledge, in noticing the lecture lately given by Mr. John Lund, on the above subject at the Society of Telegraph Engineers. In mentioning the practicability of utilising the telegraph wires for the double purpose of telephoning and synchronising, it was stated that communication was effected between the Lecture-room and Messrs. Barraud & Lund's premises in Pall Mall, whereas it should have read, between the Lecture-room and the premises of Messrs. Lund & Blockley, in Pall Mall, who are concessionaires for the West-end district. The two firms are, however, otherwise distinct.

Answers to Correspondents.

**** All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of* KNOWLEDGE, *the increasing circulation of which compels us to go to press early in the week.*

HINTS TO CORRESPONDENTS.—1. *No questions asking for scientific information can be answered through the post. 2. Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries. 3. No queries or replies savouring of the nature of advertisements can be inserted. 4. Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge. 5. Correspondents should write on one side only of the paper, and put drawings on a separate leaf. 6. Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

F. H. R. The Witch of Agnesi is one of those curves invented in former times for the solution of geometrical problems which cannot be solved by use of the circle and straight line only. We find little about it in our books. Its equation is given in Brande's "Dictionary of Art and Sciences." We must study it a little ourselves before answering your question; and, next week, hope to give a drawing of the curve and a brief account of it, geometrical, if possible.—PUZZLED. We do not wonder you are puzzled. The statement in the *Times* is out of date where it is correct, and the rest of it amusingly inexact. Newspaper science is apt to be "mixed" in this way. O. G. WAKEFIELD. Your form of solution was specially excluded when the prize was offered. We have, however, given your solution as a good illustration of the way of writing down to any required position, altering, however, your notation, which occupies too much space. W. W. WILLMOTT. Your query appears, and number containing it has been sent to author of the paragraph.—E. C. R. Thanks for interesting letter.—W. A. S. Very glad indeed to hear from you. How long it is since we met. Your reply is a specially welcome one, for I feared that particular query would remain unanswered. Sought everywhere for information, but knowing no Rabbis could get none that was trustworthy.—WALTER E. R. We hope to have many papers on Biological subjects ere long; but Science is infinite, and Knowledge is not.—JOHN BLAND. In your long letter you urge the familiar objections to the sun's being the source of heat, and advance a new theory of the tides. Of the former our readers have had a fair supply already, and the latter is quite inconsistent with known facts. You are also evidently unacquainted with the facts on which the accepted theories are based. For instance, you say the sun exercises greater attractive power than the moon, yet raises no double tide, the facts being (1) that the sun's tide-raising power is less than the moon's in the proportion of 2 to 5, yet (2) that he does raise a double tide of proportionate height. We wish you and others who propound paradoxes, to understand that your objections are in reality your difficulties. Those objections were difficulties to science students some two or three centuries ago. There is an unscientific objection to your communication on the ground of postage underpaid.—J. McGRIGOR ALLAN. We agree with much that you have written, but our pages are scarcely suited for the physiological study of the subject. We agreed to a concise presentation of your views, but supposed the column in Number 4 was what you meant; or, that if section 2 were treated at all, it would be very briefly. The other sections will be more suitable. Pray understand that we are satisfied no student of science could by any possibility object to your views or your way of putting them; but we write not for students of science only—*virginibus puerisque cantamus.*—BERTRAND E. DAWSON. There is no real difficulty. Binders have repeatedly to insert half-sheets. They will have to do so in the case of our star maps. There is much less risk of the single page separating from its fellows than of a full sheet coming out through imperfect sewing.—J. F. D. SELBST. It is impossible to insert your "intentionally ambiguous" remarks on the cause of gravity. Your replies to "Queries" 13 and 3 are unsatisfactory from a similar ambiguity. Your fears seem uncalled for. Publishing a new and sound theory on any subject whatever, by no means involves, as a necessary consequence, "starvation, despair, and early death." Wasting many years over a false theory, through unwise caution, may be more likely to lead to such undesirable results.—J. HINES. Your communication is too long for the subject, now nearly exhausted (though the sun's heat is not). The "prevailing hypothesis of the action of undulatory forces" is by no means inconsistent with the heat of the sun being "true heat in the naked form," that is (as we understand you) such heat as there is in a fire or furnace. Your theory is quite inconsistent with facts; and the growing pressure on our space, though it does not forbid our weighing objections and considering doubts, will not allow of our devoting columns to the careful enunciation of untenable hypotheses. No paradox-monger who can honestly say (and effectively show) that he has thoroughly mastered the accepted theories and the researches on which they rest, shall be refused ample space here. But paradoxes evidently based on misconceptions like those of Mr. Newton Crosland and others can no longer have the space which we earlier allowed them. They must make way for the sounder matter which reaches us.—H. M. HAASSEN. You can scarcely form an idea of the pressure on our space. Such a list as you suggest would be useful only to a small section of our readers. Almost every one who attends such meetings knows when they are to be held without our assistance.—JOHN SPILLER. Thanks for your letter, which shall appear, unabridged. It is very much to the purpose.—ACTINOLITE. Have inserted the gist of your query, but have omitted the closing words. What has KNOWLEDGE to do with Professor Rawlinson's belief, or want of belief, in Mosaic chronology? We know nothing about the matter, to begin with; and we do not want to know.—ALBERT E. HOLDEN. Thanks for your useful letter.—E. KAYCE. Thanks for your suggestions. We are proceeding tentatively at present, and, indeed, just now our unexpectedly rapid success involves certain practical difficulties which will presently disappear. The principles which will guide us in the choice of subjects will be Darwinian, to wit, natural selection and the survival of the fittest.—JOHN PHILLIPS. We consider art questions altogether suited to our columns; and shall be glad to admit correspondence on such subjects as you mention.—S. P. EASTICK. We have been promised a paper on Faure's Accumulator by a skilful electrician; but there has been great delay. If your suggested contribution were short and simple, we should be glad to use it. Spare not illustrations such as the subject may require.—DIXON KEMP. Many thanks. We should be glad to hear of the results of your experiments.—NEWTON CROSLAND. Can insert only portions of your very voluminous letters. You misunderstand our comments; but not more than you have misunderstood the teachings of science.—HENRY SIGGIN. We by no means intend to forget geology.—E. F. B. HARSTON. Thanks for kind wishes. Query appears.—A. FROOD. Many thanks for your offer, but original matter, correspondence, queries, &c., leave no room for reports of lectures, which are nearly always unsatisfactory.—T. J. H. Your remarks on "Anti-Guebre's" letter are sufficiently sound, but he has been already answered. Wonderful to relate, he sees and admits his error. We say wonderful, because when anyone has allowed misapprehension to blossom into false theories, his case is too often past cure. There are the makings of a man of science in "Anti-Guebre."—S. S. S. S. We think it better to let our readers join in answering questions even on those subjects which we have specially studied. Where no other answer comes we shall endeavour to supply the omission, and, sometimes, as you may have noticed, we take the initiative. But we wish this to be a magazine of general knowledge, not a mere organ for the expression of Mr. Richard A. Proctor's opinions on things in general. *We* have, indeed, a number of questions to ask, only hitherto we have not been able to find room. Your query about spiritualism is omitted. We could not find space for the evidence which would pour in from all sides, for and against, still less could we find time to sift it, and without sifting, it would be of little worth either way. Another question is omitted as not quite suited to our pages. We must not offend even the weakest brethren, still less the weaker sisters.—E. C. R. Your letter about parhelia in 1879, is very interesting, but crowded out by more recent matter.—R. E. WINTER. Note answer to Mr. McGrigor Allan.—B. M., F.R.A.S. Many thanks. Your interesting stories of intelligence in animals shall certainly appear.—J. PARKER FOWLER. In the great pressure of more strictly scientific matter, your hypothesis that ghosts and spectres, *et hoc genus omne*, may, perchance, be ultra violet or ultra red, and so only visible to certain eyes, cannot appear in our columns. We perceive that you do not regard it as "true, or even in any slight degree probable." We agree with you thoroughly, and also in considering that it is original. "If it has ever been started before," we, like yourself, "have never seen anything of it."—HARRIS RUSSELL. You will see that many stars are named in the maps for this month. We may shortly find space for the notes you suggest; but being astronomical ourselves, we do not wish to give our readers too much astronomy.—F. H. G. We hope to be able soon to give short biographies of eminent men of science. Space is our trouble just now. As we grow we shall do all we can.—F. COWLEY. Many thanks.—R. C. COWELL. No advertisements need be bound in; of course there will be a title-page.—P. M. TURNBULL. Compare the date of the passage you quote with that of Huxley's later utterances about automatism in animals.—ENQUIRER. Where do you get the "hydrogen of the air" in sufficient quantity to account for the heavy rainfall?—C. T. B. The question of the inferiority of woman has been now sufficiently discussed. Mathematical answer well known; chemical answer inserted.—R. J. BURNSIDE, W. MONT, and others. Thanks.—MARY B. ALDER. See reply above to C. T. B. Thanks.—J. D. HARDY. We regret that space cannot be found for your ingenious speculations about comets. Most probably the coma may consist of crystalline particles ("of the particular nature belonging to the gas" forming the comet as a whole); but the laws of optics will not permit us to regard the tail as produced in the way you suggest. Moreover, the motion of the particles under solar attraction would not be what you suppose. Each particle would travel on its proper ellipse as certainly as a planet would. We, unfortunately, *must* limit greatly the space we allow to the unsound, however ingenious, in order that we may keep room for scientific truths.—A. S. FARQUHARSON. We would rather not insert your query. Sleep preventatives are not rashly to be meddled with. Better yield to nature's hints that she needs her "sweet restorer."—AMICUS. Your mathematical problem belongs to an easy class; we have left it for our mathematical readers to deal with.—D. C. ANDERSON. Your kind suggestion noted.—W. H. PERTWEE. Have printed the passage you have kindly sent me; recognised an old friend in it, as you will see.—VEGA. Thanks; an obvious mistake.—E. M. KING. The article was not such easy reading as we could have wished; but the author is very eminent in that department.—J. A. L. R. Your reasoning, which is perfectly sound, has already been employed (p. 8).—WEATHER GUIDE. A correspondent suggests that a weather guide might be framed "without difficulty," in which the indications of the heavens, stars, moon, sun, clouds, movements and cries of animals and birds, the human body, plants, flowers, liquids, apparent nearness or distance of hills, &c., would help. We believe such a guide might be framed, but not without difficulty. "Exceptions" would, probably, occupy the larger part of the guide. But the matter is worth considering.

We are sorry to say that we continue to receive many letters calling attention to the difficulty of obtaining copies of KNOWLEDGE. We can only repeat that we have done all in our power to prevent this, and that our publishers will be obliged if subscribers will call their attention to the fact, should they experience any difficulty in obtaining KNOWLEDGE at any of the railway book-stalls, or from their local newsagents. To ensure a supply of the Back Numbers, which are rapidly becoming scarce, orders should be sent without delay.—ED.

KNOWLEDGE.—Although we offer our readers more in the way of original matter (apart from correspondence, which is not to be estimated by mere bulk) than any other journal of similar price and character, we wish to do better still. We hope so to extend the circulation of KNOWLEDGE that we may be justified in enlarging each number, in giving more illustrations, and in extending the number of our original contributors. *To attain this end we need the co-operation of our readers.* Those among them who approve our scope and plan can do more to improve KNOWLEDGE than either editor or publishers. If every reader were to obtain but one new subscriber, not only would our circulation be doubled, but our power to improve the matter placed before our readers would be increased in like proportion. If our readers will remember this, they will follow the best course for making KNOWLEDGE what we wish and hope that it may before long become.

PLAINLY WORDED-EXACTLY DESCRIBED

LONDON: FRIDAY, DECEMBER 16, 1881.

CONTENTS.

RECENT STUDIES OF VOLCANIC ACTION.

By G. F. Rodwell.

Although, during the last few years, no great eruption of a European volcano, similar to that of Vesuvius in 1872, has occurred, and no great earthquake comparable with that which devastated Calabria in 1783, the records of minor volcanic disturbances have been unusually numerous. In 1878 Etna poured out a stream of lava which ran for six miles; a few months before, Hekla threw up a new monticule, from which a quantity of lava issued; Vesuvius more than once since 1872 has furnished enough lava to run into the Atrio del Cavallo: Santorin was active from 1866 to 1870; Stromboli is always more or less energetic; and Volcano has given evidence that its vitality is by no means dormant. Again, within the last year, three disastrous earthquakes have occurred in Europe—at Agram, in Ischia, and in Chios—and many minor shocks have been recorded. In fact, earthquakes are much more common than we generally realise. A year ago (Nov. 28, 1880) an earthquake was reported from no less than fifty different stations in Scotland; some days ago a severe shock was announced from Agram; the previous day from Switzerland. During a few months of 1879, earthquake shocks were felt in such widely-distant places as Florence, Aachen, North Wales, Carinthia, Agram, Athens, and Swizerland. In 1878 there were more than a hundred earthquakes and twelve volcanic eruptions.

For another reason it appears to be a not inappropriate time for reviewing recent European Vulcanology. The literature of the subject has lately received some important additions in the form of such books as Dr. Arnold von Lasaulx's "Der Ætna"; M. Fouqué's "Santorin et ses Éruptions"; the "Studien uber Erdbeben" of Dr. Julius Schmidt; the United States' "Report of the Geology of Utah," by Captain Dutton; the "Minéralogie Micrographique" of MM. Fouquè and Michel Lewy; and the treatise on "Volcanoes" of Professor J. W. Judd, which only within the last few months has issued from the ponderous and iron jaws of the press. The rapid growth of the literature of the subject may be fairly judged of from the fact that Von Lasaulx prints sixteen quarto pages of "Ætna-Literatur."

Vulcanology is a recent science. If any one man can originate a science, Spallanzani must be regarded as the father of vulcanology. There had been many observers before his time, for the great phenomena of nature receive the earnest attention even of unlettered men, but they had observed blindly, and without method. They recorded their observations, but they made no attempt to classify or correlate them, formed no hypothesis to embrace them, and did not follow up the particular line of thought suggested by one or other of them. The value of a good working hypothesis, even in the early stages of a science, cannot be overrated. Moreover, the earlier vulcanologists did not go to work in the right way; they either watched, necessarily at a distance, some grand paroxysmal outburst, or they visited the scene of its action when the main effects had died out. Spallanzani did otherwise. He chose as the source of his observations an ever-active volcano, which never approaches the paroxysmal violence of Etna, Hekla, and Vesuvius during their great eruptions, and never sinks to the quasi-dormant condition which a Volcano commonly presents. Stromboli has been active for more than 2,000 years, and so moderately active, that the scene of its operations can be closely approached, and from a projection which is situated a little above the crater, the observer may sit for hours when the steam and vapours are blown out to sea, and watch the phenomena which are taking place within the crater. Spallanzani did this; and for the first time realised and enunciated the important fact, that volcanic phenomena are mainly, if not entirely, due to the violent escape of steam and other gases at high pressure from molten matter.

In 1874, Professor J. W. Judd, already an accomplished disciple of Scrope, visited Stromboli, and minutely examined, from the vantage-ground erst occupied by Spallanzani, the operations taking place upon the floor of its crater. He divides them into three classes. From certain large apertures in the floor steam escaped in loud, irregular puffs; within, some lava could be seen, which at intervals rose and swelled out, at the same time emitting large volumes of steam; while within the depths of other openings, viscous molten matter was seen to be heaving up and down, and violently agitated, like boiling water. Ever and anon, as the agitation increased, a great bubble of lava would swell out, and suddenly burst, emitting steam at high pressure, the force of which hurled the red-hot scum high into the air. Thus, the three essential conditions for the production of volcanic phenomena appear to be: (1) apertures or fissures affording communication with the interior of the earth; (2) highly-heated matter beneath the surface; and (3) subterranean water which, in the form of high-pressure steam, is competent to produce all the crater operations. A mass of lava within a small active crater precisely resembles a boiling fluid. In one of the lateral cones of Vesuvius the writer once saw a veritable geyser of fire, imitating in all respects its great prototype at Haukadalr. The viscous seething mass of lava within the *bocca* contains water entangled in its mass, and when this rises to the upper part of the column of lava, it is relieved from pressure, and flashes explosively into steam. This restores equilibrium for awhile, during which more steam is being generated, and presently another outburst occurs. The pressure of the steam which thus accumulates may be judged of by the fact that, during the eruption of Vesuvius in 1872, masses of vapour (and, it is said, fragments of scoriæ), were projected to a height of nearly four miles. The friction of this steam against the

rock masses generates enormous quantities of electricity, which appears as flashes of lightning issuing from the column of steam above the crater. The generation of the steam within the molten mass, and its competence to produce all volcanic phenomena, are ably discussed by Prof. Judd from a thoroughly scientific standpoint, and the result of the discussion he gives us in the cardinal generalisation—the keynote of modern vulcanology:—"The varied appearances presented, alike in the grandest and feeblest outbursts, can all be referred to one simple cause, viz., the escape from the midst of molten materials of imprisoned steam or water-gas."

Now the presence of large quantities of water within the recesses of the earth is by no means difficult to account for; but the cause of the internal heat is a far more difficult and yet unsolved problem. Astronomy has taught us that the world is not, as was long believed, a liquid mass, surrounded by a thin solid shell. Sir Humphry Davy endeavoured to account for the heat of volcanoes on the supposition that large quantities of uncombined alkali metals exist in the earth, which, when water finds its way beneath the earth, violently decompose it, generating heat and evolving hydrogen. Mr. Mallet considers that the contraction of the earth's crust can develope enormous quantities of heat. It has been calculated that if a portion of the earth's crust, fifty miles in thickness, were to have its temperature raised 200° Fahr., the surface would be raised by expansion more than a thousand feet. Moreover, crumpled and distorted strata clearly prove that enormous pressures have been exerted by contracting rock-masses. Hopkins imagines that the earth has solidified both at the centre and circumference, while cavities of molten matter are distributed between them. Captain Dutton believes that lava is pressed to the surface by the weight of superincumbent rocks, and he admits that we cannot allow one general reservoir, because lavas of different composition come from the same crater at different periods, and a lower volcanic vent sometimes remains open, while the lava rises and flows from a higher one. Some have assumed that the interior of the earth, although intensely heated, remains solid on account of the enormous pressure, and that the effect of any local diminution of pressure is to lower the fusing point, and thus cause the solid to become liquid. Volcanic phenomena would thus be exhibited at the points of diminished pressure.

But, although we seem to be as far as ever from determining the ultimate cause of volcanic effects, the phenomena themselves, as presented to our observation, are far better understood than heretofore; and this is mainly due to two causes, viz., the establishment of seismological observatories, and the microscopic study of eruptive rocks. Of course, we must add to these the application of more exact and scientific methods, and the advances due to the perfection of such instruments as the spectroscope and recording seismometer. The Vesuvius observatory was the first to be established on anything like a scientific basis, and several valuable volumes of reports have been published by its director, Palmieri. For sixteen years, Tacchini, of Palermo, and Silvestri, of Catania, have urged the erection of an observatory near the summit of Etna, and, thanks to the liberality of the Italian Minister of Agriculture and Commerce, and of the Municipality of Catania, it is now an accomplished fact. In August, 1882, the observatory will be ready for use. It adjoins the site of the old Casa Inglese, nearly 10,000 feet above the sea, and it is in telegraphic communication with an observatory in Catania, 24 ft. above the sea level, and also with observatories in the seven principal towns upon the flanks of the mountain—Aci Reale, Randazzo, Paterno, Aderno, Bronte, Giarre, and Linguaglossa. It will be furnished with all the most approved meteorological and seismological instruments, with spectroscopes, and with a fine refractor by Merz, of Munich, the object glass of which, during the winter months, will be transported to the Catania observatory and mounted in a similar telescope. Owing to the persevering efforts of Prof. M. S. di Rossi, of Rome, who is the editor of the *Bulletino del Vulcanismo Italiano*, seismological observations are now made in more than fifty towns of Italy, and although we could wish that they were better organised and placed under the control of some central Government observatory in Rome, it cannot be denied that the *Bulletino* (now in its seventh year of publication) has placed on record a multitude of observations of high interest to vulcanologists. Observatories are now being instituted in very distant volcanic centres. In January last, Lord Granville forwarded to the Royal Society some valuable "notes on the earthquake of July, 1880, at Manila," by Commander W. B. Pauli, which record the first scientific account of an earthquake in the Philippine Islands. It occurred along the line of the Taal volcanoes, and affected an area 220 miles by 75. The most severe shock lasted for 70 seconds, and combined oscillatory, trepidatory, and rotatory movement. Some very interesting engravings of pendulum curves accompany the paper, which appears in the *Proceedings of the Royal Society* for February, 1881. The curves are of great complexity, and show both the direction and relative intensity of the earthquake shocks, which were sometimes so violent that the pendulum was jerked upwards from the paper, and thus broke the continuity of the curve. Seismological instruments, although far from perfect, have been much improved since the time when the patient student of vulcanology contented himself with watching a bowl of treacle. The electrical seismograph records the direction of the shock, its intensity, and the moment of its occurrence and its cessation. Professor M. S. di Rossi has ingeniously applied the microphone to the detection of the slight subterranean noises which may be heard at any hour of the day or night in some districts. He affirms that both in his observatory in Rome, near the Ara Cœli, and at Rocca di Papa, he has often, while watching the point of a seismic pendulum in a microscope and simultaneously applying the telephone to his ear, heard harsh sounds in the latter at the instant when the pendulum has been seen to quiver.

DREAMS.

PART II.

By Edward Clodd.

KEEPING in mind what has been said about savage mental philosophy, it is not surprising that the inference drawn from the phenomena of dreams is belief in a double existence. Besides that waking self of which the savage is hazily conscious, there must be *another self*, which, roaming the world while the body is at rest, sees and does the things dreamed. Waking, the savage knows, or will be told, that whatever his dreams reveal to the contrary, he has not moved from the place where he lay down; therefore it is that ghost-soul—that *other* self—which has been away on the strange or familiar errand. And such belief in another self—*in* the body, yet at times not *of* it—is confirmed by daily experience. There are the suspensions of consciousness witnessed in swoon, apoplexy, catalepsy, and other forms of insensibility. Then there are the phenomena of shadows and reflection, actual existences to the savage, mocking doubles of himself. The shadow

accompanies, goes before, or follows him by sunlight and by moonshine, disappearing mysteriously only when these are withdrawn or intercepted. Still more complete in its mimicry is the reflection of himself—the image repeating every gesture, while perchance, as he stands shouting by the stream, the echo of his voice is thrown back from the hill-side, and adds confirmation to his notion of duality. How else can man at low stages of thinking, ignorant of the laws that govern the reflection of both sound and light, interpret the shadow and the echo? Hence it is that we find the word for "shadow" chosen to express this other-self in both barbaric and civilised speech, from the dialects of North and South American and African tribes, to the classic and modern languages, as witness the *skia* of the Greeks, the *manes* or *umbra* of the Romans, and the *shade* of our own tongue. Did the limits of a brief paper allow, it would be easy to show, from the evidence of language, how man explained to himself the mode in which this other self makes the passage from the body to the external world, and wherein lay the difference between the sleeping and waking, the living and lifeless body. It must suffice to say that throughout the entire savage and civilized world, the life, the spirit, the soul of man has been identified with *breath*. Not with that alone; but with the blood, the heart, &c., although chiefly and universally with the act of breathing, "so characteristic of the higher animals during life, and coinciding so closely with life in its departure."

It is interesting to watch the primitive nebulous theories of another self, a vaporous, ethereal, or otherwise unsubstantial, impalpable thing, condensing into theories of semi-substantiality, or of rude or refined resemblance to the body, theories which become indispensable to account for the appearance of both the living and the dead in dreams, when their persons were clasped, their forms and faces seen, their voices heard.

Such theories differ not in kind, but only in degree of refinement, and unite, as Dr. Tylor remarks, "in an unbroken line of mental connection," the savage fetish worshipper and the civilised psychologist adding their welcome witness to the similar working of untrained intelligence in different ages among different races on corresponding levels of culture, and therefore, to the underlying unity of our race. This we shall realise only as we realise that the laws of mind, like those of matter, are uniform, and approximately calculable in their operation; the phenomena of one interrelated and interdependent as are the phenomena of the other, and equally the subjects of observation and comparison, if not by identical methods, yet on like principles.

It would be an interesting and informing chapter in the history of the illusions through which man has made continuous, and as yet unaccomplished, passage to the truth, to show how belief in indwelling spirits, of fitful habit and varying form, was enlarged to belief in souls in the lower animals, in plants, and in lifeless things, from stars to stones; how the phantasms of the brain have filled earth, sea, and sky with spirits innumerable, from white-winged celestials to the degraded ghosts of haunted houses. But this would be an undue extension of the subject, for the completeness of which some reference must be made to the part played by dreams as supposed media of communication between gods and men, and as monitions of coming events.

The awe and wonder excited in the savage mind by waving trees and swirling waters, by drifting cloud, whistling wind, and stately march of sun and moon—all invested by him with personal life and will—were immensely quickened by his dreams. In their unrelated and bewildering incidents, the powers indwelling in all things around him seemed to come nearer than in the more monotonous events of the day, uttering their warnings and conveying their messages. There needed but slender data to reach conclusions. Let the death of a friend be dreamt of, and the event follow; or a hunting-feast fill the half torpid fancy, and a day's privation give the lie to the dream; the arbitrary relation is made. Lord Bacon says:—"Men mark the hits, but not the misses," and a thousand dreams unfulfilled count as nothing against one dream fulfilled. Out of that a canon of interpretation is framed by which whole races of men will explain their dreams, never staying to wonder that the correspondences are not more frequent and minute than they really are.

"To this delusion," says Cornelius Agrippa, an ancient rationalist, "not a few great philosophers have given a little credit . . . so far building upon examples of dreams, which some accident hath made to be true, that thence they endeavour to persuade men that there are no dreams but what are real." When Homer says that "dreams, too, from Jove proceed,"* painting the vividness and agonising incompleteness of those passing visions; when Tertullian says that "we receive dreams from God, there being no man so foolish as never to have known any dreams come true," both classic and patristic opinion are clearly survivals from the lower culture, its lineal and thinly-disguised descendants. For the savage, the bard, and the theologian lived in days when the conception of orderly sequence was unthinkable to them; where the arbitrary act was wrought, the isolated or the conflicting influence manifest, there the deity or the devil was present; while for us, could we discover where law is not, thence God would seem to have withdrawn.

The passage from the crude interpretation of his dreams by the savage to the formal elaboration of the dream-oracle is obvious, the more so as this latter was only one of many modes by which it was sought to divine the will of heaven, and read that "book of fate" hidden from men. This dream-lore, as ancient records far back to Accadian times show, not only called into existence a class of men whose position as interpreters of royal and other dreams ensured them commanding place, but gave rise to a mass of literature most prolific in classic times. It maintained an almost canonical supremacy down to the Middle Ages, finding its befitting level in our day in the "Libri dei Sogni" which the Italian lottery-gambler consults, and in the "Imperial Dream-Book" by which the English domestic forecasts whether King Cophetua or Police-sergeant X 32 is to be her fate!

At this nether depth, Science, content with having shown the persistence of primitive modes of thinking in all subsequent interpretation of his own nature by man; finding its evidence and the warrant of its conclusions in that human experience which the sources of our knowledge cannot transcend; may well let the matter rest. It need not concern itself with denials that dreams have been sent as warnings from Heaven to man; this were as foolish as to take pains to disprove the existence of ghosts, or to seriously challenge the predictions in Zadkiel's *Vox Stellarum*. Science need not argue; it explains; and to such matters explanation is death. For the changes which revelation of the order of nature and the establishment of that doctrine of continuity, which has no "favoured-nation" clause for man, involve, will bring about, in quiet and unmourned, the departure of belief in dreams as omens or warnings, just as they have brought about the decay of belief in witchcraft and astrology.

* "Iliad," Book I., 77.

BETTING AND MATHEMATICS.

By the Editor.

When I was travelling in Australasia, I saw a good deal of a class of men with which, in this country, only betting men are likely to come much in contact—bookmakers, or men who make a profession of betting. What struck me most, perhaps, at first was, that they regarded their business as a distinct profession. Just as a man would say in England, I am a lawyer or a doctor, so these men would say that they were bookmakers. Yet, on consideration, I saw that there was nothing altogether novel in this. Others, whose business really is to gain money by making use of the weaknesses of their fellow-men, have not scrupled to call their employment a trade or a profession. Madame Rachel might have even raised her special occupation to the dignity of "a mystery" on Shakespearean grounds ("Painting, sir, I have heard say is a mystery, and members of my occupation using painting, do prove my occupation a mystery"); and if aught of wrong in his employment could be made out to the satisfaction of a bookmaker, his answer might be Shakespearean also, "Other sorts offend as well as we—ay, and bettor, too."

My own views about betting and bookmaking are regarded by many as unduly harsh, though I have admitted that the immorality which I find in betting has no existence with those who have not weighed the considerations on which a just opinion is based. I regard betting as essentially immoral so soon as its true nature is recognised. When a wager is made, and when after it has been lost and won its conditions are fulfilled, money has passed from one person to another without any "work done" by which society is benefited. The feeling underlying the transaction has been greed of gain, however disguised as merely strong advocacy of some opinion—an opinion, perhaps, as to whether some horse will run a certain distance faster than another, whether certain dice will show a greater or less number of points, or the like. If here and there some few are to be found so strangely constituted mentally as really to take interest in having correct opinions on such matters, they are so few that they do not affect the general conclusion. They may bet to show they really think in such and such a way, and not to win money; but the great majority of betting men, professional (save the mark) or otherwise, want to win money (which is right enough), and to win money without working or doing some good for it, which is essentially immoral. That in a very large proportion of cases this negative immorality assumes a positive form—men trying to make unfair wagers (by betting with unfair knowledge of the real chances)—no one acquainted with the betting world, no one who reads a sporting paper, no one even who reads the sporting columns of the daily papers, can fail to see. Why, if half the assurances of the various sporting prophets were trustworthy, betting, assisted by their instructions, would be as dishonourable as gambling with marked cards, as dishonest as picking pockets. Here is my "Vaticinator,"* the betting man might say, who says that Roguery is almost sure to win the "Beggar my Neighbour" stakes, but if he does not, that speedy mare, Rascality, will unquestionably win. Here are the bookmakers, who seem all quite as ready to lay the odds against Roguery and Rascality as against any of the other horses, to say nothing of my friends, Verdant and Flathead, who will freely back any of these latter. Now, if I back Roguery and Rascality with the bookmakers, and lay odds against the certain losers in the race, I shall certainly win all round. Of course, "Vaticinator" is not the prophet he claims to be, but the betting-man of our soliloquy supposes that he is, and so far as the morality of the course the latter follows is concerned, the case is the same as though "Vaticinator's" prophecies were gospel. There is not a particle of real distinction between what the bettor wants to do, and what a gambler, with cogged dice or marked cards, actually does. The more knowing a betting man claims to be, the easier it is to see that he wants and expects to take unfair advantage of other men. Either he knows more than those he bets with about the real conditions of the race or contest on which they wager, or he does not. If he does, he wagers with them unfairly, and might as well pick their pockets. If he does not, but fancies he does, he is as dishonest in intention as he is in the former case in reality. If he does not, and knows he does not, he simply lies in claiming to know more than he does. In claiming to be knowing, he really claims to be dishonest and (which is not quite the same thing) dishonourable; and probably his claim is just. Of course, this is only a comparatively mild case. Men have been known to take the odds against a horse after they knew certainly that the horse would not run. Others, a shade more advanced, have been known to bribe a jockey to "hold," or "rope" a horse, or a stableman to poison or stupefy him. Owners—aye, even "noble" owners—have been known to work the market in ways fully as flagitious. Every one agrees about these. But the majority are disposed to stare, and perhaps to sneer, when Herbert Spencer describes ordinary, and what is commonly called fair gambling, as immoral; and the calmness with which a betting man claims to be knowing, shows that he, at any rate, does not think wagering with unfair knowledge (with any knowledge, I suppose, short of absolute certainty) dishonourable. He argues, and many who do not bet argue for him, that he takes his chance with others; as if it might not quite as justly be argued that the pickpocket takes his chance between a successful transaction and the prison cell.

As one of our "Five of Clubs," I gave last week a case in which a certain man of title used to offer freely—and possibly with a sense that he was acting quite fairly—a most unfair wager, though it seemed a very generous one. Odds of a thousand pounds to one are very tempting to the inexperienced. "I risk my pound," such a one will say, "but no more, and I may win a thousand." That is the *chance*; and what is the *certainty?* The certainty is that in the long run such bets will involve a loss of £1,828 for each thousand pounds gained, or a net loss of £828. As certain to all intents as that two and two make four, a large number of wagers made on this plan would mean for the clever layer of the odds a very large gain. Yet Lord Yarborough would probably have been indignant to a degree if he had been told that in taking £1 for each hand on which he wagered which did not prove to be a "Yarborough," he was in truth defrauding the holder of the hand of 9s. 0¾d.—notwithstanding the preliminary agreement, simply because the preliminary agreement was an unfair one. As to his being told that even if he had wagered £1,828 against £1 the transaction would have been intrinsically immoral, doubtless he and his opponent would equally have scouted the idea.

A curious instance of the loss of all sense of honour, or even honesty, which betting begets, occurred to me when I was in New Zealand. A bookmaker ("by profession," as

* I hope there is no turf prophet with this *nom-de-plume*. I know of none, or I would not use the name; but it may have been hit upon by some sporting man with a taste for polysyllables.

he said), as genial and good-natured a man as one would care to meet, and with a strong sense of right and justice outside betting, had learned somehow that ten horses can come in (apart from dead heats) in 3,628,800 different ways. This curious piece of information seemed to him an admirable way of gaining money from the inexperienced. So he began to wager about it, endeavouring—though, as will be seen, he failed—to win money by wagering on a certainty. Unfortunately, he came early across a man as cute as himself, and a shade cuter (*à brigand brigand et demi*), who worded the question on which the wager turns, thus: "In how many ways can ten horses be placed?" Of course, this is a very different thing. Only the first three horses can be placed, and the sets of three which can be made out of ten horses number only 10 times 9 times 8, or 720 (there are only 120 actual sets of three, but each set can be placed in six different ways). My genial, but (whatever he thought himself) not quite honest friend, submitted the matter to me. Not noticing, at first, the technical use of the word "placed," I told him there were 3,628,800 different arrangements, he rejoiced as though the money wagered were already in his pocket. When this was corrected, and I told him his opponent had certainly won, as the question would be understood by betting men, he was at first depressed; but presently recovering, he said, "Ah, well; I shall win more out of this little trick, now I see through it, than I lose this time."

I shall hereafter give some illustrations of the true principles on which all chance questions should be determined. There is no hope that men generally will give up gambling, but it is, at any rate, desirable that when they gamble, the chances should be as equal as they can be made; that, in fact, they should not play (as the opponents of Lord Yarborough and my New Zealand friend were certainly playing) against cogged dice or marked cards. The matter is one strictly appertaining to the subjects with which Knowledge claims to deal. There is science in chance, certainty in probabilities. What is thus scientific and certain is what we propose to bring before our readers.

OUR UNBIDDEN GUESTS.

By Dr. Andrew Wilson, F.R.S.E.

The fact that in most animals there may reside, as "guests," within unconscious or unwilling "hosts," certain other animal forms, is, of course, widely known. These animal "guests" form the "parasites" of the natural historian. But, although the fact of their existence is known, the general history of even the commonest parasites is a matter concerning which the general public are, as a rule, lamentably ignorant. I say "lamentably," and I mean what I say. A vast amount of disease, and that of a preventible nature, is caused by the carelessness of man in the preparation of his food. This carelessness is in its turn founded upon gross ignorance, for there are not a few persons who believe that parasites come, like Dogberry's reading and writing, by nature, and that they are part and parcel of an animal's constitution. That this opinion is very far removed from the true state of matters can easily be shown. It is perfectly provable that animals were not created with the parasites infesting them as we find them to-day. Common-sense forbids such a supposition, and the organised common-sense we call "science" shows us that the reverse is the case. All parasites are acquired, and not original "guests." This alone is provable by the facts of parasite-development. There is a bag-like parasite called *Sacculina*, for instance, which attaches itself to the bodies of hermit crabs. Now, sac-like though this parasite is, and destitute as it is of all the ordinary belongings of animal life, it yet begins its existence as a little free-swimming animal, exactly resembling a water-flea. The first stages in a sacculina's development are, in short, like the beginnings of the development of some shrimps, of barnacles, of water-fleas, and of crabs themselves, though in a less marked degree. Only after becoming degraded in structure does the sacculina become the "guest" of the crab. The mere facts that sacculina is at first as free-living as a fish, and that it afterwards settles down on the crab, testify, if we read nature's story aright, that "once upon a time" the sacculina race was not a parasitic one. Whether or not the sacculina-stage itself was the beginning of the attached existence, we do not know. It is most probable that the bag-like body we term a "sacculina" was the result of the adoption of the lower and rooted way of life. But, apart from all other considerations, the main facts that a young sacculina is always free, and that it begins life under a similar guise even to some of the shrimp race, shows that its parasitic life has been acquired, and is by no means an original condition.

Now the same rule holds good of all "parasites." The development of most of them shows us the lingering remnants of a once-free life. But there are other proofs at hand of this assertion. There are degrees and stages in the perfection of the parasitic state. There exist animals which are mere "lodgers," so to speak—who "dine out," but who repose within the anatomical establishment of a "host." This is the case with certain little fishes, which choose the very "jaws of the lion" as a dwelling-place, since they appear to live in the interior of certain big, tropical sea-anemones. These fishes may be seen to swim in and out of the anemone's mouth, and they may be enclosed within the anemone's body when that animal contracts itself, and yet swim free and unharmed out of the mouth when these flower-like animals once more resume their normal and expanded state. Here, then, there is mere "association," but it is in some such association that the beginnings of pure parasitism have orginated. Suppose the case of an animal which, at first merely "lodger," took to feeding upon the tit-bits secured by its host for home-consumption. The "lodger," in such a case, would practically become a "boarder" as well. But nature has a law as fixed as the edicts of the Medes and Persians, called the "law of disuse." This law enacts that whatever structures or organs of living beings are not normally used, will waste and tend to disappear. It is the operation of this law which has caused the two outer toes of our horse to grow "small by degrees and beautifully less," until they now appear as the "splint bones" on each side of the single toe upon which the horse walks. And applying this law to the case of the animal lodger, we see how an animal which does not require to move about when resident within another animal will lose its organs of motion. If it obtains fluid food, all ready digested, the probabilities are its digestive system will become rudimentary. Not requiring eyes or other sense-organs, these will disappear; and thus we see represented a kind of zoological backsliding, which reduces the parasite to the elementary and degraded condition we, as a rule, discover in the races of animal "guests."

The histories of some of the most common parasites are fraught with instruction, not to speak of the curiosity that invests them. Take, for instance, the history of the fluke (*Fasciola hepatica*), found in the bile-ducts of the liver of the sheep and ox. It is the presence of this parasite that makes

sheep-rot, a disease known to veterinarians as the "rot." A fluke is a little, flattened, oval body, about 1 in. or $\frac{3}{4}$ in. in length and about $\frac{1}{2}$ in. in breadth. It possesses a nervous system, a set of water vessels, two suckers, a branched digestive system, and an egg-producing apparatus. It has no organs of motion, but it is by no means a very degraded being after all. Its development is very curious. The eggs, liberated from the animal "host," get scattered abroad. Many—as in the case of all parasites—must perish, but a proportion finding their way into water, enter the body of the water-snail, where they develop into curious little tailed beings called *Cercariæ*; and there are sundry other forms assumed by the fluke in the days of its youth, but which need not be mentioned here. Sooner or later, however, these *Cercariæ* escape into the water or into the meadows; and it is believed that from the damp meadows, or from the water itself, the sheep obtains these little beings. Once within the sheep's stomach, each *Cercaria* seems to waken up to its ultimate destiny. It drops its tail, and bores its way through the tissues of the sheep towards the liver, where it soon appears as the young fluke, which will develope eggs that will repeat its own curious history. The most notable fact, however, of this development is that if a sheep swallowed the *egg* of the fluke, no development would ensue. The egg requires to pass through its water-snail stage, ere the sheep can obtain the new fluke.

STATISTICS OF SUICIDE.*

In these days, when the question is asked, as a not unreasonable comment on the phenomena of social life, "Is life worth living," the statistics of self-slaughter have an exceptional value. Suicide could not be regarded as a subject of scientific investigation at all, until after statistical researches had been made. As Professor Morselli says, the character which classical paganism attributed to suicide was simply individual. The famous phrase of the Stoics, "Mori licet cui vivere non placet" (he whom life pleases not has a free right to die), was the product of ancient philosophical individualism. Law and religion alike declare suicide criminal. But as yet the crime has not been considered as a tendency—hurtful, unquestionably, to society, but connected with society's natural development. It is this aspect of suicide which Professor Morselli discusses in the book before us. "The old philosophy of individualism," he remarks, "had given to suicide the character of liberty and spontaneity, but now it has become necessary to study it no longer as the expression of individual and independent faculties, but as a social phenomenon allied with all other racial forces."

At the outset, we may notice that if there is one thing which would render the statistics of suicide pre-eminently valuable, and if there is one thing which Dr. Morselli seems to regard as little worthy of discussion, it is the recognition of the motives which lead to suicide (and rather in their psychical than their social aspect). Can we, or can we not, from the statistics of suicide, determine the motives most potent to drive men to self-slaughter? By studying the statistics of times and seasons we may determine the physical condition which best favours the influence of such and such motives. When we find that the hot, bright months of summer are those in which the suicidal tendency prevails most, we seem to recognise physical, rather than psychical influences; or, to speak plainly, we seem to see that the state of the body, rather than that of the mind, is important, so far as this special peculiarity is concerned. When we learn that suicide is more common in the daytime than at night, and that there are three hours of maximum suicidal tendency—viz., about 8 a.m., about noon, and about 3 p.m.—we recognise the influence of social relations; as we do again when we notice the greater number of suicides on Monday, Tuesday, Wednesday, and Thursday, as compared with those on Friday, Saturday, and Sunday (except among women, with whom Sunday is the favourite day for suicide). But in these statistics the influence of motive is not readily to be recognised.

The case is somewhat different when we consider the influence of marriage on suicide. Here it comes out very clearly, as we might naturally expect, that responsibility has its influence even on those so weak that, but for some such restraining influence, they would "shuffle off this mortal coil." When in one and the same nation we find that the number of suicides among married men is far less than among single men, we may be in doubt how far the difference is due to difference of motive, or to the different stuff of which (taking the average) the ranks of the married and of the unmarried are made. It might be that the men who are either less likely to be selected as desirable mates, or who are averse to marriage, are more likely antecedently to be life-weary. But we can have no such doubts when we see that widowers without children are nearly twice as likely to commit suicide as widowers with children. It seems almost certain here that the restraining influence is the sense of responsibility. As Douglas Jerrold, when the doctors pronounced his death-warrant, looked round at wife and children, and said, "I will *not* die"; so we may well believe that even the weakest among men, who, on his own account, sees nothing that makes "life worth living," will yet feel that he cannot die and leave his little ones without a protector, or, it may be, in want. He feels that though his life may be worthless to himself, it is worth something still for them, and haply he may find later that in its worth to them it has had a worth to himself also.

We take it, indeed, that ninety-nine self-slayers out of a hundred show by their act that they feel their life to be worthless not only to themselves but to everyone. Suicide is, to all intents and purposes, an admission of utter worthlessness. Even in cases where a sort of halo of romance or heroism has surrounded the act, this has been so (we except, of course, all cases in which suicide has meant self-sacrifice—that is, no more self-murder than homicide in self-defence or defence of others is murder or even manslaughter). The lover who kills himself or herself because rejected or slighted, admits inferiority, if not worthlessness, as certainly as the man who kills himself because he has failed in the struggle of life. The Cato who kills himself rather than yield to his country's enemies, admits as certainly that his best has proved a failure, as the man who takes away his own life because he fears poverty or misery. Thus viewing suicide, one might, at a venture, predict that, other things being equal, suicide would be most frequent among that set of men who most feared contempt. Other things are not equal; but it does so happen that the proportion of suicides is greater in Paris (and the *Ile de France* generally) than anywhere else in Europe, four times greater than in London and the south-eastern parts of England, and nearly ten times greater than among the self-contented people of Southern Holland.

When we take employments, we find a similar lesson, though we cannot be quite so sure of our interpretation.

* "Suicide: An Essay on Comparative Moral Statistics." By Henry Morselli, M.D., Professor of Psychological Medicine, &c. (London: C. Kegan Paul & Co., 1881.) Price, 5s.

Men of art, science, and literature, with their keen susceptibilities, and their tendency to watch with anxiety, if not with envy, the success of their fellow-workers, stand at the head of the professions and trades in suicidal tendencies, despite the enormous increase to the value of life which the study of art, science, and literature brings with it. Military men come next, in Italy at least (with 404 to the million of their class, as compared with 618 to the million among literary men). But this may be due to other causes, as Dr. Morselli notes. "Military life" (in Italy), he says, "has the misfortune of increasing the loss of active and vigorous elements by means of unhappy sacrifice to suicide; whether that is owing to distance from home and disgust for military life, or to the severity of discipline, this is not the place to discuss."

Dr. Morselli's work is full of curious statistics, singularly ill-arranged, and at times rendered almost unmeaning for want of fuller information, or by the badness of the translation, yet well worth careful study. The conclusion to which he comes is melancholy. The cure of the suicidal tendency is indicated, he says, in one precept: "*To develope in man the power of well-ordering sentiments and ideas by which to reach a certain aim in life; in short, to give force and energy to the moral character.*" This amounts, in fact, to saying that, since the weak and idle are more apt to commit suicide than the strong and active, it is necessary to become strong and energetic in order to avoid the suicidal tendency. *But how?* "Intemperance and dissoluteness are powerful causes of weakness, and consequently of suicide." Therefore we must avoid intemperance and dissoluteness. But may it not with as much truth be said that weakness is a cause of intemperance and dissoluteness? We are no nearer the *causa causarum*—no nearer than was Hamlet when he reasoned how

> Oft it chances in particular men,
> That for some vicious mole of Nature in them,
> As in their birth (wherein they are not guilty,
> Since nature cannot choose his origin)
> By their [query "the"] off-growth of some complexion,
> Oft breaking down the pales and forts of reason
> Their virtues else . . . . .
> Shall in the general censure take corruption
> From that particular fault.

The true cure, it seems to us, is from without, not from within. Show a man that his life need not be a useless one; give him some worthy end to achieve, and his mind will be turned from the idle question: "Is life worth living?" Life is always worth living when any good work remains to be done.

THE DESTROYED COMET.

By the Editor.

BEFORE considering the theory of repulsion as applied to interpret the phenomena of comets' tails, it may be well to consider a case in which some active force (other than gravity), exerted by the sun, seems to have wrought the destruction of a comet, or, at least, to have broken up the comet into unrecognisable fragments.

No comet ever observed has exhibited phenomena more remarkable than those displayed by the comet known as Biela's (more properly called Gambart's). We wish we could agree with a modern astronomer, who has said that no comet has thrown more light on the nature of these bodies; but, in point of fact, it is only promise of light, not light itself, that we have obtained.

Discovered in 1826, Biela's comet was presently found to be identical with one seen in 1772 by Montaigne, and again by Pons in 1805. A careful study of the observations showed that the comet travels round the sun in a period of about $6\frac{2}{3}$ years, or, roughly, thrice in twenty years. Its path was found to approach very near to the path of our earth. The comet returned in 1832, when the ignorant were scared much as they have been recently by the threatened influence of the larger planets in perihelion. The comet crossed the earth's track several weeks before she herself came to the place where the two orbits approach nearest, and it is hardly necessary to say that the comet's passage did not injure the earth's roadway in any appreciable degree.

Fig. 1.—Biela's Comet in 1846, before its division into two.

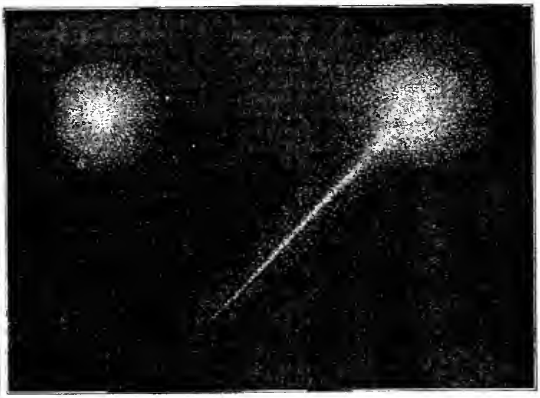

Fig. 2.—Biela's Comet on January 15, after its division into two.

In 1839 the comet returned, but was not seen, travelling across a part of the heavens only above the horizon in the day-time, so that the comet's light was hidden by the sun's.

It was at the next return in 1845-46 that the comet first attracted special attention. On that occasion, instead of behaving as comets usually do, Biela's, which in the first days of 1846 had presented the appearance shown in Fig. 1, was found to have divided into two. There is some little doubt as to the time when the comet underwent division. Lieut. Maury reported on January 15 that he had seen the

comet double on January 13; but Wichmann observed it as a single comet on the 16th. But Professor Challis, in his account of his own observations on the comets, states that even on January 15 the second comet might easily have been overlooked. M. Valz saw nothing unusual on the 18th and 20th; but on the 27th: "I was struck with amazement," he says, "to find two nebulosities, separated by an interval of two minutes of arc, instead of one nebulosity alone. . . . Each head was followed by a short tail, whose direction was perpendicular to the line joining the two nebulosities." Earlier, only the larger comet had had a tail, the appearance presented by the double comet being that shown in Fig. 2.

The two comets travelled along, side by side, until at last both passed out of view, at which time the distance between them amounted to about 157,000 miles.

In 1852 both comets returned. Sir John Herschel says, in his "Familiar Lectures on Scientific Subjects," that when they returned, the distance between them was unchanged. This, however, was a mistake. The distance now amounted to about $1\frac{1}{4}$ millions of miles. Again they passed before the interested gaze of astronomers, travelling side by side, though rather far apart, until finally they disappeared from view—we say finally, for neither has ever been seen again.

Whether the two comets returned in 1859 is doubtful. It is certain that if they did, they would have been invisible, for the same reason that the comet was invisible when it returned in 1839.

But in 1866 the double comet should have been well seen. It should be remembered that each return of a comet of short period (like that which our correspondent Mr. F. Denning, of Bristol, discovered this year) gives the astronomer more perfect mastery of the comet's motions. The return could be predicted with sufficient accuracy in 1832 to cause the comet to be easily redetected. The next visible return might have involved a difficulty, because the comet had in the interval made two circuits. But that return was successfully predicted. The return in 1845-46 was still more accurately calculated. Nor did the breaking up of the comet into two on that occasion interfere with the successful calculation of the return in 1852. The case may be compared to the rating of a clock, which is more satisfactorily effected in a week than in a day, for the simple reason that any error of observation is spread in one case over seven times as long a period as in the other, and therefore affects the estimate of any given circuit of the hands by an error only one-seventh as large. Just so, whatever error an astronomer might make in observing Biela's comet in, say, 1843, was distributed over all the revolutions of the comet which had taken place since 1826 (one might almost say since 1772), and in a correspondingly small degree affected the astronomer's estimates of the comet's motion during any single revolution. This being so, astronomers had good reason for believing that in 1866 Biela's comet would return. When the time came that it should have been visible, telescopes were turned towards the spot where it should have been seen. Night after night from that time its calculated track was swept with the finest telescopes in Europe and America. But no trace of the comet could be seen. "It is now," wrote Sir John Herschel, in February, 1866, "overdue. Its orbit has been recomputed, and an ephemeris calculated. Astronomers have been eagerly looking out for its reappearance for the last two months, when, according to all former experience, it ought to have been conspicuously visible, but without success! giving rise to the strangest surmises. At all events, it seems to have fairly disappeared, and that without any such excuse as in the case of Lexell's—the preponderant attraction of some great planet. Can it have come into contact, or exceedingly close approach to some asteroid as yet undiscovered; or, peradventure, plunged into and got bewildered among the ring of meteorolites, which astronomers more than suspect?"

Be the cause what it might, the comet was not seen in 1866. In 1872 it was looked for even more carefully. Every possible contingency depending on planetary perturbations was considered: and the telescopes of astronomers swept, not only the calculated path, but to a considerable distance on either side of it. No trace of the comet was seen, however, in 1872 any more than in 1866. So far as telescopic observation is concerned, Biela's comet seems to have come to the end of its career as a comet.

Yet the observations of 1852 were not the last which were made on this interesting object. It has been seen again, though not as a comet. Nay, the occasion on which it was seen in the way referred to was predicted, and the prediction fulfilled, even in details. We shall return to the consideration of this remarkable apparition of the comet in changed form—a form which but a quarter of a century ago no one would have thought of associating in any way with the long-tailed star whose approach had been regarded as heralding some great change in the fortunes of men and nations.

TOAD IN A HOLE.

By Dr. A. Wilson, F.R.S.E.

In letter 87, "Arachnida" asks, "What is the construction of the common toad that enables it to be enclosed for many years in blocks of solid matter?" "Arachnida" should first of all have asked, is it true that toads are ever found so enclosed? The usual story is that of some quarrymen, who, blasting stones, see a live frog or toad hopping about, after the blast, among the *débris*. Because the toad is found thus, it is *assumed* that it came from the interior of the rock. Not a particle of evidence exists to show in such a case that the animal had anything whatever to do with the rock. If "Arachnida" will read in the "English Cyclopædia" the account of Dean Buckland's experiments, he will find that the Dean enclosed healthy frogs and toads in holes cut in limestone and sandstone blocks. He buried the blocks in his garden three feet deep. At the end of the first year most had died, and the living ones, re-buried, all died long before the end of the second year. Common sense, apart from exact knowledge, would tell us that animal life of higher kind, with all its demands in the way of food, &c., could not exist under the circumstances of the popular tales and superstitions "Arachnida" inquires about. The oldest fossil toads and frogs occur in *Tertiary* rocks. If, therefore, a live toad hopped, as has been alleged, out of a *Cretaceous* or *Devonian* rock, such a fact would amount to the declaration that the live toad could be ages and ages older than its fossil relatives, which declaration is, of course, the height of absurdity. There is no doubt that a frog or toad has an elastic constitution. It is cold-blooded: it can live under water for months; it can live for months after excision of its lungs, because the skin takes on the functions of lungs in such a case: and these animals (as in Dean Buckland's experiments) can live without food for a year or two, but, like all other animals (and plants), die *starved and meagre*, sooner or later. If "Arachnida" will only take the trouble to inquire into the *evidence* on which such stories as those he mentions are founded, he will find not one single *proved* or *provable* fact which will warrant any belief in the utterly impossible existence of toads or frogs in rocks. I may refer him for a fuller account of such cases to the essay on "Some Facts and Fictions of Zoology" in my "Leisure Time Studies" (Chatto & Windus). As a naturalist, I stake my reputation on the correctness of the views stated above, and also repeated in my book.

EASY LESSONS IN BLOWPIPE CHEMISTRY.

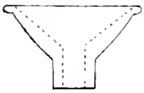
By Lieutenant-Colonel W. A. Ross, late R.A.

Introduction.

I FEEL some difficulty in expressing the satisfaction experienced by myself, in common, no doubt, with thousands of others, at seeing what has been for so long the great moral and intellectual *desideratum* of London—a *cheap* and simply-written, but at the same time thoroughly scientific magazine—so well supplied as it promises to be by Knowledge; and I beg, therefore, to offer you my humble efforts towards the accomplishment of this praiseworthy object. First, if I have your permission, in the simple exposition of a scientific subject which has attracted my most ardent attention, and extracted every leisure moment for its study, during the last twenty-two years of my life; secondly, by getting all the working people I can in my neighbourhood to spend their spare twopences weekly in the acquirement of Knowledge in the way of literature, instead of (as most do at present) in the purchase of trashy penny and halfpenny novels, boiled-down Scott, police *réchauffées*, &c., &c.

Lesson I.—How to Make a Blowpipe and Use It (Chemically).

Many English working young men already know how to use a common mouth-blowpipe in soldering and goldsmithing, &c., so that I shall have less difficulty in explaining how very little more trouble or pains are required in using it chemically. And first, as to making a blowpipe. We all know that a common conical, or "Black's blowpipe" (invented by the celebrated Dr. Black, of Edinburgh), made of tinned iron, with its brass nozzle, can be purchased for 9d.; but I would strongly advise every investor in such nine pennyworth, to add to his blowpipe a *trumpet-mouthpiece* (invented by the German chemist, Plattner), which any wood-turner will make of some hard-seasoned wood for 2d. more. If, however, my young friend is determined to make a blowpipe for himself, I will now show him how to make a far more powerful instrument than the above, and one, also, which does not require *any* art in blowing. A child can use it without being taught; indeed, my little boy (age 7 years) has already done so.



First, he must procure about a foot, in 2 in. pieces, of brass tubing, half of which should be 7-10 in. in diameter, and the other half *a little* smaller, so as to draw in and out of the former like a telescope, and yet fit air-tight. He must now solder a round piece of brass into one end of the wider tube, so as to close that for ever. These tubes are called the "Body-tubes" of the blowpipe. He can then make *the jet* of a small brass tube, tapering to a point, this form *and size*. Two holes are now to be correctly bored through

the sides of the wider body-tube above mentioned, about ½ in. from its closed end, so that this jet shall pass into them, closing air-tightly the larger hole at *a* and the smaller at *b*, which places are exactly 7-10 in. apart in the figure. A smaller hole like that in the figure is to be bored through one side of the jet, between *a* and *b*. A brass *nozzle*, this shape and size, having a bore the width of a good stout sewing-needle, is to be fitted (but on no account screwed) on the tapering end of the jet. A child's indiarubber air-balloon, of the smallest size procurable, is tied on the thick end of the jet, with waxed silk-thread, and this part of my young friend's blowpipe is complete. To complete the whole, all he has now to do is to procure a wooden trumpet-mouthpiece to fit air-tightly into one end of the smaller of the body-tubes above described; but before fitting it, he must fasten over the inner end of its bore a strip of oiled-silk cloth, rather loosely, so that air blown upon the silk from the outside shall pass into the tube, but cannot pass *back again* into the mouth. This silk, in fact, forms a simple *valve*.

The young "pyrologist," or blowpipe-chemist, now possesses a blowpipe which, with proper "re-agents,"—cheap chemical substances with which to heat and treat his minerals, &c.—will enable him, after he has been through a course of these lessons, to "analyse"—that is, take to (chemical) pieces, so as to show what they are composed of—the "rocks" of the geologist or the "stones" of the mineralogist, belonging to a whole continent, if necessary (and if a decent time is allowed him for the purpose).

The Editor will explain far better than I can, that everyone's eyes see objects (small print, for instance) best at a certain distance. This point is called their "focus," and this distance their "focal distance." Most people's eyes have not only a different focal distance, but the focal distance of the same pair of eyes is apt (unhappily!) to alter through age; also in consequence of sickness or accident. The telescopic form of this blowpipe (which was invented by me about a year ago) enables each operator to draw it out or shut it up to the length suitable to the focus of his eyes. In packing, he draws out the jet, and, folding its air-bag as closely as possible, slips the whole into the smaller body-tube; that, with its contents, is passed into the wider body-tube, and the whole shut up, telescope fashion, forming a single short tube which can be carried in the waistcoat pocket.

In using the ordinary blowpipe, a little art is at first necessary, which generally requires from one to three days' practice, according to the capability of the learner. The best way to acquire the requisite proficiency I believe to be for the student to sit down with a lighted candle, having the wick bent to one side, on a table before him; to take his blowpipe in the right hand, not gingerly between three fingers, as some writers recommend, but firmly grasped in the fist; to apply the mouth-piece to his mouth with his cheeks puffed out, and elbow on table; to thus try to produce from the candle-flame, a "pyrocone," which is simply a cone of *blue* flame, breathing through his nose all the time. He will find this quite easy, but after a time, the air, or rather breath, in his cheeks will begin to fail, when all he has to do is to pronounce the word *cow* without opening his mouth. The effort to do this will replenish his cheeks with air.

HINTS TO LOCAL METEOROLOGICAL OBSERVERS.

(Reprinted, with the Author's permission, from *Science Gossip*.)

I. Hailstorms.

AS hailstorms are essentially local phenomena, it is to local observers that we must look for any addition to our knowledge of them.

A reference to any Encyclopaedia article will show the sadly confused state of our information on the subject. Flat contradictions will be found on every page. It will be seen that while some authorities assert that hailstorms occur most frequently in summer, others maintain that winter is pre-eminently the hail season. There must be an error somewhere. As a matter of fact, false statements have been so persistently reiterated, that by mere repetition they have come to be regarded as truths.

Let me allude to one fertile source of error. I have referred to it before.* It is the confusion of hail proper, or French *grêle*, and winter hail, or *grésil*—two entirely different phenomena. *Grésil* is the small round powdery snow which often falls towards the end of a snowstorm and in the early part of a very frosty night. I suspect that Dalton and other observers did not distinguish between the two kinds of hail, and spoiled their results in consequence.

The following points are of primary importance, and should not be overlooked in taking down an account of a hailstorm:—

1. *Period.*—The date and hour at which a hailstorm occurs, though apparently small matters, are of the utmost importance. I am inclined to think that while each country has distinct maximum and minimum periods of hail-fall, the distribution of the quantity over the year varies materially. For example, in this country, the maximum occurs in summer, and is very strongly marked; while in Germany, the maximum is in spring, and is not so decided. If the periods of maxima and minima all over the world could be determined, a comparison of them would doubtless throw much light upon the nature and cause of hailstones.

2. *Area.*—When a hailstorm is not purely local, it usually assumes the form of the tornado, and sweeps over the country in one, or sometimes two, narrow bands. In the former case, it is sufficient to ascertain the area covered by the storm, but in the latter, it is necessary to determine (*a*) the length, (*b*) breadth, (*c*) direction of motion, and (*d*) rate of progression of the storm-band. Such particulars can only be obtained by the co-operation of numerous local observers. Our organised observatories are quite incompetent for such work, being too sparsely distributed over the country.

3. *Physical features of the locality.*—The proximity of mountains seem to induce the fall of hail, while that of forests has the opposite effect. Progressive storms often diverge from their course on encountering a river or valley, and follow that of the depression. It is therefore useful to note if any of those physical features be in the neighbourhood of the storm, and if so, their effect upon it. It is also of importance, especially in the tropics, to determine the elevation of the country above the sea level. It is frequently asserted, on what authority I know not, that hail never falls in the

* *Nature*, vol. xxiv. pp. 187-90.

tropical regions at a less elevation than 2,000 feet. It is worth while testing the statement.

4. *Temperature.* The fluctuations of temperature during a hailstorm are often very remarkable, and should be carefully observed. A reading of the thermometer may be taken shortly before the storm begins and another directly on its cessation.

5. *Barometrical readings* should be taken, if possible.

6. *Wind.* Its (*a*) direction near the earth's surface, (*b*) direction in the higher regions as indicated by the cloud motion, and (*c*) force, are important points. Some observers have noticed that the clouds move in various directions while a hailstorm is in progress. Kamtz actually went the length of attributing the formation of hail to the conflict of opposing winds; and Beccaria says, "While clouds are agitated with the most rapid motion, rain generally falls in the greatest plenty; and if the agitation be very great, it generally hails." Howard, in 1809, noticed the wind change from E. to S., then to W., back again to E., and finally to W., during a hailstorm.

7. *Rain.*—Rain sometimes falls before hail, sometimes after it. The area of a hailstorm is generally fringed with rain, and in the case of a moving storm, rain falls along both edges of the track. Rain before hail is somewhat rare, and its occurrence should be carefully noted.

8. *Clouds.*—Hail clouds are invariably cumulus. Volta and other theorists have assumed that there are always two strata of clouds at different elevations. Arago pointed out that they are generally of an ashen hue. Their aspect, apparent thickness, and height above the earth may be noted.

9. *Electrical phenomena.*—It is frequently stated that thunder and lightning always accompany the fall of hail, but such is by no means the case. When there is lightning, it is important to observe the relation between the discharges and the fall of the hail—whether the lightning precedes the hail, or *vice versâ.* If possible, the electricity of the air before and after the storm should be ascertained by means of an electrometer.

10. *Duration.*—The duration of the storm at one spot may be noted.

11. *Preliminary sound.*—Kahn, Tassier, Peltier, and others affirm that they have heard a peculiar rumbling or pattering sound in the air immediately before the descent of hail. This cannot be a common phenomenon, or it would have been more generally remarked.

12. *Structure and size of the hailstones.*—Observations of the structure of hailstones are seldom of any use, as the necessary precautions are generally neglected in conducting the examination. The ice of which they are composed undergoes a rapid change when exposed to a high temperature, so they ought to be collected immediately on descent. Further, as collision with the ground is liable to cause alteration of shape, if not entire fracture, it is well to catch the hailstones destined for examination upon a piece of flannel, which not only preserves the stones in their entirety, but, being a bad conductor of heat, keeps them from dissolving rapidly. The scrutiny may then be conducted in a cool room. Size should be determined by accurate measurements. Such vague terms as the "size of peas," or the "size of eggs," or "like large nuts," are useless for scientific purposes.

The above points may be supplemented by any others that the experience of observers may suggest or that peculiarities in individual storms may require.

Athenæum, Glasgow.

ANECDOTES OF DOGS.

I SEND you some anecdotes of dogs, which, I think, show most strongly that they not only have powers of reason of the same nature as ourselves, but that they share with us distinctly some of our virtues. To me, dogs have always appeared to be by far the nearest animals to man in their intelligence, and in their evident sympathy with their masters, and they show this latter by a power of expression in their faces which no other animals have a trace of. Nothing can be more distinct than the smile of pleasure which lights up a dog's face at the approach of a kind master, and that such an animal should ever become the victim of the tortures of the physiologist is to me inexpressibly horrible.

The following facts, though not actually occurring under my own eyes, were related to me by friends who witnessed them, and I am as certain of the truth of the stories as if I had been myself present:—

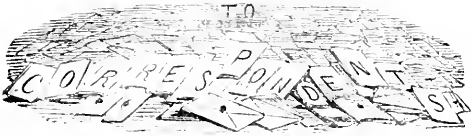
A lady residing in a house not a hundred yards from mine has a pug dog, also a cat of which the dog was always very jealous, chasing it about whenever it saw it. Not many weeks since the pug astonished its mistress by coming up to her, sitting up and begging, then barking and running a little distance from her, till it appeared evident that it wished to persuade her to come with it. It continued to beg and to run on in the same manner till it led her out into the garden, to the foot of an apple-tree, against which the dog raised itself on its hind legs and barked vehemently. On looking up the lady saw the cat with a trap on its foot, evidently in great pain. She got it down and relieved it of the trap, the dog showing the greatest joy, and on the cat being placed on the ground, the dog, who before had never done anything but hunt and worry it, licked it all over and over till it was quite wet, and ever since they have been the best of friends.

A dog had a kennel in the yard of a house which was overlooked from one of the windows. A lady, my informant, saw this dog hiding some of its dinner in a corner behind the kennel, and this performance, she noticed, was repeated for a day or two. On the third day the dog was missing some little time from the yard, but before long it was seen to return, followed by a small, half-starved canine friend, which it took up to the store of hidden food, and stood by, wagging its tail with evident pleasure, while the strange dog consumed it. Now, if these two stories do not show the virtue of charity in a dog, I don't know what can be required to prove it.

The following is of a different nature. In Ceylon the large Lambur deer is hunted by dogs, the huntsmen going on foot. The deer generally comes to bay in a stream among the hills, and the huntsmen, guided by the sound of the dogs, make their way to the spot as quickly as they can with knife or spear to end the combat. Sometimes, however, as the distance, or the form of the hills, prevent the sound of the dogs at bay from being heard, the huntsmen do not arrive, and the deer, if strong, may escape, or is, perhaps, killed by the dogs. On one of these occasions, the owner of a pack of hounds, who related this to me, lost all sound of the hounds, and came back home to breakfast. After this he sallied forth again, thinking he would go to a distant part of the jungle, where he imagined the pack might have taken the deer. Before he had gone a mile or two he met two of his pack by themselves, coming straight for home. They no sooner saw their master than they expressed the greatest delight, and at once turned round, went before him, and led him straight through several miles of jungle, to where he found all the rest of the pack, with a large buck Lambur at bay. They were quietly waiting round it, preventing its escape, and, on seeing their master, the jungle at once resounded with their voices, as they went in with renewed energy at their quarry, till the knife of their master put an end to the battle. Now, it was perfectly clear to my friend that these dogs had agreed among themselves that two of their number should go home and fetch their master, while the rest kept the deer at bay.—B. M., F.R.C.S.

Knowledge.—Although we offer our readers more in the way of original matter (apart from correspondence, which is not to be estimated by mere bulk) than any other journal of similar price and character, we wish to do better still. We hope so to extend the circulation of Knowledge that we may be justified in enlarging each number, in giving more illustrations, and in extending the number of our original contributors. *To attain this end we need the co-operation of our readers.* Those among them who approve our scope and plan can do more to improve Knowledge than either editor or publishers. If every reader were to obtain but one new subscriber, not only would our circulation be doubled, but our power to improve the matter placed before our readers would be increased in like proportion. If our readers will remember this, they will follow the best course for making Knowledge what we wish and hope that it may before long become.

Wordy Science.—It has always been characteristic of a science, real or so-called, which for any reason was not advancing, that its professors have endeavoured to give it an unreal importance by heaping over its facts a mass of incomprehensible verbiage; and the traditions of such a time have survived, in many instances, long after the branch of knowledge concerned has begun to share, or has shared even in the most marked manner, in the general advance of the human mind. Botany, chemistry, the smaller ramifications of natural history, are all still concealed beneath technicalities which are neither English, nor Greek, nor Latin, nor hybrid of any declared description, which convey no meaning, are not generally intelligible to the learned, and are not intelligible, indeed, to any, save those who have wasted precious time in learning them by heart from text books. Such technicalities are unmixed evils, because they do nothing in reality to facilitate the acquirement of knowledge, and they hinder many from even attempting to acquire it.—*Times.*



Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

DEMANDS ON OUR SPACE.—CURIOUS PUZZLES.—GRAMMAR.—CENTRIFUGAL FORCE, &c.—A PARABLE FOR PARADOXERS.—THE EARTH'S PROCESSIONAL REELING.—ILLUSIONS.—BRAIN AND SKULL.—MARRIAGE AND THE DEATH-RATE.

[121]—A correspondent remarks, and with some justice, on the space awarded to correspondence, queries, and replies to queries in No. 6. It is natural that in the first number of a magazine admitting correspondence at all, the space devoted to such matter should be much less than in later numbers. As correspondence (including notes and queries) was mentioned in the prospectus, I cannot consider that the increase of this section in Nos. 2, 3, &c., was inconsistent with our promises. But, while noting this, and that, indeed, number 6 was enlarged to oblige correspondents, I must admit that it would not do to allow correspondence often to occupy so much space. As letters come in more and more freely each week, and as we have not room for more than a third of them, it is clear that two-thirds must be omitted. Those that are most original and interesting will naturally have the best chance of being retained, and among these the concise will be preferred.

Some letters will be given in abstract, with such reply as may seem necessary, in a weekly communication from "the Editor."

"H. A. S." notes that there is an exhaustive solution of the problem of the Fifteen School-girls in the "Ladies' and Gentlemen's Diary" for 1862. Magic squares are treated fully in Hutton's "Mathematical Recreations." Nevertheless, I think the three letters on these two subjects published in this or following numbers will interest many who would not care to look up the above-named writer. They may suffice, however, for matters which are rather curious than scientific.

"L. F." remarks (*see* "A. T. C.'s" letter, 105, p. 117) that "would the editor" is more deferential than "will the editor," "might I" less manly than "may I," "I cannot but think," "I can but think," and "I can only think" equivalent expressions. He notes justly that such a sentence as "the editor requests that letters may be addressed," is incorrect. "May" should be omitted. The same with "he requests that all communications (should) be addressed," &c., "should" should be left out; or, better, "he requests that" should be left out. We have under our correspondence heading "he requests that all communications should be as short as possible." Elsewhere in our remarks, be it noticed, we adopt the correct form. Perhaps we meant to say editorially, "we request that the principle be adopted 'all communications should be as short as possible.'" We take "L. F.'s" hint, however, and put this principle down definitely as one which we are obliged to insist upon.

Mr. Newton Crosland is, I fear, offended because I have said that he misapprehends the principles on which the accepted theories which he opposes are based. I am very sorry. I have no wish to offend him. I have simply stated the facts as I see them. He describes the centrifugal force in terms entirely inconsistent with the real nature of this so-called force. (He is quite right in saying that Newton spoke of the centrifugal force; so also Newton spoke of the force of inertia. Newton, however, carefully distinguished these from "impressed forces." Modern science, to avoid precisely such misconceptions as Mr. Crosland's, ceases to use the term force except in the case of what Newton called an impressed force. Joyce, Milman, and Ferguson are not authorities in such a matter, not one of them having had any mastery of the higher mathematics.) Again: Mr. Crosland, in dealing with the Darwinian theory, uses words only applicable to the Lamarckian hypothesis. A student of science knows the Newtonian theory and the Darwinian theory, attacked by him, to be unlike what he supposes; and, therefore, is justified in saying to him that very likely these theories, so misunderstood, appear egregiously absurd. And there the matter should end. I am not interested, and I am sure readers of KNOWLEDGE would not be, in defending the straw-giants which Mr. Crosland attacks after having constructed them. But there is nothing which need offend him in the remark that he misunderstands the teachings of Newton or of Darwin. Many misunderstand both. Of the former, at any rate, which belongs to my own special department of study, I may say that few understand them. Many who understand the Darwinian theory, reject it, or regard it as so far not perfectly proven. But no one who understands the Newtonian theory questions its truth. Any one who, understanding it, yet objects to the former theory, will find his reasoning admitted here. Any one who does not understand any particular point about either theory can ask here for explanation. But all our space would be wasted if we allowed correspondents—first, to set up burlesques of scientific theories; secondly, to overthrow these shams; and, thirdly, in the triumph of an imagined victory, to invent vague theories of their own, in establishing which they assign to imaginary forces inconceivable effects.

A chemist in New Zealand once asked me, as a believer in the Newtonian theory, how I explained a balloon's ascending. Before I replied, he went on to say that, to his mind, the ascent of a balloon proved that the earth exerts a repulsive as well as an attractive influence. There was a pair of scales on the counter, in one of which I put a half-ounce weight, and as the other scale went up, I asked if its motion was due to terrestrial repulsion. "The cases are different," he said. "The cases are similar," I answered; "the light scale ascends because the heavier one has a greater tendency to descend, and cannot descend unless the light one rises; the lighter gas in the balloon ascends (taking its silk coat along with it), because the heavier air around it has a greater tendency to descend, and cannot descend unless the lighter gas rises. The heavier scale pulls up the lighter, which would else tend downwards; the heavier air thrusts up the lighter gas, which would otherwise descend as certainly as a globe of lead would." Whether the chemist understood or accepted my explanation, I do not know; but this I know, that if he had based on his misapprehension of the effects due to gravity a theory of polarity and magnetic repulsion, I should not have felt bound to discuss his views with him. In a similar way, acting according to my lights, and with the object of occupying the columns of KNOWLEDGE so as best to serve the wants of readers, I must decline to assign more than a very modest allowance of space here to paradoxical theories.

"Sirius" asks for an explanation of the "Precession of the Equinoxes." As this is a subject of general interest, I do not put this letter among the other queries, but reserve it for an answer in an early number. I note here that the change is *not* such as to cause the northern pole to be inclined from the sun in June 13,000 years or so hence. Nor is the motion of the poles such that 6,500 years hence, or at any time, the axis of the earth will be at right angles to the ecliptic. The inclination of the axis varies only within a very narrow range, and the seasons remain almost unchanged in each hemisphere, throughout the long precessional period of nearly 25,900 years.

J. E. Okill remarks that the "nest of illusions," p. 71, is illusive to him, as respects the apparent superposition of the space between the two heavy circles, only when he expects to find an illusive effect. If he looks along the lines as a carpenter looks along a piece of wood, they seem straight, and the circles seem oval. (This, of course.) He describes as an illusion what is in reality an effect of diffraction. Closing one eye, look at the edge of a window with the other, covering this eye gradually with the hand till only a fine slit is seen, when the colours of the spectrum are displayed. He remarks on letter 114, p. 121 (Brain and Brain Case), that the two doctors are in agreement. Naturally, the skull takes first a form determined by the growth of the brain, while later the brain may shrink away from its bony enclosure. Also, "may it not be that the son of a man noted for skill in some art or science may inherit the shape of his skull," but, for want of study, the brain

[illegible] spandrel of the brain-case. He replies to Query 27, that the greater number of deaths among unmarried [illegible] be due to evil living, which the married, having [illegible] avoid; also, in part, to neglected ailments. [illegible] it is, however, whether the married [illegible] in itself a prophylactic. We want better statistics than we [illegible]. The greater death-rate among widowers seems to support the views of Bertillon and Stark; but, manifestly, a cause may act in their case which affects the statistics apart from any influence married state may have. RICHARD A. PROCTOR.

JUPITER—DENNING'S COMET.

[122]—I trust that some of your readers will obtain observations of a remarkably bright spot situated slightly S. of the equator of Jupiter and on the N. edge of the great S. belt. I have observed 61 transits of this spot since October, 1880. The following are the approximate times when it comes to the central meridian of Jupiter:—

Dec.	H.	M.
17	10	40
18	6	20
19	11	51
20	7	31
21	13	1
22	8	41
23	4	22
24	9	52
25	5	32
26	11	2
27	6	43
28	12	13

Its period of rotation is 9h. 50m. 6s.6., or $5\frac{1}{2}$ minutes less than that of the red spot, which is 9h. 55m. 35s. It is in the same longitude as the middle of the red spot on December 25, and these conjunctions occur at intervals of $41\frac{1}{2}$ days.

The last time I saw the bright spot it was very plain. This was on the night of December 7, when it was noted exactly on the central meridian, at 4h. 41m. and 14h. 33m. These double transits are not unfrequently visible now that Jupiter is above the horizon during the greater part of the night.

The new comet (of 1881) was observed here on November 25, at 10h., and again at midnight. It was pretty bright and large, with ill-defined and apparently flashing edges. There were many faint stars in the background, so that I could not be certain as to the character of the nucleus.—Yours, &c., W. F. DENNING.

Ashley-down, Bristol, *Dec.* 8, 1881.

THE TRUE SPIRIT OF SCIENCE.—WATER SPHERULES.

[123]—Let me venture to express a hope that the concluding portion of the lines from which you have taken your motto may, as I doubt not they will, find expression in your magazine,—

"Let Knowledge grow from more to more,
And more of *reverence* in us dwell."

The spirit of reverence and of humility, the spirit of Newton, Herschel, and Faraday, seems gradually vanishing in many high scientific circles, and a spirit of self-sufficiency and of arrogance growing in its place. It is sad to see how frequently the student of nature of to-day, in the consciousness of his acquisitions, referred to yesterday, forgets the absurd littleness of his knowledge referred to the sum of all things.

But I must not stay to pursue this thought, as my object in writing to you was to refer to a question asked in the copy of KNOWLEDGE sent to me, No. 3, p. 60, where a correspondent asks what supports or causes the spherules of water which are often seen rolling on the surface of water. The explanation hypothetically given in your columns is, as you suspect, wholly untenable. The probable cause is a *difference of temperature* between the drop and the surface on which it rests.

Apropos of this, the accompanying short paper may, perhaps, interest some of your readers. It was read at a meeting of the Royal Dublin Society on Dec. 15, 1877, but, so far as I know, has not been published out of the proceedings of that Society.—Yours, &c., W. F. BARRETT.

[The paper shall appear shortly.—ED.]

THE WEATHER FORECASTS.

[124]—Taking great interest in the daily weather forecasts as efforts made by the director of the Meteorological Office and his staff to predict the weather in advance, I have for about two years past been in the habit of noting briefly the characteristics of each day, and comparing them at night with the predictions as published in the *Daily News* [illegible] discrepancies—not all the newspapers printing the same tables. The variations in phraseology are, however, generally unimportant, consisting in the elision of the word "very," or making trifling variations in the direction of the wind. For the period of the last six months my notes have been fuller than formerly, so that I will confine my observations to these more particularly.

As the main conclusion, I am bound to say that they are about as often wrong as right in the metropolitan area, to which my attention has been almost exclusively confined. There is great difficulty in drawing a sharp line between "successes" and "failures," for often the temperature, force, and direction of wind have proved right; but the forecast as to rain or fair weather has frequently been altogether unsuccessful, so that it is not easy to state the percentage of successes.

I have noted particularly eight occasions of excessive rain or thunder-storms happening within the months of last summer, not one of which had been predicted in our daily forecasts, although, strange to say, clear warning had sometimes been sent from America, as was noticed by a writer in the *Times* of July 9 last, signing himself "Observer." The dates I now refer to are—May 28, when we had a thunderstorm and torrents of rain in the afternoon, certainly not predicted in the forecast, "cloudy, but *fair* and warm;" June 5, when we had more than half an inch of rain—not predicted; June 25, eight hours' rain, from 10 a.m. till 6 o'clock in London—not predicted, but coming after a week of gloriously bright weather. Then came the heavy thunderstorm of July 5–6, to which I have already referred, bringing down the temperature from about 92° F. to 70° F. in one day; a disturbance not foretold by our Meteorological Office, although a warning from the *New York Herald* had already appeared in all the newspapers. July 28, when the prediction was "*fine*, hot cool in the morning." Right as regards temperature, but wrong as failing to give notice of the torrents of rain which fell before midnight. August 8, the weather predicted was "cloudy or dull at first, then clearing again, and *fine and warm*," instead of which the weather in London was fine until 4 p.m., followed by six hours' rain, which brought down the temperature so low, that at noon next day the thermometer only registered 55° F. August 12, the prediction "cool, changeable, showery," did not prepare the sportsman for continuous rain from morning till night (sixteen hours, at least, without ceasing) and not well described by "changeable" or "showery." The direction of the wind was wrongly predicted, proving East and North-east, instead of "Westerly to North-westerly," and almost calm in London, instead of "strong and squally." Passing over August 16, when we had a fine morning, succeeded by a wet evening (the reverse of the prediction), and August 18, a fine calm day, not "squally" or "showery," as predicted, we come to August 25, raining all day all over England (see the column of reports in the *Daily News* of the following day), and certainly not fulfilling the predictions "fine generally," or "greatly improved weather" promised for the English districts Nos. 2 to 5 inclusive, but, on the contrary, everywhere spoiling the harvest prospects, and remaining bad weather for the rest of the month.

Later instances of "bad shots" are in my note-book, but for the purpose of discussion the above may suffice, and with every desire to keep within the bounds of fair criticism, I wish only to point attention to the facts, in the hope that the causes of failure may be discovered and eventually remedied. Mr. R. H. Scott, in his article on "Forecasting the Weather," published in *Good Words* of July and August, admits his "inability to form any estimate of the amount of rain which is likely to fall on any day," although continually professing to take account of rain in his daily forecasts. The whole subject gained importance from the question asked last August, in the House of Commons, by Mr. Earp, M.P., as to the facilities for the promulgation of those weather-forecasts which the Postmaster-General might be inclined to give? and the seaports and agricultural towns have now the chance of getting information on very easy terms. It remains to be seen whether the local authorities rightly estimate the efforts of the Meteorological Office to provide this much-needed information. The end can only be attained after many failures, for, as Professor Huxley says, "all true science begins with empiricism." In what directions, then, are we to look for improvement in the character of the weather-forecasts? And what new means can be devised to give them greater accuracy? These are questions which appear to be well worth discussion in the pages of KNOWLEDGE.—I am, yours, &c.,

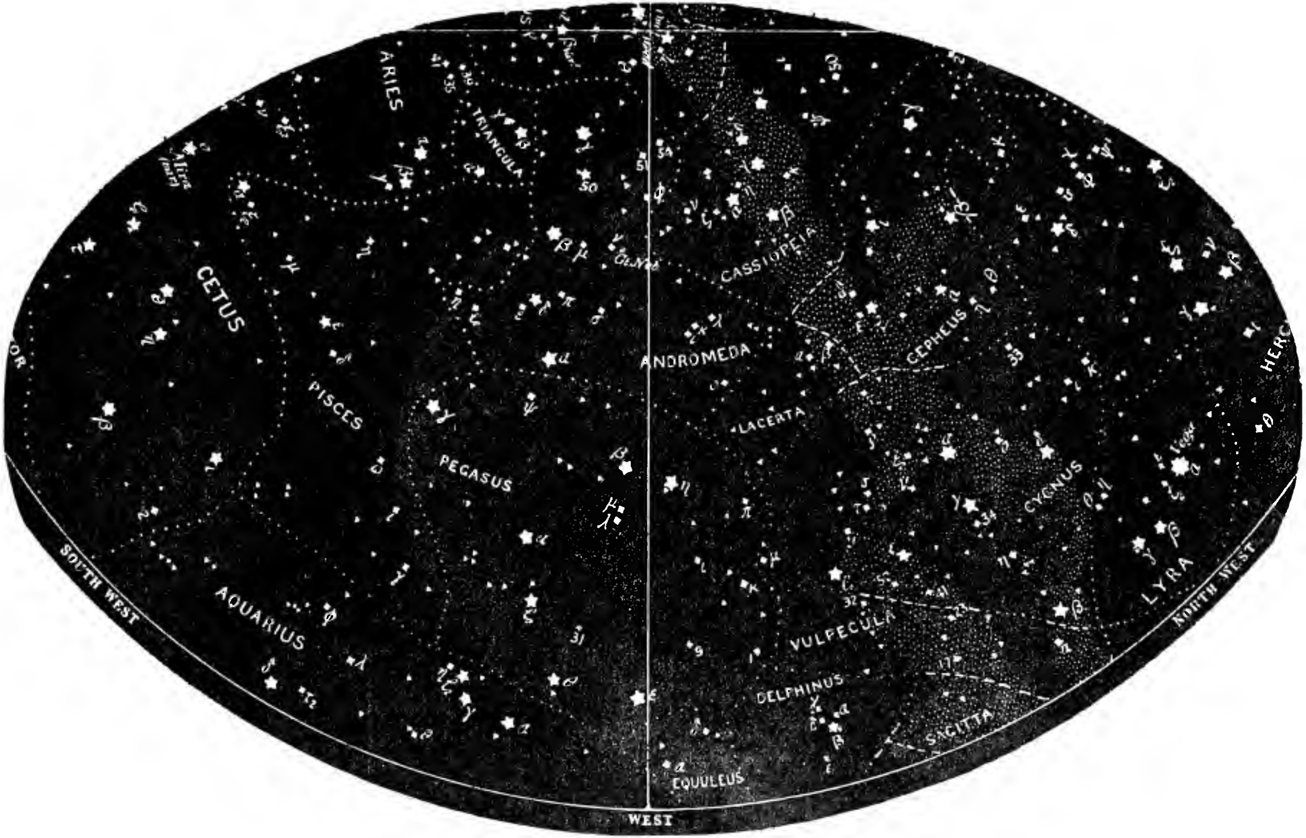
JOHN SPILLER.

WHY RATS GNAW THROUGH A WATER-PIPE.

[125].—The moisture of the atmosphere is condensed on the outside of the pipe during a change of temperature (the cold water in the pipe and the moist warm atmosphere), which induces

[*Continued on page* 143.

THE WESTERN SKIES IN DECEMBER.



This Map shows the position of the stars in the Western Skies —

On November 30, at 10½ o'clock.	On December 8, at 10 o'clock.	On December 16, at 9½ o'clock.	On December 23, at 9 o'clock.	On December 30, at 8½ o'clock.
On December 4, at 10¼ o'clock.	On December 12, at 9¾ o'clock.	On December 19, at 9¼ o'clock.	On December 27, at 8¾ o'clock.	On January 3, at 8¼ o'clock.

The stars in the western skies are passing downwards towards the horizon, moving aslant from left to right; but those shown on the right, or northern side of the map, will not set, but pass over towards the north, there to pass below the pole.

*** Stars of the first magnitude are shown with eight points, those of the second with six, of the third with five, of the fourth with four, of the fifth with three.

Continued from page 110.]
them to drink, and as the supply is only small, they naturally gnaw through the pipe. This, in my opinion, is the more correct view than to imagine they reason from hearing the fluid pass through the tube. W. MARSHALL, F.B.S.E.

ELEMENTARY ELECTRICITY.—SCIENTIFIC MEETINGS.—MYSTERY OF "PSYCHO."

[126]—Having read letter (No. 73), signed "Daniel Jones," I should like to point out that it seems to me very undesirable that you should use your valuable columns for any such papers, which can be read in any good text-book on electricity.

May I suggest that you should find room in your columns for a notice of times and days of the meetings of scientific societies during the ensuing week, with the titles of the papers to be read.

I should also like to ask through your columns whether a solution of the mechanism employed in the automaton "Psycho" has ever been given?—Yours, &c. H. W. B.

[We quite agree with our correspondent on the first point. As to the second, we believe that only a small proportion of our readers care to know the days on which the various scientific societies meet; and that all who do care, must be in the way of learning those dates elsewhere. It seems, therefore, better for the greater number—by far the greater number—to save for other purposes the space which such notices as "H. W. B." suggests would occupy. —ED.]

NAMES OF STARS.

[127]—I am making a collection of the ancient names of stars. In this I have been much assisted by the list given in your larger Atlas. I should be very much obliged to you if you could point out any books in which I could find more of these names, as well as any traditions about them. A friend of mine, who is an Arabic scholar, has promised to translate those which are not too much corrupted. It seems a pity that these names should stand a chance of being forgotten, as much of the popular interest in stellar astronomy dies out when stars are only designated by a letter in a shapeless constellation. Apologising for thus troubling you, Yours, &c., J. H. THOMSON.

R. A. Mess, Shoeburyness, *Nov.* 28, 1881.

[There is much that will interest Mr. Thomson in "Smyth's Bedford Cycle," the old edition. From the new one we understand the matter in question has been removed.—ED.]

DONATI'S COMETS.

[128]—In Figures I. and II. on page 49 we have two pictures of Donati's comet, as also, judging from the stars given in the diagrams, the distance and direction travelled by the same. Now, if the stars depicted on the plate have relative places in the firmament, the comet must have been travelling in a side direction, and consequently the tail must not have been pointing from the sun.

A YOUNG ASTRONOMER.

[The picture is right. There is no such difficulty as "Y. A." supposes. The comet's path is not on a line towards the sun.—ED.]

PASTEUR'S PLATES OF GERMS, &c.

[129]—Would Dr. A. Wilson, if possible, kindly give us Pasteur's plates in connection with the subject. He may intend to do so; if so, my suggestion is premature. I am sure they would be interesting. A friend, a few years ago, lent me Pasteur's plates on the germs generated in brewing, and many a pleasant hour have I spent in trying to obtain the different germs by experiments on beer, yeast, &c.

I have read a good many of the scientific papers of the day, but have never been so interested in any of them as I have in KNOWLEDGE, which, I feel sure, has only to be known to be a complete success and boon to the public.—Believe me yours, &c.

F. C. S.

COLOURS IN ANIMALS AND PLANTS.—DARWIN ON WORMS.—REASONING ANIMALS.

[130]—The tendency of men of science to run investigation to extreme tenuity is become a danger. Knowledge whittled to a point is knowledge reduced to nothing. Casual inquirers recoil from infinitesimals and the overwrought.

Dr. Wilson, in KNOWLEGE, No. 2, labours to show that the colours of wild birds and beasts are designed by Nature to obscure the animals from their enemies, and, when predatory, from the eyes of their prey. It might be affirmed that the colours of flowers are designed to put the flowers conspicuously before the eyes of men and insects. Nature is not given to special amenities and providences. The dark colours of the sole and the flounder are no protection. When in repose, they are concealed by a covering of sand.

Mr. Darwin's theory of worm action on the soil is, to my mind, an elaboration of exceptional minutiæ to huge paradox.

The paper on Intelligence in Animals is in another category. Anyone capable of accurate observation, and daily among them, knows that animals do reason. I could name many instances, but one shall suffice. A duck came opposite our day-room window, which looks into the orchard. Mrs. D. noticed her uneasiness and persistent waiting, and concluded that it indicated hunger. She took madam duck some corn. The food was simply looked at, but the look was followed by movements that plainly meant "come with me." The request was accorded to, on supposition that the duck was shut out of her cote. But, no; the cote was open, and the duck urged "come on, come on." She led to a hole in the hedge that fenced the stackyard from the orchard; and there, on the other side, was a lame duck, that could not make passage of the hole, in a fever of despair. Mrs. D. went round and brought the poor bird into the yard. Meanwhile, the kindly-hearted duck made her way to where she knew her mistress would return, and the rest of the flock gathered with her. The meeting of the two ducks was a little drama. Between them there was a wonderful talk, soon joined in with by the whole flock; and they marched off with what was taken to be loud cheers.

Reason! Surely animals, furred and feathered, reason; some better than others, but all reason. The fox is a rapid and acute reasoner.

I have but limited intimacy with pigs. So far, however, as I am acquainted with them, nothing is so manifest to me as that they reason; and they are humorous and inclined to fun, when at liberty. A well-known sportsman had a pig for pointer. Dogs all reason, the high-bred sheep-dog in particular; and more, understand sentences of speech addressed to them directly, or in their hearing, and in the latter case, they will, if so minded, circumvent you on the knowledge they have gained.

Ducks and dogs have the human propensity to sulk with you, or with one another.

Memory, no observer will deny them. But is not an effort of memory reasoning; calling together ideas previously known, and linking them, absolutely or tentatively, in sequence, till the desired lost idea is regained?

Professor Jevons' logical abacus, in work, really represents the mode of an effort of memory, as well as a logical concatenation.—Yours faithfully, B. DONBAVAND.

Picton, Chester.

ATMOSPHERIC ABSORPTION AND TERRESTRIAL RADIATION OF HEAT.

[131]—In his "Heat a mode of motion," (1880) page 317, Prof. Tyndall says:—"I never on any occasion suffered so much from solar heat as in descending from the 'corridor' to the grand plateau of Mont Blanc on Aug. 13, 1857. Though Mr. Hirst and myself were at the time hip-deep in snow, the sun blazed against us with unendurable power." Mr. W. Mattieu William's letter 68, page 96, and B.M., F.R.C.S., No. 36, page 77, bear similar testimony. I think Prof. Tyndall explains the whole matter (page 317). "The beams of the sun penetrate glass without sensibly heating it; the reason is, that having passed through our atmosphere, the heat has been in a great measure deprived of those constituents liable to be absorbed by glass." Prof. Tyndall refers to the invisible (the hottest) rays, see page 316. It seems to me too much stress is placed on the atmospheric absorption of terrestrial radiation. From the foregoing references a large proportion of the sun's invisible rays are intercepted before they reach the earth; and then all those which do impinge on the earth raise its temperature, and by "convection," more heat is transferred to higher altitudes of the air, so that only a comparatively small proportion of the heat is radiated from the earth compared with what enters the atmosphere as solar radiation. J. A. L. R.

[A large portion of the invisible solar rays remain (compare figs. 112 and 113 in Tyndall's book) after passing through the air, and to these, constituting at least twice the visible rays, the reasoning of Mr. Dyer (in letter 20, p. 56) applies.—ED.]

"KNOWLEDGE" AND THE SCIENTIFIC SOCIETIES.

[132]—I see that some of your readers are asking for Reports of the Proceedings of the Learned Societies, and that you have replied very practically by showing them a sample of what the most meagre outline would amount to.

In confirmation of your decision, I may state my own practical experience. When my genial friend, the late George Dawson, started the *Birmingham Morning News*, I undertook the functions of

"Our London Scientific and Educational Correspondent," whose work was to supply a weekly column or two, by means of which the readers of the paper should be kept acquainted with the general progress of science and scientific education. My original programme included an account of the proceedings of the Scientific Societies, but I met with a rebuff at the outset. The secretary of the Royal Society informed me that I should not be admitted to any of their meetings if I reported any portion of the discussions or conversations following the reading of their papers, and that they would rather not have any newspaper anticipations of the official publication of the paper themselves. The titles of the papers were at my service. I began by heading each of my communications with a list of the papers read at the principal London Societies, and supplementing this by a short notice of some of those likely to be popularly interesting; but alas! how few were they—not 5 per cent. of the whole. This was in January, 1871. By the middle of May, I gave up even the titles of the papers, finding them about as readable as the Post-office Directory, and practically worthless as a record of scientific progress, seeing that London is not all the world. If I had added the titles of papers read at foreign societies, my weekly column would have been filled with these alone.

To give your readers an idea of what would become of Knowledge if you gave abstracts of current scientific papers, I have counted the number included in one month's *Journal of the Chemical Society*, wherein abstracts of papers read outside of the Society are given:—

General and Physical Chemistry	26	papers
Inorganic Chemistry	25	,,
Mineralogical Chemistry	74	,,
Organic Chemistry	113	,,
Physiological Chemistry	7	,,
Chemistry of Vegetable Physiology and Agriculture	10	,,
Analytical Chemistry	23	,,
Technical Chemistry	23	,,
Making a sum total of	371	papers

in one month (June last) on one branch of science only. A staff of thirty experts, Fellows of the Society, are engaged in making these abstracts. The annual volume of abstracts (all very short) averages above 1,000 pages, besides the transactions, which usually run to about 800 pages.

To the professional chemist these are invaluable; to the general public they are mere waste paper.

W. Mattieu Williams.

THE MISSING LINK.

[133]—This question seems to generate new ideas (and not always reasonable ones) as time passes. One correspondent, "Another Ignoramus," says: "Common ignorance (?) will continue to ask the unfortunate question." Why "unfortunate" is more than I can imagine. In my previous answer I tried to show that the phrase "missing link" was a misnomer. It implies that there was but *one* link connecting man in the past with lower life, and it thus implies an amount of knowledge which honest science declares it does not yet possess. Persons whose demands are all for the "missing link," generally ignore the overwhelming evidence of evolution as a fact of nature that Mr. Darwin, Mr. Wallace, and others present. Nobody calls anybody else an "ignoramus" except those bigoted minds who object either to receive evidence, or who are unable to appreciate and weigh evidence of evolution or any other topic. I certainly called no one an "ignoramus." On the contrary, I did my best to assist a comprehension of the question concerning man's relationship to his lower neighbours. Any one may object to the views of another, but objections should be stated in full. Querulous complaint assists no cause, least of all that of scientific truth.

"Mitchell" likewise writes on the "Missing Link" subject. Has "Mitchell" any knowledge whatever of geology, or of the history of fossils? I ask this, because if (as I suspect) he expects to find every animal and plant species that lived in the past preserved as fossils, he is simply quarrelling with Nature's flaws, and neither with evolution nor with me. I refer him to the "History of the Horse," as disclosed by Professor Marsh in America, for an excellent illustration of the transformation (or evolution) of one order, genus, and species into another. He will find the account in Huxley's "American Addresses." To answer his second inquiry, he should acquire a knowledge of geology. "The imperfection of the geological record," as treated by Darwin in the "Origin of Species," will give him a capital outline of the whole case, and an acquaintance with geology as a whole will show him that the probabilities of evolution are overwhelmingly supported by the conclusions drawn from fossil history. People must know there is no "royal road" to the truths of nature, either in the pages of Knowledge or anywhere else. My advice to "Mitchell" and to "Another Ignoramus" is, to acquire a general knowledge of biology and geology in a classroom, or by a course of wide reading. Otherwise they will always be encountering difficulties, or, perchance, complaining of the lack of light in others.

Andrew Wilson.

DIFFICULTY OF OBTAINING "KNOWLEDGE."

[134]—Can you tell me why there is so much difficulty in procuring Knowledge? I never had so much trouble in procuring any periodical or paper before. So far, I have never been able to procure any of the numbers until perhaps six, seven, and eight days after date of publication, although it is regularly ordered (every day) by my bookseller here, who has a London parcel daily. Every time I call at the bookseller's I meet with the same disappointment—"not yet arrived; must be published irregularly, or perhaps it is dying." Now I think it fills a great want, and would be sorry if it ceased to exist, although I myself will be obliged to give up, as I cannot go on calling at the bookseller's eight, nine, and ten times for each number.

However, wishing Knowledge all success, as it deserves to succeed,—Yours, &c., H. Armstrong.

[We regret that our correspondent should have been so badly treated. Not knowing either his bookseller or the bookseller's London agents, we cannot tell where the fault lies. One or other must have neglected to do what he was asked to do. Knowledge is published exceptionally early, and with perfect regularity. So far from dying, it thrives amazingly.—Ed.]

THE EQUALITY OF THE SOLAR ILLUMINATION THROUGHOUT THE SYSTEM.

[135]—I have lately fallen in with a rather curious theory concerning the "Solar Illumination throughout the System." Its originator appears to be perfectly satisfied that he has completely disposed of the long-accepted law of inverse squares, and seems to think that he has conclusively demonstrated that the sun's light is equally intense throughout the system. According to his theory, scientific men have for ages been labouring under a great delusion. Their idea that light decreases as the square of the distance, is a mistake. In our atmosphere, he admits, there is a decrease with the distance; but this, he affirms, is due to absorption by the air, and he is prepared to prove (to his own satisfaction, at any rate) that in space, where there is no absorbing medium, light does not diminish as the square of the distance. This theory is so bold and startling, that I should like to have the opinion of the readers of Knowledge concerning it. For my part, the arguments the author of the theory (Mr. Collyns Simon) uses are not conclusive enough to warrant our rejection of long and firmly-established principles. The admission of the truth of the theory necessitates a number of absurd consequences. The stars should appear to us as bright as our sun. And if the sun's *light* follows this law, so also must his radiant *heat*, which amounts to saying that the sun's heat would remain constant, even although it were possible to approach to his surface. Hoping to hear other of your readers on the subject,—I am, &c.,

An Admirer of Knowledge.

[Our correspondent is right in rejecting the theory of Mr. Collyns Simon. It is utterly untenable. I have had many letters from him, as well as books and pamphlets. Analysing his case, I find he misunderstands the evidence which leads to the sound theory, that apart from absorption, a luminous body presents a surface of equal apparent brightness from whatever distance it may be viewed—so long as it presents a visible surface at all. If we receded from the sun till our distance was twice as great as it is, his disc would look just as bright, but only one-fourth as large, as it does. The correct inference is that we should get but one-fourth of the light we actually receive. But somehow Mr. Simon makes out that we should get quite as much as we do at present.—Ed.]

[Note.—We have been compelled to omit the Chess Column for this week, owing to the pressure of correspondence on the one hand, and the necessity of assigning a certain portion of our space to original matter on the other. Our correspondents must not be surprised at the compression in many cases, and the omission in others, of letters, many of which we should have been glad to publish in full, had space permitted. A long letter from our esteemed correspondent, "A Fellow of the Royal Astronomical Society," is deferred till next week. It contains answers to many of the questions which have been asked by correspondents.—Ed.]

Queries.

[92]—Falling Bodies.—Would a body, let fall from a height fall directly towards the centre of the earth or not? If not, would deviation be caused

(a) by the attraction of neighbouring bodies,
(b) by centrifugal force,
(c) by the velocity imparted by rotation round the earth's axis; or,
(d) by a combination of these causes?

Would not a body in the northern hemisphere fall to the S.E.; and one in the southern hemisphere to the N.E.?—$\frac{W}{g}$. [We have had greatly to shorten $\frac{W}{g}$'s question; but the above gives its purport. We answer it ourselves, to save space, and also the trouble of selecting between several answers. First, then, cause (a) is usually very slight, but in the case of a mountain or other great irregularity of contour or of internal structure of the earth's crust below the point of suspension, would produce a slight deviation from the vertical; (b) and (c) really relate to the same cause of deviation, which operates everywhere except at the pole. If h be the height of the point of suspenion above the surface, and r the earth's radius, then before falling, the body has a velocity due to rotation which bears to the velocity of the point on the earth's surface vertically below it, the ratio $(h \times r) : r$. Owing to this difference of velocities, the course of the body as it falls is not directly towards the point below but is, such as to carry the body somewhat to the east of that point (in both hemispheres). There would be no deviation north or south in either hemisphere, because a plane through the earth's centre and the point of suspension, and tangent to the circle in which this point is carried round the earth's axis, cuts the earth's surface at the point below the point of suspension in an east-and-west line. All the motions which affect the falling body, considered with reference to the earth, take place, during the fall, in this plane, and therefore cannot cause the body to leave that plane or to deviate from the east-and-west line. If the time of fall be t, the earth's rotation period P, height of the point of suspension h, and latitude of the place λ, the easterly deviation will be $2\pi h \frac{t}{P} \cos \lambda$.—Ed.]

[93]—Water of Ayr Stone.—I should be glad if any reader of Knowledge would tell me how water of Ayr stone is cut into slips ⅜ in. by 1¼ in. by 6 in.? They have the appearance of being sawn with a circular saw. If they are, is the saw blunt, or with teeth; if with teeth, coarse or fine cut? Also if sand or water is used in cutting, or both?—T. G. H.

[94]—Watch Pivots.—How is arbor held and revolved in turns to reduce a pivot? Also how to proceed in renewing a broken pivot?—T. G. H.

[95]—Watch Jewel.—What tools are used in putting in new jewels, and how to proceed?—T. G. H.

[96]—The Earth's Centre.—If pressure (or weight) at the surface of the earth depends on gravity, then at the centre of gravity of the earth this attraction will be upwards in every direction, and weight will consequently be nil. The region of greatest pressure will thus be situated somewhere between the centre and the surface. Will this have any influence on the relative densities of the earth's interior; and will not the matter at the centre be "light as air?"—J. A. L. R. [J. A. L. R. confounds pressure with attraction. Attraction vanishes at the centre, but the pressure, which results from the weight of all matter between the centre and the surface, is there at a maximum.—Ed.]

[97]—We know the inclination of the earth's axis produces the change of seasons, and that the northern winter occurs at perigee, and the southern winter at apogee. Also, that in about 12,000 years this condition of things will be reversed, and the northern hemisphere will then be most favourable to a glacial epoch, which undoubtedly the southern hemisphere now experiences. Is there any significance (bearing in mind the preceding statements) in the fact that the land predominates in the northern and the water in the southern hemisphere? And may we assume that when the climatic conditions of the two hemispheres change, the physical features likewise will change, and the maximum of water then be in the northern hemisphere? Or is it a mere coincidence?—J. A. L. R. [A French student of science, Adhèmar, started the theory that the relation referred to by "J. A. L. R." is not a mere coincidence, but there is no evidence to show that the hemisphere where there is most water is necessarily that where the earth's nearest approach to the sun occurs in the summer time. The changes in the eccentricity of the earth's orbit, and the position of the place of nearest approach, are not quite so regular as Adhèmar supposed. See my article "Astronomy," in the "Encyclopædia Britannica," pp. 795 and 796.—Ed.]

[98]—Kindly inform me when Mars will be at its next best point for telescopic observation, and the simplest method for arriving at the result.—Algol. [On Dec. 27 Mars will be most favourably situated for observation. What result do you mean?—Ed.]

[99]—Summer Days and Winter Nights.—My almanack tells me the sun reaches its most northern declination of 23° 27′ 14″ on June 21, when it rises at 3 h. 45 m. and sets at 8 h. 18 m.; that on Dec. 21 the declination south is 23° 27′ 12″, sunrise at 8 h. 6 m., sunset 3 h. 51 m. How is it, if (as I have always understood) the condition of things is exactly reversed on these days, that the length of the *longest* day and *longest* night are not equal? Why does not the winter day commence at 8 h. 18 m., the time the summer night begins? The June day has a duration of 16 h. 36 m., the December night a length of 16 h. 12 m. How is this?—F. F. [The difference is due to the refractive action of the air, which causes the sun to appear to rise sooner than he actually does, and to set later. This causes every day to be longer than it otherwise would. The actual interval between sunrise and sunset (for sun's centre) would be 16 h. 24 m. on June 21, and this would also be the interval between sunset and sunrise on Dec. 21, were it not for refraction.—Ed.]

[100]—Stings of Wasps, &c.—How do you account for the stings of hornets, bees, and wasps not affecting the toad when it eats them?—Ornithorynchus.

[101]—Industry of Ants.—Are ants in reality the models of industry which they are proverbially reputed to be?—Ornithorynchus.

[102]—The Unseen Universe.—Can you refer me to any book or lecture of Professor Tait, of Edinburgh (I think it was Tait, not Crum Brown), in which the wonderful theory was expounded, as part of the idea of conservation of energy, that our words and actions, whether good or bad, come not to an end on the spot, but, converted into some form of indestructible energy, wander away into space, there, in some passage of eternity, in their accumulation, to work for the good or ill of the producer? I am so certain that I have seen something like this from Tait, a sort of scientific demonstration of the possibilities of a future state, that an early reply in Knowledge would much oblige.—A. A. F. [Probably the "Unseen Universe," by Tait and Stewart, is the work A. A. F. requires.—Ed.]

[103]—Could you recommend me a good book on "Histology" (of animals), and one on the Undulatory Theory of Light, treated mathematically?—D'Artagnan.

Replies to Queries.

[29]—Garden Tripod for Telescope.—Let the top of the tripod be a circle, 1 in. diameter, and 1 in. thick; into this the brass leg which the telescope probably now has may be screwed, or it may pass through and be clamped at any height, preferably the last, but I could scarcely explain it without an illustration. The legs should taper from 2 in. square to 1¼ in., of whatever length you require, so that they touch the ground about 4 ft. apart. The upper ends must be bevelled, so as to fit accurately against the circular top, and had better be hinged on the inner side, that they may fold inwards when not in use. The whole must be firmly made, or it will be useless.—Paugul.

[30]—Solar Heat.—(1.) The difference in distance is as nothing compared with the distance of the sun. Any physical geography will explain that it is because of the less vertical direction of the sun's rays. (2.) Both the sun's direct action, and the reflection of his rays from bright objects, snow, sand, &c. Radiation from the earth plays no part in the matter.—Paugul.

[41]—The Planet Vulcan.—I don't believe that Lescarbault ever saw an intra-mercurial planet, but it appears that not only one, but three or four have been seen.—Paugul. [The existence of an intra-Mercurial planet is very doubtful.—Ed.]

[42]—B.Sc. and D.Sc., Lond.—Surely this "Enthusiast" has no conception of the vast store of learning for which he is asking when he speaks of the questions set in the D. Sc. Exam., Lond. If he intends to graduate in science, he should study at a university. If he will write to me, I will give him a long list of works which will cover a portion of the syllabus he mentions.—Paugul.

[50]—Wasted Energy?—The light which is absorbed is converted into heat, and raises the temperature of the body which receives it.—Alfred J. Shilton.

[52]—Microscope.—One of the kind called medical microscopes, having the body tube sliding in the stand, and in two parts. The objectives should be made to slide into position and not to screw—it saves time. This microscope permits a more rapid change of amplification, while still giving all other facilities for work as well as any other.—Paugul.

[54]—Chemical Questions.—The explanation of (1) given by C. T. B. is very good, but he is wrong in supposing that hydroferrocyanic acid has not been isolated. Mr. Theophilus Pitt accuses "Castor and Pollux" of being "inattentive" and "careless," adjectives which are very applicable to himself, as he has misread the question, or else he is entirely ignorant of the fact that ammonia and hydrosulphuric acid form ammonium sulphide; and he apparently thinks that ferrocyanide of potassium should give a precipitate with ammonia and ammonium sulphide, which is a serious mistake. With regard to question (2), C. T. B. suggests that the solution might be alkaline. How can a solution of potassium bisulphate be alkaline? The true explanation is that tartaric acid is unable to displace sulphuric acid from potassium bisulphate, although it can take up one equivalent of potassium from the neutral sulphate (K_2SO_4), forming bisulphate ($KHSO_4$), and bitartrate ($KHC_4H_4O_6$). Potassium iodide should give a precipitate if the solutions are strong. The tartaric solution ought to be very strong (1 part in 4 of water). A solution of platinum tetrachloride is a far more delicate and reliable test for potassium; it should be used in the same way as tartaric acid, and, like it, also precipitates ammonium salts.—E. F. H.

[55]—Tables of Meridional Parts.—The meridional parts inserted in most works on navigation, as in Norie, Bowditch, Inman, Raper, Chambers, &c., are very old, and were computed for compression 0, in fact, for the earth as a sphere; these differ among themselves only in so far as Chambers and Inman give the quantities to two places of decimals. Mendoza Rios used compression $\frac{1}{321}$, and these are the tables given by Riddle. Rümker used compression $\frac{1}{305}$, and are the same as given by Caillet; but, by far the best table of meridional parts is that given in the "Projection Tables" computed for the United States Coast Survey Department and Hydrographic Office, and reprinted in England in the last edition of Raper's "Nautical and Logarithmic Tables"; the compression is here taken as $\frac{1}{299{\cdot}1528}$, based on Bessel's determination.—W. H. R.

[56]—Roscoe and Schorlemmer's "Treatise on Chemistry" (Macmillan).—Alfred J. Shilton.

[58]—Sirius and Orion.—The statement was, of course, wrong. Betelgeux must have been meant.—Paugul.

[62]—Algol.—Perseus is represented as holding the head of Medusa; the stars he mentions are one.—Paugul.

[63]—Algol and Mira.—Mira was at its maximum early last July, and will be a month earlier next year. Algol every couple of days.—Paugul.

[65]—New Star in Cassiopeia.—We do not know. A star has been seen, or is said to have been seen, two or three times in or near Cassiopeia, at such dates that, if correct, it is nearly due now. That is nearly all we are able to say; a small star has certainly been seen lately in Cassiopeia where one was not noticed before, but it may have nothing to do with the supposed variable.—Paugul.

[77]—Horrible dreams are often due to the quantity and quality of food taken at supper. I think Pliny the younger tells you to eat heartily of roast pork just before retiring if you want horrid dreams. The worst dream I ever had was due to pickled cabbage and cheese just before going to bed. The results are thought to be due to pressure on the solar plexus of nerves in the abdomen, which set up some irritant action in the brain. To avoid bad dreams, eat light suppers, at least three hours before retiring; take a little gentle exercise if possible, and avoid startling romances at night.—T. R. Allinson, L.R.C.P.

[79]—Mental Physiology.—"S. S. S. S." should have stated how far he wished for works of a "specialist" physiological character. Outside these, I don't think he can have a later, or a better or more complete work on the *mental* side of the subject (and which gives references to all needful works) than "An Inquiry into the Process of Human Experience, &c.," by William Cyples, published by Strahan & Co., 34, Paternoster-row, price 21s.—S.

[79]—Mental Physiology.—Dr. Carpenter's "Mental Physiology" is a capital book. "S. S. S. S." should look over the list of the "International Science Series" (Kegan Paul & Co.) for several works on the brain and mind. Dr. Maudsley's books on mental subjects will also be found very useful by a student of mental science.—Andrew Wilson.

[83]—In answer to (*a*), Berthelot describes the powdery form of sulphur in vol. xlix. of "Annales de Chimie." It is formed also at the zincode of a battery, in the electrolysis of sulphurous and sulphuric acids. (*b*) Nitric oxide in meant.—C. T. B.

[83]—Sulphur Modification.—There are five modifications of sulphur known. The two crystalline forms, the plastic form, a dark brown powder left on treating the plastic form with CS_2, and a light yellow powder insoluble in CS_2 (carbon disulphide) deposited from solutions of sulphur in CS_2, on being allowed to stand. The above is from "Roscoe and Schorlemmer's Chemistry," Vol. I., paragraph 156. (C.) It should be nitric oxide.—A Greenwich Student.

[84]—Ancient Man.—"Clio" (Query 84, p. 123) desires some information as to the reliability of the researches of Professor Horner. The Professor published them in 1854. He states that he made ninety-five vertical borings in the alluvial deposits of the Nile valley, and at the depth of 39 ft. fragments of pottery were found, and the conclusion drawn is, to use the Professor's own words, "if there is no fallacy in my reckoning, these fragments of pottery must be held to be a record of the existence of man 13,000 years ago." The whole data of his conclusion rests upon the assumption that the deposit of the Delta was gradual and uniform. This he assumes from calculating the interval between B.C. 1150, the time of the erection of the statue of Rameses II., and the time at which the exploration took place. And judging from the thickness of the deposits around the statue, from its base upwards, he infers that the Delta accumulated, if my memory serves me, at the rate of two and a-half inches a century. It will be perceived that this calculation takes as its basis that the accumulation was successive; but we have no means of ascertaining how far the base of the statue stood above the reach of the inundation when first put up, and so have no basis for any calculation. Again, the water of the inundation having been for ages kept out, according to Egyptian custom, from the enclosure in which the statue stood, the accumulation of the deposit there was the more rapid when, in after times, the water was admitted. This accounts for the thickness of the sediment without any *successive* deposit. Herodotus (Book ii., p. 99) mentions that Menes, first king of Egypt, B.C. 2350, was supposed to have diverted the course of the Nile by a dam twelve miles south of Memphis, and thus to have dried up the old bed. It may be that the statue of Rameses II. stands on the old bed, and the fragments of pottery were deposited by after inundations. Less than a thousand years ago the Nile flowed close to the western shore of Cairo. It is now separated from it by a plain more than a mile in width. At a depth of 30 ft., fragments of pottery were found less than a thousand years old. Professor Horner says that "fragments of burnt brick and pottery were brought up from the lowest part, viz., 50 ft. from the surface." Now it is an undoubted fact that there is not a single structure of burnt brick from one end of Egypt to the other, earlier than the Roman dominion. Mr. Birch, the Egyptologist, refers the burnt brick to B.C. 1300. On these and other grounds I think it may safely be said that the evidence for man's existence as derived from the researches of Professor Horner is not reliable.—R. S. Couch.

[88]—Brain Injuries.—The brain is divided into two parts. One controls involuntary motion, as breathing, the heart's action, &c.; the other is used for thought, the reasoning powers, and passions. The brain is also double, so that, injure one part, and the other side takes up its action. This is true with the reasoning and thinking powers. Injure a part governing any member, and you see at once paralysis of that member. From this is inferred that injury to the intellectual part is not followed by any noticeable change, but injure any of the motor parts, and you get at once paralysis. The brain is the organ of feeling, in that it makes us aware of injuries inflicted anywhere on the body: so that we make an effort to remove the injured part from the irritant.—T. R. Allinson, L.R.C.P., &c., 2, Kingsland-road, E.

[90]—The best theory is, that the earth is an electro-magnet; currents of electricity travelling round at about right angles to the axis. It is based on the fact that lodes of metals generally lie in the same direction, and they would be able to keep up thermo-electric currents at the expense of the earth's heat. This theory does not explain magnetic variation.—C. T. B.

[105]—A Question of Grammar.—"A. T. C." will, perhaps, understand the phrases, "I can but think" and "I cannot but think," by remembering that the word "but" is used in three senses:—(1) As an adverb = "only," as in "I can but think"; (2) as a conjunction, its most common use; (3) as a preposition = "except," as in "I cannot but think"—this expression being elliptical, for "I cannot do any other thing but think." In this last case (which, by-the-bye, some older grammarians ignore) "but" is the representative of the Anglo-Saxon *butan* = without; and is used by Chaucer in the lines:—

"But meat or drinke, she dressed her to lie
In a dark corner of the house alone."

The broad Yorkshire dialect has such expressions as "I can do bout it"; where the "bout" is not merely a corruption of "without," but the old Anglo-Saxon "but."—J. H. L.

Our Mathematical Column.

THE WITCH OF AGNESI.

[Reply to E. H. R., Mathematical Query, 2.]—The Witch of Agnesi is a curve of the third order described in the "Analytical Institutes" of Maria Gaetana Agnesi (1748). It may be thus drawn geometrically :—

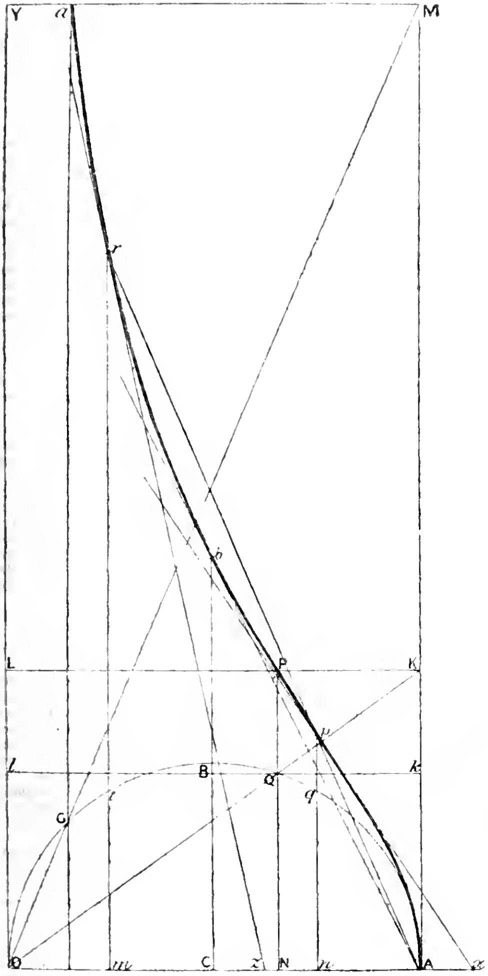


Fig. I.

Take a circle OBA and draw a diameter OA; then if QN perpendicular to OA be produced to the point P, such that

$$NP : NQ :: AO : NO$$

P is a point on the "Witch of Agnesi."

It is evident that the curve will extend indefinitely on either side of OA (we only show one branch); and that the tangent to the circle ABO, at O, will be an asymptole to both branches. Again, if C be the centre of the circle; OC, CA, bisected in m and n; and BC, qn, and tm, perpendicular to OA, are produced to meet the curve in b, p, and r, it is obvious that

$$bC = OA = 2a \text{ (putting } OC = a)$$

$$pn = \frac{OA}{On} \cdot qn = \frac{4}{3} qn = \frac{2}{3}\sqrt{3}a$$

$$rm = \frac{OA}{Om} \cdot tm = 4tm = 2\sqrt{3}a = 3pn$$

Thus, a straight line drawn from A to p and produced will pass through r.

Again, if we draw AkM a tangent at A and LPK, lQk parallel to OA, it follows from the fundamental property of the curve that

$$\text{rect. } LN = \text{rect. } lA,$$

whence Q is on the diagonal OK. Thus, we have a simple geometrical method of drawing the curve, as follows :—

On AM take any point K, and join OK cutting circle OBA in Q; then parallels KP, QP to OA and OY, intersect in P a point on the curve. (We give the construction for the point a on the curve, joining MO, which cuts OBA in G, and drawing the parallels Ma, Ga.)

For the equation to the curve, take OA as axis of x, and OL as axis of y. Then, we have—

$$ON.PN = OA.QN; \text{ that is}$$

$$xy = 2a\sqrt{2ax - x^2}; \text{ or } xy^2 = 4a^2 (2a - x).$$

From this equation to rectangular co-ordinates we can deduce the properties of the curve. Differentiating—

$$\frac{dy}{dx} = -\frac{2a^2}{x}(2ax - x^2)^{-\frac{1}{2}} \qquad \text{(i)}$$

$$\text{and} \quad \frac{d^2y}{dx^2} = \frac{2a^2}{x^2}(3a - 2x)(2ax - x^2)^{-\frac{3}{2}} \qquad \text{(ii)}$$

From (ii) we see that $\frac{d^2y}{dx^2}$ disappears when $3a - 2x = 0$, or $x = \frac{3a}{2}$; so that there is a point of inflection at p.

Putting x successively equal to $\frac{a}{2}$, a, and $\frac{3a}{2}$ in (i) we find :—

$$\frac{dy}{dx} \text{ at } pt. \ r = -4a\left(a^2 - \frac{a^2}{4}\right)^{-\frac{1}{2}} = -\frac{8}{\sqrt{3}}$$

$$\frac{dy}{dx} \text{ at } pt. \ b = -\frac{2a^2}{a}\left(2a^2 - a^2\right)^{-\frac{1}{2}} = -2$$

$$\frac{dy}{dx} \text{ at } pt. \ p = -\frac{4a}{3}\left(3a^2 - \frac{9a^2}{4}\right)^{-\frac{1}{2}} = -\frac{8}{3\sqrt{3}}$$

From these values, remembering that

$$rm = 2\sqrt{3}a; \ bC = 2a; \text{ and } pn = \frac{2a}{\sqrt{3}},$$

we see that the tangent at r cuts OA at a point z, such that $mz = \frac{3a}{4}$; the tangent at b passes through A; and the tangent at p cuts OA at a point x such that $nx = \frac{3a}{4}$.

A geometrical construction for finding the point x in which a tangent at a point p cuts the axis of x is easily obtained. For we have $\frac{dy}{dx} = -\frac{2a^2}{x}(2ax - x^2)^{-\frac{1}{2}}$ whence since $qn = \sqrt{2ax - x^2}$ it follows that

$$\frac{pn}{nx} = \frac{OA.OC}{On.\ qn}, \text{ or } \frac{pn.On}{nx} = \frac{OA.\ OC}{qn}$$

$$i.e.\ \frac{OA.\ qn}{nx} = \frac{OA.\ OC}{qn}; \text{ or } (qn)^2 = OC.\ nx.$$

Hence, if we take $nm = OC$, a perpendicular at q to mq will cut OA (produced, if necessary) in the required point x, such that xp is a tangent at p.

We have not by us any treatise bearing on the history of this curve, and are, therefore, unable at the moment to state the properties which led to its invention. In Brande's "Dictionary of Science and Art" the definition of the curve is given, and we have based on that the above investigation. Most probably the curve was one of those which mathematicians were fond of inventing (in the 17th and 18th centuries) for the purpose of squaring the circle. (Such a curve they would call a quadratrix.) It is manifest that the curve can readily be swept out mechanically. Thus, let there be a semicircular groove OBA (Fig. 2) and a straight groove OT square to OA, and let bars Nn', Ll slide between the parallels AT, Oa (square to OA) so as always to be parallel to AT and OA respectively. Then if a rod OG swinging around O, carry points along AT and ABO, which respectively bear with them the parallels Ll, $n'N$, a pencil so carried as to lie always at the intersection of these parallels, will trace out the curve APb.

It is readily seen that the curve is a quadratrix. For, take any two points, K, J, near together on OA, and about O as centre take circular arcs Kq', Jq to the semicircle AqO. Draw OqL, $Oq'L'$, as in fig. 2, and parallels $L'P'l'$, LPl, $mP'q'M$, $n'PqN$, giving two points, P', P, on the curve. Draw qn perp. to mM. Let $Oq\,Ll$, cut mM in e' and i respectively, arc $q'K$ cutting Oq in o. Draw the quadrant Ara about

O as centre, cutting OL, OL' in e, e' respectively, and join Jr, Kr' which are obviously perp. to OA (triangle AqO equal in all respects to triangle rJO, &c.) Then triangle $e'q'q$ is in the limit obviously isosceles, $q'o$ perp. to qe', and $e'q = 2\ q = 2KJ$.

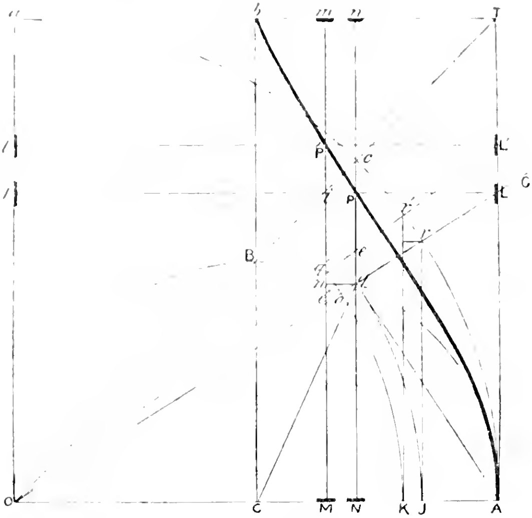

Fig. 2.

$$\text{Now area } PM = PN.\ qn = qN.\ \frac{OA}{ON}\ e'q.\ \cos.\ e\,q\,e'$$
$$= qN.\ \frac{OA}{ON}.\ 2KJ.\ \frac{ON}{Oq} = 2qN.\ \frac{OA}{Oq}.\ KJ$$
$$= 2qA.\ KJ = 2rJ.\ KJ = 2 \text{ rect. } rK$$

This being true of all such areas, as OL passes from OA to OL and onwards, it follows (proceeding to the limit) that

area PNA = 2 area rJA

and entire space between OA, Oa produced indefinitely, and the curve APb carried on indefinitely

= 2 quadrant $AraO$
= 4 semicircle OBA

Therefore, entire area between the "Witch of Agnesi" and its asymptote is equal to four times the area of the circle from which the curve is formed in accordance with its definition.

It may be noticed that we can thus (after a fashion) square the circle, without carrying on the curve to infinity. For, let CB perp. to OA meet the witch in b, and let OB produced meet the quadrant in c. Then we know that

Area $APbC$ = 2 area AcN.
= 2 (sector AOc − triangle cON).
= quadrant AOa − triangle OAT.
= circle ABO − its inscribed square.
= $\pi a^2 - a^2$.

So that if $APbC$ be regarded as determined by this mechanically constructed curve, $\pi a^2 - a^2$ is determined, too; or since a^2 is known πa^2 the area of the circle OBA is determined.

In passing, it may be noted that from the above construction follows a ready demonstration of the property of the tangent, established analytically above. For the limit PP' is a straight line, and the tangent of the angle which PP' makes with OA is ultimately the $\frac{dy}{dx}$ of our analysis.

$$\text{Now tan. } P'PL = -\frac{P'i}{Pi} = -\frac{LL'}{nq}$$
$$= -\frac{q'e'}{nq} \cdot \frac{OL}{Oq} = -\frac{q'q}{nq} \cdot \frac{OL}{Oq}$$

But

$$\frac{PN}{qN} = \frac{OA}{ON} = \frac{OL}{Oq}$$
$$\therefore \text{tan. } P'PL = -\frac{q'q.\ PN}{nq\ \ qN} = -\frac{Cq.}{qN}\ \frac{PN}{qN}$$
$$= -\frac{OC}{(qN)^2}.PN$$

This is the same relation as we have already obtained; for if a tangent at P meets AO produced, in a point x, we have

$$\tan\ P'PL = -\frac{PN}{Nx} = \frac{OC}{(qN)^2}PN \text{ as just shown.}$$

So that $\quad Nx = -\frac{(qN)^2}{OC}$ Ed.]

"G. P." considers that he has solved the very difficult simultaneous equations

$$x^2 + yz = a^2 \text{ (i)} \qquad y^2 + zx = b^2 \text{ (ii)} \qquad z^2 + xy = c^2 \text{ (iii)}$$

by showing, what is in truth obvious, that

$$x^3 - a^2x = y^3 - b^2y = z^3 - c^2z.$$

"It is now reduced to a cubic" (we fail to see this) "which might be solved in a variety of ways. For instance, if we suppose $x = ny$, we get :—

$$y = \sqrt{\frac{a^2n - b^2}{n^3 - 1}}\ ;\ x = n\sqrt{\frac{a^2n - b^2}{n^3 - 1}}\ ;\ z = \sqrt{c^2 - n\left(\frac{a^2n^2 - b^2}{n^3 - 1}\right)}$$

(Where we have written b^2, "G. P." writes 1, through some error.) From which by substituting in (i) (ii) and (iii), we find n, and hence x, y, and z. It is evident G. P. has not tried substituting in (i) (ii) and (iii). If he had, he would have found, first, that substitution in (i) or (ii) would suffice [(iii) giving only an identity], and that the resulting equation in n would be of the 6th degree!

MATHEMATICAL QUERIES.

[5]—Differential Calculus.—"G. P." next asks why, if we take the relation

$$\sin.\ x = \frac{2 - x}{2 + x}$$ and differentiate with respect to x, we get

$$\cos.\ x = -\frac{4}{(2 + x)^2} \text{ instead of } \cos.\ x = \frac{2\sqrt{2x}}{2 + x}$$

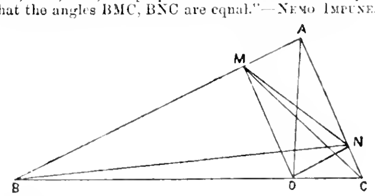
as by trigonometry. "Whence the contradiction?" Simply because "G. P." has applied the differential calculus the wrong way. His relation assigns a definite value to x and to sin x, and that being so, we cannot differentiate. Take a simpler relation, and we may find the differential calculus, applied in this way, contradicting common sense. Thus take $x = 1$, and differentiate both sides with respect to x, and we get $1 = 0$.

[6]—Indeterminate Equation.—Is it possible to solve

$$x = 12 + 2y?$$

to find the value of x and y, without *assuming* any numerical value. —J. A. L. R. [There must always be some assumptions in the solution of indeterminate equations.—Ed.]

[7]—Could you kindly favour me with a solution to the following rider on II. Book of "Euclid":—"The angle A of a triangle ABC is a right angle, and D is the foot of the perpendicular from A on BC; DM, DN, are perpendicular on AB, AC, respectively: show that the angles BMC, BNC are equal."—Nemo Impune.



[As a rider on Book VI., thus:—

Triangle BAC similar to triangle AND,
∴ BA : AC :: AN : ND (= AM).

Hence BA.AM = AC.AN, wherefore points B, M, N, C, lie on circumference of a circle,

∴ angle BMC = angle BNC.

But the problem can be as readily solved without the aid of any properties beyond those in Book III., thus:—Join MN. Then, triangle AMN being in all respects equal to the triangle NDA, the angle AMN is equal to the angle ADN, and therefore to the angle ACD (ACD and ADN being obviously equal, because each with the angle DAN makes up a right angle). Hence the angles BMN and BCN together are equal to the angles BMN and AMN together, or to two right angles. Therefore B, M, N, C are points on the circumference of a circle, and therefore as above

Angle BMC = angle BNC. —Ed.]

Our Whist Column.

FORCING AT WHIST.

Sir,—I gather from the character of your published articles that you presuppose in your readers some knowledge of the theory of whist. So much, in fact, has been written upon whist that it is difficult to find anybody absolutely ignorant of its principles. It is of great value, however, to the young player, to place before him in a condensed form the digested experience of the best players, and thus raise him gradually from domestic to scientific play. "When may I force my partner?" is a question frequently put. There are, undoubtedly, many positions in practice where the thoughtful but inexperienced player finds himself in difficulty. It is easy enough to understand the reasonableness of forcing an adversary who has shown great strength in trumps, or a partner who has shown great weakness. But suppose, for example, as an original lead, a player were to lead from manifest weakness, an honour having been turned to his right, that which in ordinary cases appears to be an invitation for a force, would, in fact, amount almost to a direction to lead through the honour. But I will endeavour to lay down the cases when a player, not having trump-strength, may, nevertheless, force his partner :—(*a*) When, with no indication of strength, he asks for a force. (*b*) When the position shows a cross-ruff. (*c*) When the adversaries have signalled. (*d*) To make the fifth or odd trick, or to save the game, when the hand of the forcing player, or the development of the game, does not raise a high degree of probability that the necessary trick may otherwise be made. But an interesting point relating to the force is where the player, in a position to force, has trump-strength amply justifying it. It often happens that a player renounces to the lead of his partner, who, with ample trump-strength, has no strength in the then declared suit. If he forces, and the declared suit be not headed by Ace King, or King Queen, the result is, after a force, a lead up to ruinous weakness. No trick is gained by the force, for another trick is lost in the suit. If, however, the player gives his partner his declared suit, the adversaries may infer that he has no strength in trumps, and lead trumps to their disadvantage. I send you a game illustrative of this position, and hope it may be interesting to your readers.

Frederic H. Lewis.

THE HANDS.

A.
Clubs—Q, 9, 4.
Hearts—6, 3.
Spades—A, K, 8, 7.
Diamonds—Q, 5, 4.

Y.
Clubs—Kn, 3, 2.
Hearts—A, 10, 9.
Spades—Q, 10, 5, 3.
Diamonds—A, K, 3.

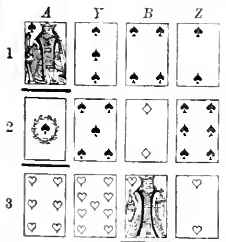
B.
Clubs—10, 7, 6.
Hearts—K, Kn, 7, 5, 4.
Spades—4.
Diamonds—Kn, 10, 6, 2.

Z.
Clubs—K, 8, 5.
Hearts—Q, 8, 2.
Spades—Kn, 9, 6, 2.
Diamonds—9, 8, 7.

B
Dealer. Z
Trump Card, King of Clubs.
A

Score:—A B = 1; Y Z = 4.

Note.—The underlined card wins trick, and card below it leads next.

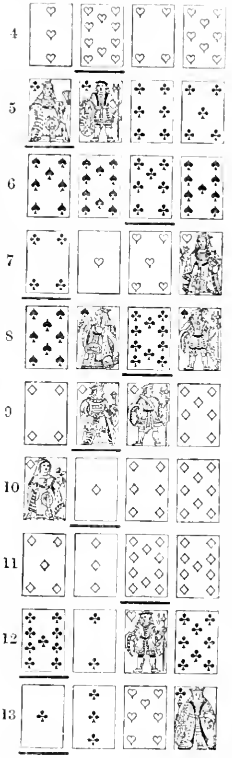


INFERENCES.

1.—*A* leads from his strongest suit.

2.—The fall of the cards, and the discard of Two of Diamonds, the lowest of the suit, shows *A* that no one is signalling for trumps.

3.—*A*, having here two honours in trumps, might very well force his partner, but, having only Six and Three of Hearts, prefers to give his partner his suit.*



4.—*B*, although having no strength in trumps, is here quite justified in returning the Heart. If his partner has avoided forcing him, in consequence of weakness, the chances are that the game is lost. If, however, a cross-ruff can be secured, such a position would be most advantageous.

5.—*Y* sees that a cross-ruff must be secured. He has the tenace in Spades, the best Heart, an honour has been turned; he has the command in Diamonds, and *A* has avoided forcing *B*. All this is too much for weak human nature, and he cannot resist a trump lead; he therefore leads the highest of his three trumps.

6.—*A* is now in a position to force his partner advantageously.

7.—The cross-ruff: conveying also to *A*'s mind, from the fall of the cards, that the two remaining Hearts are with *B*.

8.—*A* is in a position to give another force.

9.—*B* cannot lead one of his long Hearts, such play would be very bad, and accordingly he leads the best of his remaining Diamonds, treating the suit as though he had originally but three.

10.—*A* now has the tenace in trumps, but he requires three tricks to win the game. If he keeps the Queen of Diamonds he can make only two; he, therefore, cleverly throws the Queen, taking the chance of his partner having the Ten of Diamonds. The fact being so, he secures four by cards and the game. The rest of the hand plays itself.

* If he had forced him, the game would, probably, have proceeded as follows :—

	A	*Y*	*B*	*Z*
3.	S 7	S 10	C 6	S 9
4.	H 3	H 9	H 5	H 2
5.	D 4	D K	D 6	D 7
6.	D 5	D A	D 10	D 8
7.	D Q	D 3	D Kn	D 9
8.	S 8	S Q	C 7	S Kn
9.	H 6	H 10	H 4	H 8
10.	C 4	H A	H 7	H Q
11.	C 9	C Kn	C 10	C 5
12.	C Q	C 2	H Kn	C 8
13.	C A	C 3	H K	C K

and the result would be two, instead of four, by cards.

Answers to Correspondents.

*** *All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of* Knowledge, *the increasing circulation of which compels us to go to press early in the week.*

Hints to Correspondents.—1. *No questions asking for scientific information can be answered through the post.* 2. *Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries.* 3. *No queries or replies savouring of the nature of advertisements can be inserted.* 4. *Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge.* 5. *Correspondents should write on one side only of the paper, and put drawings on a separate leaf.* 6. *Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

W. We cannot afford space for your long letter, containing only assertions without evidence. Newton waited nineteen years before advancing his theory of gravitation, because, though it agreed in all other respects with observed facts, it would not stand one test—the reason being that the accepted measurement of the earth's globe was incorrect. Cannot Mr. Crosland's friends allow his astronomy of the future to wait until it has been shown that it accounts in measure and number for at least one single observed fact? We promise to give all the space you ask for vague generalities, for the first demonstrated case of the kind.—H. J. Pearson. (1) Strictly speaking, the exact sciences are those which are based on mathematics, as optics, astronomy, &c.; but the term is usually extended to all sciences depending on observation and experiment, so that it includes chemistry, and other physical sciences not strictly exact. The term is not a well-chosen one. (2) It cannot be "demonstrated" that the nearest way from one point to another is the straight line joining the two points; but we show that the latter path is shorter than any path made up of straight lines, and since a series of very short straight lines may be made to approximate as nearly as we please to a curved line, this can at any rate be demonstrated, that a curved line from one point to another differs by an indefinitely small amount from a length which is greater to an assignable degree than the straight line joining the two points.—Thos. Smith, Jun. Phrenology is not so young that, were it really a science, it should be unable to take its own part. It is much older than spectroscopy, which can stand alone very well. We did not, however, mean that phrenology is absurd, when we spoke of the absurdities of phrenology; there are reasonable features as well as absurdities in it. Much may be said in favour of a rational phrenology. Gall and Spurzheim were both scientific observers, and both made useful scientific discoveries; but their system of mapping out the cranium has now no adherents among men of science.—W. J. M. We have ourselves seen and heard a dog which was said to speak; but one had to make believe a

g... deal. Thus if ... (French dog) he would make a noise about as near to the sound of the word as the note of the cuckoo is to the word cuckoo, but no nearer. If one had been told he said "hurt," the noise would have done just as well for that word, or for half-a-dozen others. In some such way, doubtless, the dog "seen and heard by M. Leibnitz" could say, in German, tea, coffee, &c. We had a dog once which could sing, but that required a good deal of "make believe" too.—John Steele. Your explanation not necessary, but well received. Science no more questions the sun's heat than we question the heat of a fire which warms us.—Altair. Query 61 already answered. Thanks. As regards 62, Algol is shown in the maps for this month. It is scarcely a sufficient answer to 63 to note that Algol and Mira are brightest when at their maximum brilliancy. Note our reply to 61.—Q. E. F. Your own figure should have shown you that your solution is unsound, for the angle is obviously not trisected.—Ridiculus Mus. Your first result amounts to this, that if you have made a certain number of moves in the Fifteen Puzzle, you can come back to the position from which you started; your second, to this, that starting from a certain position and making any number of moves, you cannot work back to a certain other position, closely resembling, but not identical with, the former. But this does not deprive the puzzle of its interest as a mathematical enigma. You can hardly have proved "by numerous experiments" (only) that these results are invariable, for there are twenty billions of different positions which can be attained from one or other of your two starting positions. If you had, (that is, if you had worked at the puzzle ten times or so a day, during a life of some twenty thousand years) there would still remain the problem—pretty, though not difficult—of showing why these results can invariably be attained. Then there is the neat puzzle in every case, how to attain any assigned position from another of the same order, in the smallest number of moves. On the whole, it is as pretty a little puzzle, I think, as any invented since "Solitaire," which involves some very neat mathematical relations.—Chromo. Thanks; but questions sufficiently answered already.—M. E. Pendred. Your fears were expressed for others, but seemed to be yours. Anyhow, we know your letter would have raised most undesirable controversies.—F. H. F. The lunar illusion is not dependent on the vastness of the sun's distance. "M.'s" explanation was sound. The plane through the observer's eye and the horizontal sagitta due south passes through the east and west points on the horizon. Would print your letter did space permit.—H. Rayment. Hope shortly to insert your letter.—An Admirer. You are very good, but fear readers of Knowledge would not quite like it.—E. Burgess. Thanks for "Help to Chess Students." Crowded out at present.—Athos. Of course you are right in saying that the solar dark lines, as interpreted, prove the sun to be intensely hot. The argument would be above comprehension of the paradoxers, however.—Rob. S. Couch. Letter shall shortly appear, if possible.—G. W. Niven. Short notes on such tricks would suit well enough.—S. N. B. G. No space at present. Thanks for replies.—A. L. S. Thanks for account of lunar rainbow (why call it Iris Lunaris?). No room for it at present.—J. Fraser. Still hold the accepted theory of the tides. No earthly reason why the earth should fall into the moon. Your theory wholly untenable.—T. Thanks.—F. W. C. Cannot insert answers recommending instruments by particular makers. We are sure of your *bona-fides*; but others would claim right to do likewise with less worthy motives.—J. M. Many thanks; but the question had been answered sufficiently, though we could not find room at once for reply. W. F. Denning. Thanks; your letter shall appear.—Carlo F. Johnson. Thanks; but we take replies respecting comets as part of subject we are discussing in articles—if only we could get a line or two in edgewise. Other questions answered.—H. G. Hollingworth. Will try to find room.—D'Artagnan. Airy's Essay on "Undulatory Theory of Light" (in his mathematical essays), Lloyd's, and Potter's treatises were what we used to read at Cambridge.—Inquirer. Moore's "Lalla Rookh" is not a recognised astronomical authority; still "half retired" (from the earth) would correspond nearly enough with time when Venus "looks loveliest."—S. N. W. You evidently have not yet grasped the meaning of the modern theory of evolution. Your remarks apply well to such theories as Lamarck's and others; but they are dead; why play Falstaff at Shrewsbury over them?—J. D. "As fast as we fix a telescope," you say, "the earth's motion ought to displace it." That is just what the earth's motion does. It is this motion that the driving clock of a telescope is devised to correct, by constantly carrying the clock the other way.—F. H. S., J. Gottfried, and others. Thanks; "Magic Squares" crowded out for the present.—L. Ferrers. Received; thanks.—Mabel W. L. Pressure of time was the cause of printer's error; but it was of the less importance, as Brewster's ideas were entirely incorrect.—S. H. F.—We prefer our "happy laughter" to be independent of comparatively "low replies." Your method of studying the luminary in question is unsound.—J. Gottfried. Thanks for your magic squares; the method shall appear. There are others yet.—Andrew Aitken. Your answer to Cymro's question is sufficiently sound, but we have not room for second solutions. The first was correct. The first part of answer to Query 48 is also omitted, as the trisection of a right angle is familiar to all students of geometry. The other solution is really the same as that on p. 117, but if our space were not so crowded we would give it. Thanks for your communication all the same. We must ask you to consider our position with regard to space. Note beginning of our letter in correspondence column, and reply to W. R. W. below.—James Shaw. Article on "Right-handedness" shall appear shortly.—Eclecticus. We give you alone this *nom de plume* now. Have been obliged to much shorten your letter.—W. H. R. Thanks, but longer letter on meridional or meridinal parts could not be placed. There is no Latin word *meridionalis*. *Meridianus* is the word. Albeit we leave such points to the printers.—W. T. Lynn. Thanks, but the exact time when Halley's comet was first observed in 1759 is not likely to interest the majority of our readers, and space considerations trouble us. We put in your first letter, because it involved a correction of our own statement. Otherwise, these questions of dates, priority, manner of observation, and so forth, seem of little importance. How often has the error about Tycho Brahe and the new star been repeated, and what harm has it done? We must not be microscopical in such matters.—Sirius. To save space, have been obliged to incorporate your letter in our own.—Alex. J. E. Your 3-square puzzle is very neat.—Musicus. Why want to learn how to "get in the way of talking" while you play the piano? Did you ever hear anyone do so who had the least feeling for music? None such can play well when *others* talk. Probably, it is as easy for a mere "performer" to talk while he plays as to talk while someone else is playing, and as difficult (rather as impossible) for a real musician to do one as the other. To anyone with the slightest particle of musical feeling, there can be nothing much more trying than to hear people talk while a noble air is nobly rendered, unless it be to hear a skilful executant talking while the notes of a noble air pass without life or expression under his agile but not musical fingers.—E. F. H. Thanks.—Herbert R. Welter. Unquestionably a meteor. Some meteors move, apparently, quite slowly, and the larger often have the cometic appearance you indicate.—H. A. S. "Puzzled's" problem is sufficiently explained. It is much older than the publication you mention, though, doubtless, new to him. Your other problem, depending on half a live man being equal to a man half dead is amusing, but would be out of place here.—K. J. P. Why will correspondents take so much care to make their communications too long for insertion?—A Biologist. Your reply to No. 52, if inserted, would lead to others being sent, which might read like advertisements. Thanks equally.—J. H. W. L. We ... see when first half-yearly volume approaches completion. Thanks for getting new subscribers.—C. J. Chambers. Your suggested paper would range too much, we fear, over the ground covered by text-books of Acoustics.—F. J. Brodie. Correction inserted. Thanks. Should receive such notes as you suggest with pleasure. Brevity essential, you will understand.—J. F. S. Thanks for extracts; several we had already cut out, but correspondence crowded them out. Note letter from W. M. Williams, and consider the cheerful task of weeding out and boiling down such abstract reports.—Camille Flammarion. Thanks for your obliging offer, of which we gladly avail ourselves. Book safely to hand. Again thanks.—Edward P. Thompson. Thanks; yet the quotation would hardly add to our knowledge: it tells us only what everyone knows—that fancy often mimics reason.

> But misjoining shapes
> Wild work produces oft, and most in dreams
> Ill matching words and deeds long past or late.

G. Cuttle. Your reply to Query 90, No. 6, is hardly explanatory. The question really is why the earth acts as you say—justly enough—she does act. By-the-way, the magnetic poles are no longer where you say. Changes both in the declination and inclination all over the earth sufficiently prove that these poles have shifted largely since the northern was determined and the southern inferred.—Paugul. Many thanks for your replies; a few, as relating to queries already answered, we omit, space being crowded. The paradoxers think me too hard on them, instead of "too indulgent."—R. E. W. We omitted the third extract, but failed to omit the reference to it.—Rev. W. H. K. S. Your explanation of ice-yachts sailing faster than the wind is not available in many known cases, where the relative wind is less than the absolute wind, and the velocity of yacht exceeds that of either. The principle of the Rhine ferries is different. Thanks.—J. H. Lampkey. Unquestionably, the "Knowledge of the Ancients," would be full of interest for students of modern knowledge; and occasional papers on the subject might suit us. But we cannot, as yet, arrange for the systematic treatment of ancient knowledge here. If you send us a short paper you may rest assured it will receive due attention.—Rev. W. Houghton. Thanks for your interesting letter, which shall appear in full.—J. Taylor. Your suggestion attended to; see "Dates and Hours for Stars in November," in this column below.—W. R. W. Are you not a little unfair? There was, of course, less correspondence in No. 1, than later; it would not have been strange had there been none. In No. 6, the correspondence occupied too much space, but most of the letters were interesting. Two were specially written for us, and might have been put among the original articles, only their writers modestly suggested that the matter should be put among the correspondence. You must remember that we have to consider those who ask questions, or feel moved to make replies. You rather miscount the pages in No. 1 and No. 6, including the star map in one estimate and omitting it in the other. However, No. 6 was exceptionally overweighted with correspondence. Hereafter we must be more strict, though, as it is, we are rebuked for hard-heartedness.—R. G. We cannot undertake to give the accents of technical terms. Miss Kingsford's statements claim courage for fruit-eaters as well as strength. Roman and Spartan soldiers were not altogether wanting in pluck. Many cases are recorded of flesh-meat acting as an intoxicant, even to people in sound health. However, the Indians who gesticulated may have been intoxicated otherwise. The question whether it is the use of flesh-meat which has raised man above his fellow Primates is, of course, open to discussion. It scarcely seems probable, in the face of the admitted high intellectual and physical standing of many races which eat no flesh.—Rev. J. H. L. I have had very little to do with fixing the price of my books, and doubtless it is the same with other writers. I wish the publishers of books on science could find reason, in the increased number who take interest in science, to lower prices.—T. R. Allinson. Have slightly shortened your reply; space inexorable.—Arnold Ramsden. You can hardly do better than get Madler's smaller map of the moon, or Webb's "Celestial Objects for Common Telescopes," in which there is an excellent map, based on Madler's. Webb's book is about 10s.; Madler's map alone, from the German publishers, would cost, I suppose, a shilling or so.—Thomas Thorpe. Your ingenious instrument to appear in early number.—J. J. F. The mistakes of T. P. (A. K. C.) corrected elsewhere. Thanks.—Thomas H. Bamford. It is an open secret that Dr. Robert Chambers was the author of the "Vestiges of Creation." It would only waste time to discuss the claims of Lord Byron's daughter. By the way, no one who has read Lyell's remarks on the book in his "Antiquity of Man," could for a moment suppose he was the author.—G. C. D. M. We perfectly agree with your remarks about corporal punishment for boys. The cases are very few indeed where due obedience cannot be obtained without such punishment. But we cannot quite hold with you, that at birth the predilections for evil and for good in a child are exactly equal. Children differ singularly. Certainly George Eliot's skill as a novel writer would not of itself show that her brain was abnormally developed, but her novel-writing was only the means by which her real brain power was shown. Pray excuse non-appearance of your letter in full. The subject has now been pretty fully treated, and readers are asking that more space be given to articles.—Lionel T. Waller. Hope to give weekly weather reports shortly, if space can be found.—Wisray. Will see whether it can be done without injuring the maps. Doubt it.—A. J. Shilton, Not Castor and Pollux, and Others. Thanks. Query 54 sufficiently answered.—A Well-wisher, and others, repeat a request to which we have several times responded, that advertisements should be printed so that the bound volume need not contain them. This is already provided for: no advertisement page is now numbered so as to form part of the bound volume. Compare Nos. 1 and 2.—Ed.]

Dates and Hours for the Stars in November.—These are as follows in the first four numbers:—Oct. 30, at 10¼ o'clock; Nov. 3, 10¼ o'clock; Nov. 7, 10 o'clock; Nov. 10, 9¾ o'clock; Nov. 14, 9½ o'clock; Nov. 18, 9¼ o'clock; Nov. 22, 9 o'clock; Nov. 25, 8¾ o'clock; Nov. 29, 8½ o'clock; and Dec. 3, at 8¼ o'clock.

Contents of Knowledge *No.* 6.

KNOWLEDGE
AN ILLUSTRATED
MAGAZINE OF SCIENCE
PLAINLY WORDED-EXACTLY DESCRIBED

LONDON: FRIDAY, DECEMBER 23, 1881.

CONTENTS.

THE SO-CALLED ELEMENTS.

By Prof. C. A. Young.

My own spectroscopic observations bearing on the elementary constitution of matter have not been very numerous or important, as compared with those of several other investigators; at the same time, they have had a place in the discussion of the subject, and I cheerfully comply with the Editor's request to present a short account of them to the readers of Knowledge.

The idea that our so-called chemical elements are not really and absolutely elementary, but are built up either of atoms of some one universal matter, or of some few substances of a higher order of simplicity than themselves, is neither improbable nor new. As Mr. Lockyer points out, Dumas in 1836, and Brodie in 1867, not to mention others, have expressed themselves very clearly in this direction.

But the present special interest in the question is due mainly to Mr. Lockyer himself, who, in 1873, by an able and extensive induction from all available spectroscopic observations, put the theory in a new light, and brought together in its favour a great body of evidence, to which he has since then been continually adding.

In the discussion of the subject, certain observations of my own have been made use of along with those of others, always, I believe, with due and courteous acknowledgment, and in a manner to which I have nothing to object, unless, perhaps, that too much weight has sometimes been given to certain numbers which I had assigned only provisionally, and on a very short experience.

These observations of mine were for the most part made in July and August, 1872, during a six weeks' stay at Sherman, the summit station of the Union Pacific Railroad, at an elevation of 8,300 feet above the sea level. The party was connected with the organisation of the Coast Survey, and the results of the observations are published in the "Coast Survey Report" for 1872.

The work consisted mainly in a record of the bright lines observed in the spectrum of the solar prominences, and of the lines which were widened or otherwise modified in the spectra of sun-spots. The resulting catalogues contained respectively 273 and 156 lines, but only that portion of the spot spectrum lying between B and b was included. In these catalogues an attempt was made to assign numbers indicating the relative intensity of the lines and their proportional frequency of appearance; but, as has been intimated, the number of observations was far too small to make such figures very reliable.

Several remarkable facts were, however, very clearly brought out. In the first place, those lines of the spectrum of any particular substance (iron, for instance) which are most conspicuously and frequently seen, as *bright* lines in the spectrum of the chromosphere and prominences, are not generally the same as those most notably *widened* in the sun-spot spectrum; nor are either of these the ones which are most prominent in the ordinary solar spectrum or in the spectrum of the electric arc. Each of these four spectra selects and emphasizes, so to speak, its own set of so-called iron lines, and the same is true of other substances. Second: Where distortions and disturbances of the lines indicated rapid motions of the solar gases along the line of sight (approaching to, or receding from, the observer), it frequently happened that neighbouring lines, due to different substances, were differently affected; certain lines of iron might be violently displaced, while the adjacent lines of calcium were not disturbed at all. In some instances, also, it was noticed that lines, given in the maps as belonging to the same element, and actually in the same field of view, behaved very differently; one of them indicating violent motion of the gas concerned, the other showing nothing of the kind. But this observation seemed at the time so strange, and the instances were so few, that, in view of the possibility of mistake, it was not thought best to publish it without further confirmation, which it has since abundantly received.

In the third place, and most important, it was found that a very surprising proportion of the lines conspicuous in the spectra of the chromosphere and sun-spots are lines which on the maps are given as common to the spectra of two or more elements—lines which Mr. Lockyer has since designated by the term "basic." Nearly one-third of all the lines in the two catalogues belong to this class, while in the ordinary solar spectrum, they amount to less than four per cent. of the whole.

At that time the prevailing opinion, I think, was that these common lines were due to impurities in the specimens of the metals employed in mapping the spectra. If, for instance, in making a map of the spectrum of iron, the bits of iron used for the electric spark to play between (technically the "electrodes") were slightly contaminated with calcium, then we should expect the more important lines of calcium to appear faintly in the map of the iron spectrum; and the difficulty of getting perfectly, or even "spectroscopically," pure iron is enormous.

It was evidently possible also that these coincidences might be such only in appearance—cases of accidental juxtaposition too close for resolution by the existing spectroscopes.

But the instances were so numerous, that, on the whole, it looked more probable that the true explanation of such coincidences would be found in something common to the elements concerned; and at the time, I thought a similarity of molecular structure more likely than a community of substances. It appeared very possible that metals so closely alike in many of their properties as iron and chromium, for instance, might owe this general resemblance to such a likeness of their molecular architecture as would also carry with it certain identical vibration-periods. If atoms are vortex-rings in a continuous medium, the likeness might be in the size and configuration of the rings; if, on the other

hand, we are to think of the ultimate atoms as little hard balls, all exactly alike, and the chemical (elementary) molecules as aggregations of a greater or less number of these atoms, variously arranged, it would be easy to imagine some such likeness in the molecules of allied substances as would account not only for the spectroscopic facts, but many others.

Mr. Lockyer, however, after experimentally disposing of the theory that these "basic" lines are due to impurities, has preferred the hypothesis that what is common to two elements which show certain identical lines in their spectra, is some *constituent substance*, found in both, and liberated in greater or less proportion with change of temperature; and he finds in the existence and behaviour of these lines one of his strongest arguments in favour of the compound character of the chemical elements.

But I fear that the foundations of this argument are insecure, however it may be with the other evidence upon which he rests his case.

My observations in 1872 were made with a spectroscope inferior to very few then in use. It had a dispersive power equivalent to that of a train of twelve flint glass prisms of 60°, with collimator and view-telescope of 10 in. focal length. In optical perfection I have never seen, and do not expect to see, its superior: of course, it easily showed every line laid down upon the maps of Kirchhoff and Angstrom, and a multitude beside.

But soon after this time Mr. Rutherfurd's diffraction gratings began to come into use: and as they were made of continually increasing fineness and excellence, something like a new world opened before observers in respect to the details and structure of the solar spectrum. Up to 1877, no gratings were made with a ruled surface exceeding about one square inch in area; but in that year Mr. Chapman (Mr. Rutherfurd's mechanician), at my request, and with Mr. Rutherfurd's hearty concurrence, altered the machine so that it could draw a line $1\frac{3}{4}$ in. long, and ruled for me three plates on speculum metal, with diffraction surfaces of nearly four square inches. One of these new plates allows the use of so much larger object-glasses, that, by giving a suitable focal length to collimator and telescope, the available dispersion is increased four-fold over that obtainable from the smaller plates, with the same apparent brightness of the spectrum. Perhaps I may mention in an aside that one of our most distinguished American physicists has now in hand a machine, nearly completed, and bidding fair to be perfectly successful, which rules lines four inches in length. With this he expects to make gratings having a ruled surface 4 in. by 6 in., and with 20,000 lines to the inch, or even finer. *Quod faustum sit.* One would be almost ready to die after a good study of the solar spectrum with such a grating and accessories to match. But with one of Mr. Chapman's best gratings, $1\frac{3}{4}$ in. by $2\frac{1}{2}$ in., containing over 10,000 lines (17,300 to the inch), combined with collimator and telescope of 42 in. focus and 3 in. aperture, and a magnifying power of 250 (which is perfectly borne under the best conditions, when the grating is in good humour, perfectly flat and of uniform temperature throughout)—with this instrument, I say, one reaches about the limit of present abilities. Hundreds of lines shown as single in the older maps of the solar spectrum turn out to be double, triple, or multiple, and the vacant spaces of the spectrum are filled with crowds of fine lines and details of shading before undreamed of.

When attacked with this instrument, nearly every one of the "basic" lines of the solar spectrum is resolved; out of seventy such on Angstrom's map, only seven withstand its power, and three of these seven are probably on the "basic" list by mistake, as the numerical tables of Thalen are at variance with the map regarding them. With an instrument almost identical with my own, Professors Living and Dewar have recently investigated the electric-arc spectra of nearly all the metals involved. Their results accord with mine in almost every instance. They find that the apparent coincidences between the lines of different substances always break down under powerful dispersion; so that as matters now stand, I see no evidence to be drawn from such coincidences in favour either of Mr. Lockyer's view, or of the slightly-different hypothesis which I advocated myself.

The spectra of different metals, so far as we can now make out, have absolutely no points of exact agreement.

As to the remarkable and disproportionate number of these apparently common lines which are found in the catalogues of chromosphere and sun-spot spectra, may not the explanation be substantially as follows:—A line which is really composed of two or more belonging to different elements is much more likely to catch the eye than others. In the first place, this line will appear when either of the metals vigorously reverses its lines, even though the other does not; and again, in cases where both metals reverse their lines, but too feebly to be detected against the background of the atmospheric spectrum, this line, of double brightness, will be clearly seen. Since, probably, all, or pretty nearly all, of the lines are actually reversed close to the sun's limb, though only a few are usually bright enough to be caught by ordinary instruments under ordinary atmospheric conditions, it is easy to see that a slight advantage of the kind indicated above would give a composite line a great lift in the scale of relative frequency and brightness.

I have not yet been able to apply the highest obtainable dispersion to the examination of the spots and prominences, as the great spectroscope is too large to be attached to the eye-end of our 12 ft. equatorial. I have, however, used the same grating with collimator and telescope of 12 in. focus, giving about one-fourth the resolving power of the large instrument. Even this is more than four times as powerful as the prismatic spectroscope used at Sherman, and with it, it becomes perfectly clear that the catalogues of prominence and sun-spot lines contain many serious errors, the correction of which will be likely to remove some puzzling anomalies. In a number of cases, lines which are noted in the catalogue as bright in the spectrum of a prominence, or thickened in that of a spot, turn out to be entirely unaffected, the real culprit being a neighbouring line, so fine and so close to the larger one, as to be absolutely indistinguishable from it with the old instrument.

When our great equatorial (of 23 in. aperture, and 30 ft. focus) is mounted, as it will be next spring, it will be able to carry the large spectroscope without difficulty, and I shall then hope to review the catalogues with power enough to settle most of the questions of this sort. Until such a review is made, it seems to me that generalisations founded on our present data must be very cautiously handled.

WHAT IS A GRAPE?

By Grant Allen.

THEY make a beautiful picture, these big English hot-house black Hambros, with their purple bloom and their waxlike texture, clustered thickly together in rich luxuriance on their slender and heavily-weighted branching fruit stalks. Indeed, we have now cultivated them to such a pitch of excellence, that their old wild ancestors would hardly recognise them to-day for members of the same

original woodland family of Oriental climbers. Yet, after all, we have only been able to carry a little further, by careful selection and tillage, the peculiarities which Nature had long since produced in the primitive native stock. At best, man can only develope more fully what the plant itself has well begun. Our ornamental flowers are but the handsomest chosen wild blossoms; our cereals and edible roots are but the starchiest wild seeds and tubers; and our garden fruits are but the pick of the hips and haws and wayside berries, improved and altered by ages of cultivation.

The grape-vine, they say, comes to us originally from the shores of the Caspian. Even in its native condition it produces little sweetish acid grapes, hanging in purple clusters among its green festoons. The question is, then, of what use to the plant itself are these juicy fruits? For we now know that whatever use man may make of this, that, or the other organ in any particular plant or animal is, so to speak, an accidental after-thought; the organ always subserves besides some useful purpose in the economy of the plant or animal itself to which it belongs. Now, of course, the main use of all fruits is to produce or contain the seeds. They are merely seed-vessels, and, in most cases, they are dry and brown when ripe, like the pea-pod, the poppy-head, or the capsule of the mignonette. The problem we have to answer in the case of the grape is therefore this: Why should it be pulpy and prettily coloured, while these other fruits—and, indeed, the vast majority of all fruits—are mere dry and unattractive organs?

The analogy of red and white and yellow flowers affords us a good hint towards the solution of this problem. We know that flowers have acquired their bright hues, their honey, and their perfume, for the sake of attracting the insects which fertilise them by carrying pollen from head to head. Is there any way in which fruits can similarly benefit by alluring the eyes of any animal race? At first sight this would seem impossible; but a little consideration will show us a way out of the difficulty. Most plants, it is true, can only lose by allowing their seeds to be perceived and eaten by animals. In such cases the fruit, be it pod or capsule, is usually inconspicuous in colour, and drops its tiny little seeds quietly out upon the ground beneath. Those plants which best succeed in diverting the attention of seed-eating birds or mammals from their fruits, outlive, in the long run, their less adapted neighbours; and so the survival of the fittest has brought it about that ninety-nine kinds out of a hundred in our own day have unnoticeable little green or brown seed vessels, such as those of the chickweed, the pimpernel, and the clover tribe, which nobody but a botanist ever observes at all. Suppose, however, that any plant happens to have its seeds covered with a moderately hard and indigestible outer coat, would it not then be rather benefited than otherwise by having these seeds enclosed in a soft and juicy bed of edible pulp? For in that case birds and other animals might eat the seeds, fruit and all, for the sake of the pulpy covering; and as the hard little shell would protect the young embryo within, this vital part would not be digested, but would pass uninjured through the creature's body. By such an arrangement the plant would not only get its seeds dispersed—in itself a most important matter—but would also have the young seedling well manured and started in life under unusually favourable auspices. If such a tendency were ever to be set up even in the slightest degree by a mere sport or chance variation, we may be sure the variety in which it appeared would be so favoured by circumstances, that it would soon become a marked and distinct species.

As a matter of fact, it is pretty certain that such has been the origin of all edible pulpy fruits. Take, for example, these grapes here. If you cut one of them open, you will find inside a number of hard little seeds. Slice one of these again with a sharp penknife, and you will see that it consists of a tiny embryo plant in the centre, surrounded by a very solid bony shell. Each seed is in fact a miniature nut; and the kernel, so to speak, consists of the tiny plantlet within, together with the albumen on which it feeds when it first begins to germinate. Now, if any bird were to swallow and digest this vital part of the seed, the plant would, of course, be an obvious loser. But the hard shell prevents such a catastrophe from happening: and, therefore, the plant is benefited by the soft, eatable pulp which surrounds these little minute nuts. Observe, too, that the fruity part of the grape is sweet; it contains grape sugar. Now sugar is always laid up in those parts of plants which specially seek to attract the animal world. In flowers, the nectar allures the fertilising bees and butterflies; in fruits and berries, the sweet juices allure the birds which disperse the seeds; nay, even the pitcher plants secrete honey to wile flies into their insect-eating cups; and certain acacias store it up in hollow thorns to attract the epicurean ants, which, in turn, protect the tree by driving away their leaf-eating relations. In almost every case, one may say that where sugar is found in any organ of a plant, it is placed there for the sake of engaging the attention of some animal ally; while conversely, all flower-feeding and fruit-eating creatures always manifest a marked taste for sweet substances, dependent upon their long habituation to sugary food.

Not only, however, are the grapes sweet, but they are also brightly coloured. Naturally, among succulent fruits bidding for the attention of birds, those would best succeed which were most visible at some little distance. Accordingly, just as the insect-fertilised flowers have developed brilliant pigments in their petals, so the fruits which depend upon birds for the dispersion of their seeds have acquired prettily-coloured coverings. We all know how noticeable are the hips and haws, the holly-berries and rowan-berries, even among our northern woodlands; while the oranges, mangoes, and pomegranates of the tropics appeal even more vividly to the sharp eyes of monkeys, parrots, and toucans. At the same time, it is noteworthy that the tastes of birds with regard to colour seem to differ somewhat from those of insects; for, as Mr. Wallace points out, white, which is a common colour for flowers, is rare among fruits; while purple and bluish-black, which are seldom met with among flowers, may almost be considered as the ordinary colours of most wild fruits.

Looking closely into my cluster of grapes, again, I see that it still contains two or three unripe and stunted specimens. These, of course, are pale-green, like the leaves, and when I taste one of them I find it unpleasantly harsh and acid to the palate. This reminds me that grapes, like other fruits, are not at all stages of their existence sweet and brightly coloured. While the seeds are still immature, they would only lose by being eaten, because they are not yet fit for germination. In this stage, therefore, the skin is filled with green colouring matter, and the cluster is quite inconspicuous among the foliage which surrounds it. It does not *want* to attract attention in its present stage. Furthermore, the pulp at this period is filled with tartaric acid and other sour juices, to repel any too-inquiring or too-impatient visitor. But as the seeds mature, the fruit ripens—that is to say, a chemical change goes on in the pulpy portion, which results in the formation of grape-sugar. At the same time, other chemical changes taking place in the skin result in the production of the

purple bloom, which advertises to the birds the presence of the sweet juice within. The whole process obviously aims at concealing the fruit and rendering it unpalatable while the seeds are immature, and at making it conspicuous as well as pleasant the moment the seeds are ripe for dispersion. Hence we are justified in concluding that the development of the grape is due to the long selective action of fruit eating birds. Originally, no doubt, the primitive ancestral vine produced smaller and harder seed-vessels, which were probably green when young, and brown when ready to fall upon the ground. But some of them happened to show a tendency towards producing larger and juicier fruits, and these were constantly favoured by the unconscious friendliness of the neighbouring birds. The colour and the sweetness would soon follow, as they have followed a thousand times over in the development of each separate edible fruit. A grape, in short, viewed from the standpoint of the vine itself, is merely a cunning device for ensuring the assistance of birds or mammals in dispersing the little, nut-like seeds of which man takes, as a rule, such scanty notice.

STUDIES OF VOLCANIC ACTION.

By G. F. Rodwell.

PART II.

Of late years the microscopic study of eruptive rocks has revealed many facts of importance. The most opaque black lavas and basalts are seen to be mainly made up of colourless transparent crystals, when a slice less than a hundredth of an inch in thickness is placed under the microscope. Polarised light enables us to distinguish the nature of the crystals, and the angles can be readily measured. Zirkel, Rosenbusch, and Rutley have done much to promote this branch of petrology. One of the most recent and beautiful works on the subject is the "Minéralogie Micrographique" of MM. Fouquè and Michel Levy, which contains more than fifty coloured quarto plates of rock sections seen under the microscope, usually by polarised light. The rocks are, for the most part, eruptive. A peculiarity of the book is an ingenious plan for recognising in a moment the different mineral constituents of the section; for this purpose each plate is covered by a loose piece of transparent paper upon which an uncoloured outline of the engraving is drawn, and each mineral has its own number placed within the outline. The same number is used throughout the book to designate the same mineral.

The frontispiece of Prof. Judd's "Volcanoes" shows six beautiful sections of eruptive rocks, in which the passage from the perfectly glassy to the highly-crystalline structure is strikingly illustrated. The first specimen is that of a volcanic glass or obsidian, a lava which was rapidly cooled from a condition of complete fluidity, and which shows nebulous patches scattered through a glassy base. A very high power reveals that these patches are composed of minute crystals, called *microliths* or *crystallites;* and we are forcibly reminded of the resolution of the heavenly nebulæ into thickly-clustered stars by the microscope's twin-sister. Sometimes the microliths are built up into germ-like forms within the ground mass of the lava; and again, as the crystalline forces come more and more into play, the microliths form radial groups about definite centres, and thus build up globular masses, called "sphærulites." Crystals are made up of microliths grouped about certain axes, and a completely amorphous glassy lava may [illegible]

and thus giving the molecular forces time to act in the grouping of the microliths. Most lavas, when viewed under the microscope, exhibit a glassy paste or ground-mass, containing microliths, among which distinct crystals are distributed. Or again, when lavas consolidate at a great depth beneath the surface, the ground-mass is made up of small crystals, through which larger crystals are distributed. And, finally, we arrive at the granitic structure, in which the rock is completely made up of large crystals without any ground-mass. One and the same rock may exist in each of these forms, according as it has been cooled slowly or rapidly, at a great depth beneath the surface, or near to it. Thus, while *basalt* represents the lava form of a volcanic rock, *gabbro* is its granitic or crystallised form, and *tachylyte* its glassy or obsidian form. They all have the same ultimate chemical composition.

The larger crystals probably separated from the amorphous masses beneath the volcano, and were carried up to the surface by the fluid material forming the ground mass of the lava. Crystals frequently furnish abundant evidence of having been formed under enormous pressure. When examined by high powers of a microscope the crystals of granitic rocks are sometimes seen to contain cavities filled with liquid or gas, or with two liquids and a gas. Sometimes the liquid is water, sometimes a hydrocarbon like the mineral oils which are found in abundance in deep-seated rocks in various parts of the world. Not unfrequently the inclosed substance is liquefied carbonic acid, a gas which requires a pressure of nearly 600 lb. on the square inch to liquefy it at the freezing point of water, and a much higher pressure at the temperature which exists a short distance beneath the surface of the earth. We have thus every reason for believing that the crystals of a rock have been formed in deep recesses in the earth, while the ground mass has solidified at the surface.

Of recent volcanic outbursts, there can be no doubt that the eruption of Etna in May, 1879, was the most considerable. It was studied very fully by Professor Silvestri, who considers that it was the fulfilment of the abortive attempt made by the volcano in 1874. On the 29th of August of that year a rift opened on the N.E. side of the mountain between the crater and Mojo, and thirty-five monticules were thrown up along its course, with one large crateriform mound from which lava was discharged. After seven hours of activity the dynamic forces suddenly decreased, and in two days all the effects ceased, but the rift remained open, and earthquakes were common in the vicinity. Silvestri then predicted that when the next eruption occurred the rift would prove the line of least resistance, and that lava would flow from it, and craters be opened along its course, and this prediction was completely verified in the eruption of 1879. The fissure then extended itself to a length of six miles, passing through the great crater. Eight eruptive mouths opened on the south side of the mountain, and discharged a small amount of lava; but the lava presently found an exit at a lower level on the north side, and on May 28 Silvestri observed a great column of smoke, soon followed by the gloomy leaden tint observed during an eclipse, and by showers of volcanic sand. In ten minutes he collected more than two pounds of this sand in an inverted umbrella. He then approached nearer to the scene of action, and, when about 6,200 ft. above the sea, he heard loud detonations and experienced considerable oscillations of the soil. As he approached the great rift, he noticed three new craters near Monte Nero, from which issued dense clouds of steam. From one of them lava flowed which formed a considerable stream, reaching to a distance

half a mile from the village of Mojo, and then had a breadth of 23 ft. and a height of 32 ft. When the lava stream was examined near its source by the spectroscope, it showed the lines of hydrogen, calcium, sodium, and potassium. Silvestri has embodied his observations in a monograph; he has also just finished an important work, illustrated by photographs showing various phases of eruption of Etna. The work will no doubt be in print before the end of this year.

From Sicily, we pass at one stride to that country of which the Danes say: "God made the rest of the world; the devil made Iceland." A few months prior to the outburst of Etna, Hecla, which had not been in eruption since 1845, showed signs of disturbance, and threw up a hillock about four miles to the N.E. of the Great Crater. A large quantity of very pumiceous lava was emitted, and, at the time when the writer visited it, great quantities of hydrochloric acid were discharged from crevices in the lava, but the eruption was otherwise unimportant.

Since 1872, Vesuvius has been only active at intervals. Palmieri has published a full account of the 1872 eruption, and in annual reports has given the history of the mountain since that date. The eruption of Santorin, which began in January, 1866, and lasted till October, 1870, has furnished results of great interest to vulcanologists, and it has led to the publication of M. Fouqué's magnificent "Santorin et ses Éruptions," in which the whole history of the volcanic phenomena and the products is given. The mineralogical results have been of especial interest. Also we may note the peculiarity that, in the most violent period of activity, inflammable gaseous exhalations, which took fire on coming into contact with red-hot lava, were emitted. The flames, when examined by the spectroscope, were found to consist of hydrogen, containing small quantities of copper, sodium, and chlorine. As the gaseous emanations of Santorin are emitted under water, they are not burned at the point of issue, and can hence be examined readily. As much as 56 per cent. of hydrogen was found in some of the exhalations, and the author concludes, we think without sufficient warrant, that the enormous quantities of water-vapour emitted in volcanic eruptions exist in the red-hot magnia of lava, not as water, but as dissociated hydrogen and oxygen.

The record of recent earthquakes will be fresh in the minds of our readers. Three calamitous earthquakes have occurred within the last eight months—at Ischia, in Chios, and at Agram. In the latter 4,000 persons perished, double that number were maimed, and 30,000 were rendered homeless. It commenced on April 3, but several months afterwards a minaret and a tottering wall were overthrown, and in all there were at least 250 shocks. In 1870, a great earthquake occurred in Phocis, north of the Gulf of Corinth. Professor Julius Schmidt, the Greek Astronomer Royal, has given a detailed account of it. It is asserted that during the first three days a shock was felt every third minute, while Schmidt himself counted nearly 2,000 in the twenty-four hours, four days after the great outbreak. Altogether, during five months of 1870, it is calculated that the shocks and detonations exceeded half-a-million. In October, 1870, the most severe shock of earthquake observed during the present century in the north-eastern states of North America was felt at Quebec. It was instantly telegraphed to Montreal, and the message arrived nearly half a minute before the shock. The Peruvian earthquake of Aug. 13, 1868, was felt the same evening in Hawaii, 6,300 miles distant.

We are as far as ever from the knowledge of the cause of earthquakes, but, undoubtedly, high pressure steam has much to do with it. The author of the article, "Earthquakes," in the July *Quarterly Review*, propounds a theory to the effect that electricity is the true cause, but in what manner he has not clearly defined. We do not consider that his arguments will bear criticism. Here is one of them:—"The vicinity of hot springs, volcanoes, mud lakes, regions of intense heat, and centres of electric influence, are the special haunts of earthquakes, and science has pretty well proved that heat and electricity are convertible."* One word in conclusion as to volcanic products. But few new minerals have lately been found. Professor Scacchi announced two years ago the discovery of a new element, which he termed *vesbium*, among the lavas of Vesuvius, but we have not heard that it has ever been isolated. The most remarkable volcanic product lately discovered is undoubtedly a substance from the crater of Volcano, analysed by Professor Cossa, of Turin. It was found to contain seven non-metals and eight metals, among the latter the rare and recently-discovered elements, cæsium, rubidium, and thallium.

OUR UNBIDDEN GUESTS.

By Dr. Andrew Wilson, F.R.S.E.

PART II.

It is much the same with the tapeworm-tribe as with the fluke (considered in Part I.) The common tapeworm of man (*Tænia Solium*) consists of a very minute "head," attaching itself by suckers and hooks to man's intestines; of a slender "neck," and of hundreds of "joints." Each "joint" is really a semi-independent *animal*; and the tapeworm is therefore a *compound* animal, and presents us with a *colony* of similar beings. A large tapeworm may measure 20 or 30 ft.; and new joints are continually being "budded" out from the head and neck. Hence the physican can never be sure that he has cured a case of tapeworm until he has seen the head and neck of the animal. If a man swallowed the *egg* of a tapeworm, he would not be infested thereby. The young worm has to pass its early life in the body of another warm-blooded animal; and in the case of the common tapeworm, it is "the gintleman that pays the rint," which acts the part of nurse or first host. Man, in other words, obtains his common tapeworm guest from the pig. When this animal swallows the egg of a tapeworm, the young worm bursts through the egg-case and bores its way to the pig's *muscles*. If the porker is affected by numerous embryos, that is, if it has swallowed a large number of *eggs*, it will become feverish and ill, and it will then be said to have developed "measles." The "measles" of the pig are the visitations of young tapeworms. In the muscles of the pig, then, these young worms rest. *Je suis ici; j'y reste*, is decidedly the motto of the young worm. It developes a little head and neck, and it also, by way of a tail, produces a little bladder or bag. Before naturalists knew its true nature, it was regarded as a special kind of parasite, and was named a "cystic worm."

If the pig dies a natural death and is respectably interred, or if the pig should live long enough, these youthful tapeworms will respectively perish, or will degenerate and disappear from the tissues of the aged porker. But assuming that the usual Nemesis of the pig race overtakes the animal, then, in the form of pork, it will gladden the heart of certain members of the human race. Now, let us suppose that a man eats a portion of the "measly pork." Let us further suppose that the pork has been

* The article is utterly without scientific value. How it found its way into a magazine of good position is a mystery.—Ed.

imperfectly cooked; then comes the "tide of fortune" to the young worms. For when the young worm has been eaten by the man, the bladder-tail drops off. Each little head and neck finding itself in the human stomach, recognises its lawful *habitat*. Each attaches itself to the lining membrane of the human intestines, and each by a process of budding produces joint after joint, until man is presented with his matured "guest."

If we tabulate matters thus, the history of the tapeworm will become clear:—

1st Epoch.	Stage 1. The egg derived from parent tapeworm of man. " 2. Swallowed by the pig: developing. " 3. The "Resting Larva," or cystic worm, in the pig's muscles, and forming "measly" pork.	Passed in the pig as host.
2nd Epoch.	" 4. Swallowed by man. " 5. Development of the head and neck, and attachment to man's intestine. " 6. The production by budding of the adult worm.	Passed in man as the host.

As a last piece of parasite biography, we may glance at the history of a form which now and then attracts the notice of even Imperial Parliament itself. This form is the famous *Trichina*, which acquires an unenviable notoriety, in that it may, unlike the tapeworm race, cause the death of its "host." Each trichina is a minute worm, coiled, in its immature condition, within a little sack or bag, which in numbers may be found again in the muscles of the pig. Where the pig gets its trichinæ from is hardly certain, but rats are believed to be the sources of supply for the pig race. In the muscles of the pig each trichina is, as already remarked, in an imperfect and youthful condition. If the pig lives long enough, the trichinæ will disappear from its muscles, or will degenerate to become mere specks of lime. But should a man eat a portion of trichina-infected pork, the youthful worms will undergo, in his digestive system, a rapid and extraordinary development. The trichinæ will develope enormous numbers of young; and the young brood will now naturally seek the muscles of man for a habitation, as their parents before them sought those of the pig. Then ensues the tug of war for the afflicted human. The pain caused by the boring of these microscopic worms from stomach to muscles is intense. It is this pain and attendant symptoms that constitute the disease known as trichiniasis. If the patient's strength holds out, he is safe whenever the young trichina-brood enter the muscles. There they rest, and remain to degenerate—unless, indeed, cannibal instincts were represented in the human race; in which case the cannibal world experience a few of the tortures and troubles which are said proverbially to afflict the just and unjust alike.

The great lesson to the learned, from our survey of parasites, is care in the choice and increased care in the cooking of our food. It should be remembered that the germs of these parasites are killed by a sufficiently long exposure to heat. Hence, whilst underdone meat may have its charms, it has likewise its grave dangers. Pork, in any and every fashion, should at all times be thoroughly cooked. In this latter case, the parasitic horde may not merely be destroyed, but may even contribute in a microscopic way, to human nutrition.

Mr. S. L. M. Barlow, one of the trustees of the Metropolitan Museum of Art, New York, has presented to that institution, through its director, General di Cesnola, a collection of vases lately discovered

SOLIDS, LIQUIDS, AND GASES.

By W. Mattieu Williams.

PART V.

As already stated, in Part 3 of this series, page 88, the conversion of water into steam under ordinary atmospheric pressure demands 966·6° of heat over and above that which does the work of raising the water to 212°, or, otherwise stated, as much heat is at work in a given weight of steam at 212°, as would raise the same quantity of water to 1,178·6° if it remained liquid.

James Watt concluded from his experiments that a given weight of steam, whatever may be its density, or, in other words, under whatever pressure it may exist, contains the same quantity of heat. According to this, if we reduced the pressure sufficiently to bring down the boiling point to 112°, instead of 212°, the latent heat of the steam thus formed would be 1,066·6° instead of 966·6°, or if, on the other hand, we placed it under sufficient pressure to raise the boiling point to 312°, the latent heat of the steam would be reduced to 866·6°, *i.e.*, only 866·6° more would be required to convert the water into steam. If the boiling point were 412°, as it is between 19 and 20 atmospheres of pressure, only 766·6 more heat would be required, and so on, till we reach a pressure which raises the boiling point to 1,178·6°, when the water would become steam without further heating, *i.e.*, the critical point would be reached, and thus, if Watt is right, we can easily determine, theoretically, the critical temperature of water.*

Mr. Perkins, who made some remarkable experiments upon very high pressure steam many years ago, and exhibited a steam gun at the Adelaide Gallery, stated that red-hot water does not boil; that if the generator be sufficiently strong to stand a pressure of 60,000 lb. load on the safety valve, the water may be made to exert a pressure of 56,000 lb. on the square inch at a cherry red-heat without boiling. He made a number of rather dangerous experiments in thus raising water to a red-heat, and his assertion that red-hot water does not boil is curious when viewed in connection with Dr. Andrew's experiments.

I cannot tell how he arrived at this conclusion, having been unable to obtain the original record of his experiments, and only quote the above second-hand. It is worthy of remark that the temperature he names is about 1,170°, or that which, if Watt is right, must be the critical temperature of the water. Perkins' red-hot water would not boil, as he states, being then in the intermediate condition.

So far, we have a nice little theory, which not only shows how the critical state of water must be reached, but also its precise temperature; but all this is based on the assumption that Watt made no mistake. Unfortunately for the simplicity of this theory, Regnault states that *his* experiments contradict those of Watt, and prove that the latent heat of steam does not diminish just in the same degree as the boiling-point is raised, but that instead of this the diminution of the latent heat progresses 30½ per cent. more slowly than the rise of temperature, so that, instead of the latent heat of steam between boiling-points of 212° and 312° falling from 966·6° to 866·6° it would only fall to 895·1° or 69·5° for every 100°.

If this is correct, the temperature at which the latent heat of steam is reduced to zero is much higher than 1,178·6°, and is, in fact, a continually receding quantity never absolutely reached; but I am not prepared to accept these figures of Regnault as implicitly as is now done in text

---

* Watt's own figure for the latent heat of steam at 212° was 950°,

books (I was nearly saying "as is now the fashion"), seeing that they are not the actual figures obtained by his experiments, but those of his "empirical formulæ" based upon them. His actual experimental figures are very irregular; thus, between steam temperature of 171·6° and 183·2° a difference of 11·6°, the experimental difference in the latent heat came out as 4·7°; between steam temperature of 183·2° and 194·8°, or 11·6°, again the latent heat difference is tabulated as 8·0°.

Regnault's experiments were not carried to very high temperatures and pressures, and indicate that as these advance the deviation from Watt's law diminishes, and may finally vanish at about 1,500° or 1,600°, where the latent heat would reach zero, and there, according to the above, the critical temperature would be reached. Any additional heat applied after this will have but one function to perform, viz., the ordinary work of increasing the bulk of the heated body without doing anything further in the way of conferring upon it any new self-repulsive properties.

Our notions of solids, liquids, and gases are derived from our experiences of the state of matter here upon this earth. Could we be removed to another planet, they would be curiously changed. On Mercury water might rank as one of the condensible gases; on Mars, as a fusible solid; but what on Jupiter?

Recent observations justify us in regarding this as a miniature sun, with an external envelope of cloudy matter, apparently of partially condensed water, but red-hot, or probably still hotter within. His vaporous atmosphere is evidently of enormous depth, and the force of gravitation being on his visible outer surface 2½ times greater than that on our earth's surface, the atmospheric pressure in descending below this visible surface must soon reach that at which the vapour of water would be brought to its critical condition. Therefore we may infer that the oceans of Jupiter are neither of frozen, liquid, nor gaseous water, but are oceans or atmospheres of critical water. If any fish-birds swim or fly therein they must be very critically organised.

As the whole mass of Jupiter is 300 times greater than that of the earth, and its compressing energy towards the centre proportional to this, its materials, if similar to those of the earth and no hotter, would be considerably more dense, and the whole planet would have a higher specific gravity, but we know by the movement of its satellites that, instead of this, its specific gravity is less than a fourth of that of the earth. This justifies the conclusion that it is intensely hot, for even hydrogen, if cold, would become denser than Jupiter under such pressure.

As all elementary substances may exist as solids, liquids, or gases, or, critically, according to the conditions of temperature and pressure, I am justified in hypothetically concluding that Jupiter is neither a solid, a liquid, nor a gaseous planet, but a critical planet, or an orb composed internally of dissociated elements in the critical state, and surrounded by a dense atmosphere of their vapours, and those of some of their compounds, such as water. The same reasoning applies to Saturn and the other large and rarefied planets.

The critical temperature of the dissociated elements of the sun is probably reached at the base of the photosphere, or that region revealed to us by the sun-spots. When I wrote "The Fuel of the Sun," thirteen or fourteen years ago, I suggested, on the above grounds, the then heretical idea of the red-heat of Jupiter, Saturn, Uranus, and Neptune, and showed that all such compounds as water must be dissociated at the base of the sun's atmosphere, but being then unacquainted with the existence of this critical state of matter, I supposed the dissociated elements to exist as gases with a small solid nucleus or kernel in the centre.

Applying now the researches of Dr. Andrews to the conditions of solar existence, as I formerly applied the dissociation researches of Deville, I conclude that the sun has no nucleus, either solid, liquid, or gaseous, but is composed of dissociated matter in the critical state, surrounded, first, by a flaming envelope due to the recombination of the dissociated matter, and outside of this another envelope of vapours due to this combination.

THE EVOLUTION OF MAN.

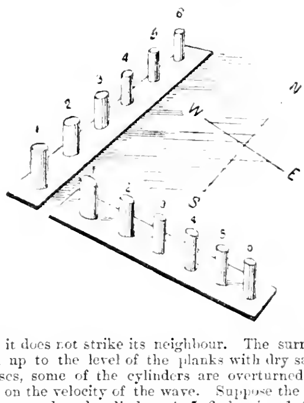
By Dr. A. Wilson, F.R.S.E.

In letter 103, "G. M." asks, "has evolution effected any change in man? If so, what change? If not, why not?" These are weighty questions, and "G. M." will find difficulty in answering them. Let him remember firstly that evolution has only been studied—rather nature, in the light of evolution, has only been studied—for some twenty-five years or so. That is, of course, a mere fractional space in the history of human thought. If we refuse to admit (as science does) that man was created a perfect being, and then became degraded, there exists only another supposition—that of evolution. If man has arisen from a savage to a civilised state, that surely is evolution. We do not yet know, because such knowledge is difficult to acquire, if the human frame is subject to the same influences as those of lower animals. But there is little doubt that elevation from savagery to civilised life means and implies "evolution," and that of considerable extent. Mentally, man's evolution cannot be doubted; the ever-widening sphere of thought has sprung from small and rude beginnings, like language itself. But man's ways of life, his power of adaptation to his surroundings, and countless other circumstances, have made the facts and course of his "evolution" very difficult to trace. If "G. M." will read Tylor's "Anthropology" (Macmillan) he will find there summarised facts and phases of human life which go powerfully to answer the interesting queries he puts to Knowledge.

MALLET'S SEISMOMETERS.

The "Encyclopædia Britannica," 9th edition, "Earthquake," mentions and describes a seismometer of extreme simplicity:—

"Its construction, which is due to Mr. Mallet, will be understood by reference to the figure. Two sets of right cylinders are turned in some hard material, such as boxwood. The cylinders are all of the same height, but vary in diameter. Two planks of wood are fixed to a level floor, one having its length in a north and south, and the other in an east and west direction. The cylinders stand upright on the planks in the order of their size, with a space between each pair greater than their height, so that when one



pillar falls it does not strike its neighbour. The surrounding floor is covered up to the level of the planks with dry sand. When a shock passes, some of the cylinders are overturned, the number depending on the velocity of the wave. Suppose the shock knocks over the narrow-based cylinders 4, 5, 6, leaving 1, 2, 3 standing,

then the intensity of the horizontal component must have been greater than that needed to overturn No. 4, but not great enough to overturn No. 3."

Then follows a formula for determining approximately the velocity—which, perhaps, it may not be necessary to trouble you with.

A. T. C.

THE FAURE ACCUMULATOR.

By W. Lynd.

THANKS to Professor Sylvanus Thompson, who has just sent me the results of his latest experiments with secondary batteries, I am able to give a brief sketch of the Faure accumulator.

So far back as 1860 M. Planté constructed a secondary battery, consisting of nine cells, in each of which two long and wide strips of lead, separated by coarse cloth, were rolled together in a spiral form and immersed in dilute sulphuric acid. A few months later he modified this form by placing side by side in a rectangular box two series of lead plates, alternately connected together, each plate being about eight inches high. He recurred afterwards to the spiral form as being more convenient, but replacing the coarse cloth by narrow strips of gutta-percha. But the cells thus constructed were not ready for immediate action. Two clean lead plates give no current of their own; they are only intended to receive and store up what is sent into them from some external source; and at first, while the lead is bright, when a current is sent through the cell from some suitable source, such as three or four Grove or Bunsen cells, the separated oxygen and hydrogen gases bubble up to the surface, for the most part leaving only a very small percentage as an adherent film, and, in consequence, yielding only very transient secondary currents. The plate of lead by which the current enters is, however, attacked by the oxygen, and becomes covered by a thin layer of brown peroxide of lead, and this film, though thin, is powerfully electro-negative towards metallic lead and towards the film of hydrogen on the Kathode plate. The cell in this condition will therefore produce a current, and in so doing, the peroxide is partially reduced to the metallic condition, and assumes in its reduction a spongy or loosely crystalline texture. If now the cell be again charged, and charged in the opposite direction, the other plate of lead becomes in like manner peroxidised, while the hydrogen bubbles are less freely evolved, for the atoms of gas unite as fast as they are liberated with the oxygen of the peroxide and reduce it to the metallic condition; every time the charging current is thus reversed, the films of peroxide, as of spongy metal, become thicker, until the lead to a considerable depth is bitten into. And every such operation increases, therefore, the power of the cell to store up in this electro-chemical fashion the energy of the currents sent into it. M. Planté ascribes the process of "forming" to a sort of electro-chemical *tanning*. The first day the alternate charging should be done at intervals of a quarter to half an hour, the cell being discharged between each operation. The next day the duration of the alternate charges may be increased from a quarter of an hour to a whole hour; the day after to two hours. After repose for a week or a fortnight, the charges may last several hours; and by the end of several months, the cell will be well "formed;" after which, it should, when used, be charged in one direction only, otherwise the whole thickness of the lead plates will be bitten into, and transformed into peroxide. These magnificent researches were carried on by Planté through more than twenty years, and it seems remarkable that even in the scientific world, that gentleman's claim to the discovery of the accumulator are not duly acknowledged.

M. Camille Faure, who has been awarded by the public press the lion's share of the glory, conceived the idea of constructing a secondary battery, in which, though the tedious process of "formation" is modified and shortened, the ultimate result is the same; namely, to produce upon lead plates, immersed in dilute sulphuric acid, a coating of peroxide of lead that can readily be reduced to the loosely crystalline metallic condition.

The Faure accumulator, of which we have heard so much lately, is simply a modification of the Planté secondary battery, and is constructed as follows:—Eleven sheets of lead, of such thickness as to weigh about 2 lb. to the square foot, are cut to the size of 12 in. by 10 in., an ear-piece being burnt on at one corner. Or six sheets are taken, five of them being twice the above size, and folded double. These are painted thickly with red lead on both sides, and against each side is pressed a piece of felt, the face of which is also thickly coated with red lead, there being about 17 lb. of lead and 23 lb. of red lead altogether. These sheets are placed side by side in a water-tight case, alternate sheets being connected together by the projecting flaps. The cell is filled up with dilute acid, the total weight being about 50 lb.

When thus prepared, the cells are formed by a process of charging by means of the current of a dynamo-electric machine, the current being sent through them for six or seven days without intermission before they are ready for use. The red lead is reduced gradually on one side to the metallic state, and on the other assumes the condition of peroxide; but the cell does not attain its fast condition for some weeks. Such is a brief résumé of the wonderful accumulators which are destined to work a revolution in electrical science. Those who desire to gain a thorough knowledge of the theory of the secondary batteries cannot do better than purchase a copy of Professor Thompson's work on electricity and magnetism. It is published by Macmillan & Co.; the price is only 1s. 6d.

THE WYANDOTTE INDIANS.

By Miss A. W. Buckland.

AS bearing upon the subject discussed in KNOWLEDGE, Are women inferior to men? the account given by Mr. John W. Powell, vice-president of the American Association for the Advancement of Science, of the form of Government among the Wyandotte Indians, will probably be found interesting.

In the Wyandotte Government, says Mr. Powell, four groups are recognised—the family, the gens, the phratry, and the tribe.

The family is nearly synonymous with household. The head of the family is a woman.

The gens is an organised body of consanguineal kindred in the female line. "The woman carries the gens," is the formulated statement by which a Wyandotte expresses the idea that descent is in the female line. Each gens has the name of some animal—the ancient of such animal being the tutelar god.

There are four phratries in the tribe, and this division seems to be used chiefly for religious purposes, in the preparation of medicines, and in festivals and games. The eleven gentes, as four phratries, constitute the tribe. Each gens is a body of consanguineal kindred in the female line, and each gens is allied to other gentes by consanguineous kinship through the male line, and by affinity through marriage. The family or household is not a unit of the gens or phratry, as two gentes are represented in each—the father must belong to one gens, and the mother and her children to another. The civil government belongs of right to a system of councils and chiefs. In each gens there is a council composed of four women. These four women councillors select a chief of the gens from their brothers and sons, and this chief is the head of the gentile council. The tribal council is composed therefore of one-fifth men and four-fifths women.

The four women-councillors of the gens are chosen by the heads of households, themselves being women. There is no formal election, but by frequent discussion it is decided that, in the event of the death of any councillor, a certain person will take her place. When a woman is installed as Councillor, a feast is given by the gens to which she belongs, to which all the members of the tribe are invited. The woman is painted and dressed in her best attire, and the sachem of the tribe, who is chosen by the chiefs of the gentes, places upon her head the gentile chaplet of feathers, and announces in a formal manner to the multitude, that the woman has been chosen a councillor.

The gentile chief is chosen by the council women, after consultation with the other women and men of the gens. At his installation, the council women invest him with an elaborately ornamented tunic, place upon his head a chaplet of feathers, and paint the gentile totem on his face.

Meetings of the gentile council are very informal, but the meetings of the tribal councils are conducted with due ceremony. The chief of the wolf gens, who is of right the herald and sheriff of the tribe, calls the assembly to order, fills and lights a pipe, sends one puff of smoke to heaven and another to the earth. The pipe is then handed to the sachem, who, filling his mouth with smoke, and turning from left to right with the sun, slowly puffs it over the heads of the councillors, who are sitting in a circle. The pipe is then smoked by each person in turn. The sachem then explains the object of the meeting, and each person tells what he thinks should be done. If the majority agree, the sachem simply announces the decision; but if there is a tie, the sachem is expected to speak.

It is the function of government to preserve rights and enforce the performance of duties.

These rights are:—1, Rights of marriage; 2, Rights to names; 3, Rights to personal adornment; 4, Rights of order in encampments and migrations; 5, Rights of property; 6, Rights of person; 7, Rights of community; 8, Rights of religion.

Marriage between members of the same gens is forbidden. Polygamy is permitted, but the first wife remains the head of the household. A man seeking a wife consults with her mother, and the mother of the girl tries to obtain the consent of the women council-

dies, the children belong to her sister or nearest female kin, the matter being settled by the council women of the gens. Once a year the council women of the gens select the names for the children born during the year, and the chief of the gens proclaims them at the festival. No person may change his name, but by honourable conduct he may win another.

Within the tribal area, each gens occupies a tract for cultivation. The women councillors partition the gentile land among the householders. The ground is repartitioned once in two years. Cultivation is communal, that is, all of the able-bodied women of the gens take part in the cultivation of each household tract.

The wigwam, or lodge, and all the articles of the household belong to the woman—the head of the household; and at her death are inherited by her eldest daughter or nearest of female kin. The matter is settled by the council women. If the husband die, his property is inherited by his brother, or his sister's son, except such portion as may be buried with him. His property consists of his clothing, hunting and fishing implements, and such articles as are used personally by himself. Usually a small canoe is the individual property of the man. Large canoes are made by the male members of the gentes, and are the property of the gentes.

Each gens has a right to the services of all its women in the cultivation of the soil. Each gens has the right to the service of all its male members in avenging wrongs, and the tribe has the right to the service of all its male members in time of war.

This is a short abstract of Mr. Powell's paper, as far as it relates to the status of woman among the Wyandottes, and I feel sure it will be a surprise to many to find that the despised Indian squaw holds a position so honourable; one to which her civilised white sisters may never hope to attain; but the truth is, we find here, among the Wyandotte, the survival of a social state once very widely spread, and which probably existed wherever we find kinship traced on the female side—that is, through the mother instead of the father. It was, perhaps, the earliest of all forms of government, especially among people of Mongoloid affinities. Among the Semites, the government was patriarchal and paternal; but even among the Hebrews, we find prophetesses, possessed of no small amount of authority. It remained for the Aryan races to deprive woman of every shred of real power, whilst professing to treat her with chivalrous deference, and it is to this probably that we may attribute the diminution in the size of the heads of women in modern times, as compared with those of men—a difference which is not to be found in the more ancient skulls, as the late Professor Rolleston and other able anatomists have so often pointed out; and which it might be safely affirmed would not be found among the Wyandotte councillors; for there can be little doubt that the brain develops by use, and that in a tribe or nation wherein the burden of government is divided between the sexes, there will be no disparity in the brain power of men and women, nor in the skulls wherein those brains are contained.

NOTE ON THE SPHEROIDAL STATE.

By W. F. Barrett, F.R.S.E.

(Professor of Experimental Physics in the Royal College of Science, Dublin.)

In a paper read before the Royal Dublin Society, Mr. G. Johnstone Stoney has given a new and beautiful explanation of the so-called spheroidal state of liquids, wherein he showed that the force detected by Mr. Crookes, and which is the cause of the motion of radiometers, was also competent to explain the phenomena of the spheroidal state. A liquid drop is said to be in the spherodial state when falling upon a hot body it does not come into contact with the surface but rolls over it as a flattened spheroid. A mobile elastic spring evidently buoys up the drop until such times as the hot body cools, when, with a sudden rise of temperature and generation of steam, the drop comes into contact with the surface below it, spreads out into a film, and rapidly disappears into vapour.

Hitherto this phenomenon has been regarded as due to the fact that the proximity of the hot surface converts a portion of the liquid into vapour, the elastic force of which sustains the drop. There are, however, several phenomena, applied to the spheroidal condition, to which this generally received explanation gives no solution,—such, for example, as the mobility of light powders in a hot crucible, or the formation of globules on the surface of water and other liquids. Mr. Stoney's explanation, on the other hand, embraces the whole of these outstanding and hitherto enigmatical phenomena. Briefly stated, this theory is based on the fact that whenever two bodies at *different temperatures* are brought sufficiently near each other, a modification takes place in the molecular structure of the layer of gas or vapour between them, given rise to the so-called "Crookes' force," wherein there is an excess of pressure in the direction joining the hot and cold surfaces over the pressure in transverse directions. Now this excess of pressure depends partly on the quantity of heat making its way across the intervening layer of gas or vapour, and partly on the proximity of the two surfaces,—a proximity not to be estimated absolutely, but with reference to the length to which a molecule of the gas will travel in the intervals between its encounters with other molecules. Hence there are obviously three modes whereby the excess of pressure, this Crookes' force, may be developed or augmented:—

1st. By lengthening the paths of the molecules between the warm and cool surfaces, accomplished by attenuating the gas.

2nd. By bringing the hot and cold surfaces very near together.

3rd. By increasing the difference of temperature between the two surfaces.

Now if the support of the spheroidal drop be due to this Crookes' force a difference of temperature must exist between the drop and the surface over which it stands, and the greater this difference of temperature the larger the drop that ought to be supported, and the more persistent the phenomenon. Mr. Moss has shown (Proc. R. D. S., Dec., 1877) that by securing a continual difference of temperature a globule of ether may be supported on the surface of its own liquid for upwards of an hour, until in fact some accidental derangement occurs. The conditions of the two theories being thus defined, it is easy to see that several crucial experiments might be devised which should help to decide the question at issue.

The following experiment the author has made with this object in view. Upon the surface of the ordinary petroleum of commerce, liquid globules of transient duration can readily be formed, simply by removing a small quantity of the liquid in a pipette and carefully depositing a drop on the surface of the liquid. These drops are clearly in the spheroidal condition, and they are easily and abundantly formed by dipping a vibrating tuning-fork into the liquid, or by drawing a fiddle bow over the edge of the vessel containing the liquid. According to the ordinary explanation the drops are supported by the elastic force of the vapour of the liquid, which would, of course, be greater the higher the temperature of both liquid and drops. According to Mr. Stoney's theory the drops are supported by the Crookes' force, generated by the proximity of the drop and liquid, and by the fact that they are at different temperatures. Evaporation rapidly cools the drops jerked up from the liquid, and thus a slight difference of tempera- instantly comes into play. If, however, Mr. Stoney's theory be true, then a drop of cool petroleum would be more easily and longer sustained on a surface of warm petroleum, or *vice versâ*, than a drop taken from the mass of liquid below it, where only a slight temperature difference is created.

Two beakers were filled with petroleum from a common source, one (A) at the temperature of the air, the other (B) at a temperature of 100° F. With a pipette some liquid was taken up from A and a drop carefully deposited on its own surface, a globule was formed, floated for a fraction of a second, and then disappeared. The same occurred with a drop from B placed upon B. A drop of B was now removed and deposited on A, a large globule was easily formed on the surface, floated about from 10 to 20 seconds, and then disappeared. A drop of A was now placed on B, the same thing occurred, but the duration of the drop was not quite so great, owing to the greater density of the cool drop tending to sink it below the surface of the warm liquid, thus rapturing the Crooke's layer and destroying the difference of temperature.

There is no doubt or uncertainty whatever about this experiment, and it shows that, if the ordinary explanation be correct, the second case, where B rests on B, should give the best result, whereas the reverse is the case. Further, the experiment wherein the best result is obtained, is such as best fulfils the condition of Mr. Stoney's theory.

The limit of formation of these spheroids, when the liquid is uniformly dropped through a gradually-increasing height, may be employed to test the relative degrees of force which sustain the globule, and careful experiments made by the author in this direction still further corroborated the truth of Mr. Stoney's views.

The Light of the Stars.—For a number of years the special work carried on at the Harvard Observatory, under the direction of Professor Pickering, has been the measurement of the intensity of the light of the heavenly bodies. Some of the results presented at a recent meeting of the Society of Arts, at the Institute of Technology, Boston, indicate measurements almost incredibly fine. The light which falls upon the earth from the satellites of Mars, for example, is about equivalent to what a man's hand on which the sun shone at Washington would reflect to Boston. The labour of measuring the brightness of all the visible stars was begun two years ago. It has since gone on at the rate of about 40,000 a-year, and will be completed next fall.—*Scientific American.*

AN INSTRUMENT FOR DRAWING THE CONIC SECTIONS.

By Thomas Thorp.

THE instrument shown in the accompanying sketch, Fig. 1, may be used for tracing figures of the conic sections. It is quite original, I believe, and can be made without any great difficulty.

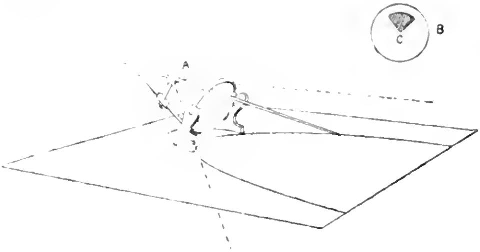


Fig. 1.

The rod through the ball and socket joint at A should be as enlarged at B, the edge in line with the scribing-point being exactly central, as shown at C.

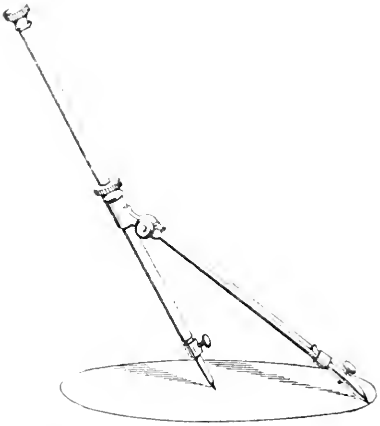

Fig. 2.

The instrument is sketched as describing a parabola, but is equally suited for any other of the conic sections. Further details if required.

For describing ellipses, the instrument shown, Fig. 2, is extremely useful, and may not be known to many of your readers.

Our Next Number. We have been obliged to defer to next week two illustrated articles, one by a "Fellow of the Royal Astronomical Society," on Work with a Small Telescope; the other by the Editor, on the Great Pyramid. In compliance with the wishes of many readers, the star maps, which have hitherto appeared weekly, will be combined into a single map (on the same scale), which will appear in the first week of each month. In the other weeks some subsidiary maps will be given, illustrating the motions of the heavenly bodies during the month. There will also be given each month a paper dealing with star names, constellations, figures, &c. — Ed.

Errata.—The comet referred to in Mr. Denning's letter of last week (letter 122, p. 140), was not the one which bears his name (comet *f*, 1881), but comet *g*, 1881. The letter *g* was misread. In Reply to 55, p. 136, last line but one, [illegible]

Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of Knowledge; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

**** All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.*

All Letters or Queries to the Editor which require attention in the current issue of Knowledge, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

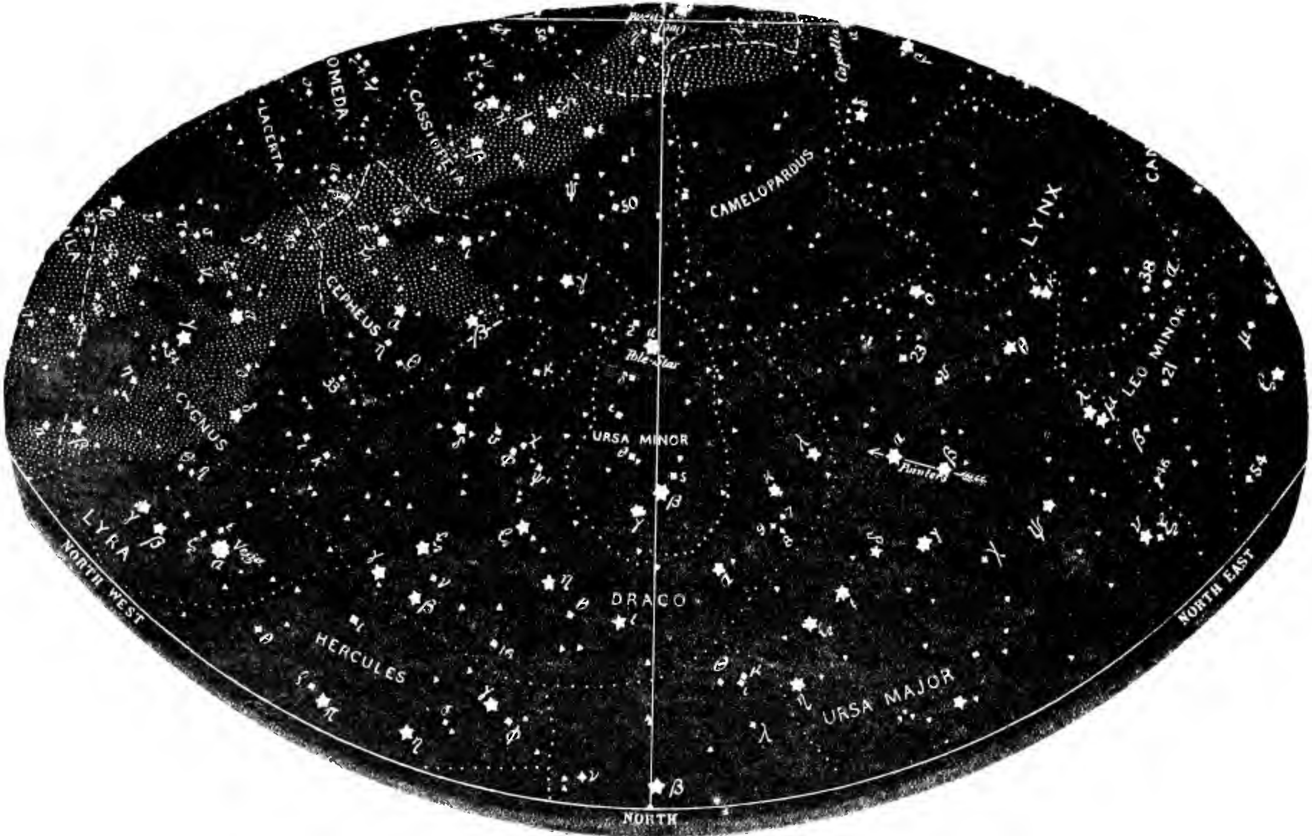
Our Correspondence Columns.

PLANS FOR THE NEW YEAR.—DARWIN AND DESIRE.—SPIRITUALISM.—PLANETS HIDING STARS.—VIBRATIONS OF LIGHT IN ÆTHER.—VECTORS VESTIGES OF CREATION.—NEWSPAPER SCIENCE.—THE GREAT PYRAMID.

[136]—With the first number of the year 1882 we shall somewhat modify our plan, experience and the suggestions of many correspondents having shown that some features which we have not yet introduced would be desirable, and that others which we had thought desirable are either not so, or inconsistent with some presenting greater advantages. The task of selection is not altogether easy. We have been reminded much of the old man with his donkey and two sons in the fable, whose fate, it will be remembered, when he tried to please every one, was to be thrown into the river, along with his three companions. We are urged—(1) to widen our space for correspondence; (2) to keep out correspondence; (3) to encourage paradoxers to disport themselves in our pages; (4) to silence them utterly; (5) to explain simply the principles of every science on the face of the earth, all at the same time; (6) to leave all such explanations to text books; (7) to increase our size; (8) by no means to do so; (9) to publish all the four maps for the month at the beginning of each month; (10) to publish them weekly, as we do, but with a page or two of explanation, &c.; (11) to have the stars punched out of the paper; (12) to have the names of all the stars; (13) to have as little writing on the maps as possible; (14) to leave out the small stars; (15) to letter them as well as the others; (16) to give also weekly zodiacal maps, with paths of planets, moon, comets, &c.; (17) to announce all astronomical phenomena; (18) to remember that the almanacs do that for us; (19) to have more astronomy; (20) to have less astronomy; (21) to be rather less simple; (22) to be more simple; (23) to give reports of societies; (24) to give digests of reports; (25) to give no reports at all; (26) to announce meetings of societies; (27) to devote space to no such purpose; (28) to limit the mathematical column to the discussion of really difficult problems; (29) to use it to explain matters for beginners; (30) to omit it altogether; (31) to extend the whist and chess columns; (32) to shorten them; (33) to leave them out; (34) to have exchange columns, sixpenny sale columns, &c.; (35) to have none of these; (36) to offer prizes, have essay columns for girls and boys, &c.; (37) to eschew such allurements; (38) to have longer articles; (39) to let no article exceed a page, and few be longer than a column; (40) to have articles on ancient philosophy, modern scientific biographies, art and the drama, puzzles, enigmas, hints for collectors of shells, medals, seaweed, &c., &c., &c., *ad infinitum*. To all which, all that we can reply is that we will do our best to please the greatest number.

Mr. Newton Crosland, accusing me of verbal shuffling, claims from me an apology. Darwin, he says, does speak of the "endeavour," though not of the "desire," of the rattlesnake to frighten away its enemies; and the two mean the same. Truly they differ little; but what Mr. Crosland said was that "Darwin attributed the

THE NORTHERN SKIES IN DECEMBER.



This Map shows the position of the stars in the Northern Skies:—

n November 30, at 10½ o'clock.	On December 8, at 10 o'clock.	On December 16, at 9½ o'clock.	On December 23, at 9 o'clock.	On December 30, at 8½ o'clock.
n December 4, at 10¼ o'clock.	On December 12, at 9¾ o'clock.	On December 19, at 9¼ o'clock.	On December 27, at 8¾ o'clock.	On January 3, at 8¼ o'clock.

The stars in the northern skies are carried from left to right under the pole, and from right to left above the pole, descending to the left or west of the pole, and ascending to the right or ast of the pole. They are carried, in fact, round the pole in a direction contrary to that in which the hands of a watch move.

*** Stars of the first magnitude are shown with eight points, those of the second with six, of the third with five, of the fourth with four, of the fifth with three.

Continued from page 160.]

evolution of the rattlesnake to the desire—or endeavour—of the animal to frighten its enemies," and it is just here that he misunderstands Darwin. The theory he attacks is Lamarck's, not Darwin's. Darwin and Lamarck may agree in saying that the rattlesnake uses his rattle with the desire (or in the endeavour) to frighten its enemies; but whereas Lamarck attributed to such desire or endeavour, and the resulting "habit," the development of the rattlesnake, Darwin would do nothing of the sort (rather attributing the habit to the development). If Mr. Crosland will read Darwin's remarks on the views of Lamarck (preface to "Origin of Species," and elsewhere), and remember that Lyell became a convert to the general theory of evolution only when the Darwinian theory replaced Lamarck's, he will see that there is an important difference between the two. Mr. Crosland's diatribe on Dr. Darwin would only be permissible if he had been violently and personally attacked by that eminent geologist, which, I take it, has not happened. May I venture to remark that if Mr. Crosland thought me really guilty of shuffling, he would not "expect to receive an apology from me." He has quite wrongly accused me of shuffling, but I do not want an apology, and certainly I do not expect one.

"Tentative" thinks we do wrong in excluding spiritualism. He thinks it would be "a great gain if we would encourage a searching inquiry into the causes, electric or other, of the singular mind problems continually presented to us." We will do so, by publishing the first scientific results of such inquiries which may reach us. A story he relates seems to illustrate only the effect of an excited imagination.

Ebenezer Kelby writes respecting my remarks about the Great Pyramid, that if certain singular coincidences were noted, and those who had noted them were told it was mere accident, they would say, with a sceptical sneer, "it is a very strange accident," and many readers of KNOWLEDGE say the same of my "opinion with regard to Mr. Baxendell's wonderful calculations showing the wonderful correspondence of pyramid measures with astronomical data." If Ebenezer Kelby will wait awhile, he may find I can give reasons for my remark that the very closeness of some of the coincidences noted by Mr. Baxendell, and of some other coincidences which he has not mentioned, disproves the argument from coincidence.

"O. R. B." asks why occultations of stars by planets, which must be continually occurring, are not alluded to or tabulated? They occur far less often than he imagines. Very few are recorded, and still fewer have been properly observed. I know, indeed, of only one really satisfactory case, viz., the occultation of a sixth magnitude star in Aquarius by Jupiter, well observed by Ellery and Turner with the great Melbourne reflector. The star disappeared gradually, and was visible (just before it disappeared) at a depth of more than 500 miles below the apparent surface of Jupiter—doubtless, therefore, through a great range of the planet's cloud-laden atmosphere. "O. R. B." is mistaken in supposing the size of a star could be determined by noting how long it was in disappearing behind the comparatively slow-moving planet. If a planet's outline were sharply defined, the disappearance even of the largest and nearest star would be to all intents and purposes instantaneous.

"Practical" sends an interesting letter on the use of flesh meat, which shall appear as soon as we can find space for it.

"G. P." asks how it is that if the elasticity of the æther is almost infinite, vibrations set up in it by solar influence have such short duration? Why should darkness so soon follow sunset? The vibrations may be compared to those on the surface of water. When a stone has been thrown into water, the vibrations travel all around, ceasing first at the place where they began, and thence all round as the wave circle expands. The elasticity of the water shows itself in the wide expansion of the wave circle, not in the continuance of the oscillation at any point or points traversed by the wave. So with the æther of space, its elasticity is shown by the great distances to which light travels without appreciable extinction. The æther cannot at the same time carry on the light impulse from each point passed, and continue its vibrations there. Another question by "G. P." has not been answered, that respecting the use of vectors in Maxwell's little book on Matter and Motion. I venture to express the opinion that in a work of that kind, the use of vectors is as entirely out of place as the use of Latin and Greek technical terms would be in a treatise on domestic medicine. To the mathematician, vectors are of use to shorten reasoning and simplify statements, precisely as technical terms are of use in science. But they should have no place in elementary treatises.

We have received many letters besides those published, relating to the "Vestiges of Creation." Pressure on our space, and the comparatively small importance of the subject, prevents our publishing these. It is well known that Robert Chambers was the author of the work, but that he had excellent reasons when he wrote it, and during many years after, for not desiring to acknowledge that it was his. Lyell, in his Antiquity of Man, says of the work, that "written in a clear and attractive style, it made the English public familiar with the leading views of Lamarck in transmutation or progression, but brought no new facts or original line of argument to support those views, or to combat the principal objections which the scientific world entertained against them." Darwin says, "from its powerful and brilliant style, the work, though displaying in its earlier editions little accurate knowledge, and a great want of scientific caution, immediately had a very wide circulation; in my opinion it has done excellent service in this country in calling attention to the subject, in removing prejudice, and in thus preparing the ground for the reception of analogous views." Lieut.-Col. Ross writes us that he has overwhelming evidence to show that Sir C. Lyell *must* have written it; but Lyell opposed the Lamarckian hypothesis; also that Chambers could not have written it, but in the later years of his life Chambers acknowledged to many that he had done so. A.T.C., Eclecticus, and others, have written very fully on this subject. "Eclecticus" regards Darwin's work as a fit and complimentary (query complementary) sequel to the "Vestiges," which reads to me very much as though one should say that Newton's "Principia" was a fit sequel to Kepler's "Prodromus." The question of scientific value, be it understood, is not as between the work of Darwin and Chambers, but as between the theory of Lamarck and that of Natural Selection.

It is pointed out by a writer, who desires that his name may not be published, that a newspaper paragraph recently commented upon in our columns somewhat unfavourably, correctly represented the statements of a French chemist in the *Comptes Rendus*, and that newspaper science does not deserve all the vilification it receives. As I have myself written a good deal about science in the newspapers, I need hardly say that I am not disposed to regard *all* newspaper science as unsound. Still, it remains true that newspaper science cannot be regarded as trustworthy, simply because the general reader cannot distinguish the sound from the unsound, and has no means of ascertaining to whom particular statements are due, while it is well known that some editors of leading daily papers have themselves no knowledge whatever of science, and would as soon insert a column of utter nonsense, if foisted on them as the work of a known science student, as the most carefully-reasoned article by a Darwin, a Tyndall, an Airy, or a Huxley. From my own experience I know that many newspaper editors have no idea whatever of the progressive nature of science. Articles which I have written, the appearance of which has been delayed for one reason or another, would have been inserted just as they were written, had I not insisted on the proofs being sent to me for changes rendered necessary by the lapse of time. In one case, an article which I wrote for the *Times* immediately after the eclipse of June, 1878, was recast by me in this way several times, at great cost of labour, until at last, when I left England for America in the autumn of 1879, I gave up further attempts to make the article fit for reading at the time of publication. I had supposed my labour lost, but, to my horror, I saw that very paper quoted in an American newspaper in December, 1879, and thus first learned that at last it had appeared in the *Times*. Other papers were delayed with the intention of eventually using them, until, at last, I gave up all idea of their being patched into fitness for later dates. Some articles I have seen in the daily papers suggest to me, by their time-worn aspect and other evidence of decrepitude, that all writers are not honest enough to remind the editor of the deterioration a scientific article is undergoing as time passes (or has already undergone), preferring that an article should appear long after it has ceased to have any value than that they should lose the money which is only paid after an article has appeared. In America, the editors of leading papers adopt a plan which is at once more sensible and—in my judgment—more honest, making the question of payment (so my esteemed friend, the editor of the *New York Tribune*, tells me) independent of the use of an article which has been accepted and sent in type to an author for correction. This surely is better than the system of some of our English leading papers (the *Times* amongst others), by which an unskilful editor, after inviting and accepting more contributions than he can find room for, calmly suffers the loss to fall on the authors, and selectively on those who may be honest enough to tell him that their papers no longer have the value they originally possessed. It is because all writers are not careful to do this that we so often see old truths presented as novelties, and exploded errors presented as accepted truths, in our daily papers.

Mr. Baxendell has written a letter, in reply to Mr. Ranyard's remarks, letter 85, p. 113. We would insert the letter, though it does little more than express Mr. Baxendell's unchanged confidence in his views, were it not for passages showing that Mr. Baxendell has entirely misapprehended Mr. Ranyard's remarks respecting fortune-telling, weather prediction, alchemical promises, and so

forth. Mr. Ranyard, we are sure, had no thought of citing Mr. Baxendell as an example of the objectionable class of science workers (or rather of persons who want to work science) to whom he referred. Mr. Ranyard's letter has been regarded by quite a large number of correspondents as unduly considerate towards paradoxers, while others consider it as very gentle towards them, but not unwarrantably so. RICHARD A. PROCTOR.

SIR RICHARD PHILLIPS.

[137]—"Delta" offers to send weekly paragraphs, giving startling and important theories propounded by Sir Richard Phillips, which he believes would be read and studied with profound interest by readers of KNOWLEDGE. After reading the specimens "Delta" forwards, I decide that only one paragraph relating to Sir R. Phillips shall appear in these columns so long as they are under my charge. It is not one of his own writing, but by the late Professor De Morgan, and runs thus:—

"Sir Richard Phillips had four valuable qualities—honesty, zeal, ability, and courage. He applied them all to teaching matters about which he knew nothing, and gained himself an uncomfortable life and a ridiculous memory." RICHARD A. PROCTOR.

RETROGRADATION OF A PLANET.—ORRERY.—SOLAR HEAT.—ASTRONOMICAL SLIDES.—DENSITY OF NEPTUNE.—VULCAN.—THE GRAVITY OF SIR R. PHILLIPS.—PLANETARY RINGS.—THE GREAT BEAR.—SIRIUS AND ORION.—ALGOL AND MIRA.—STAR LETTERS AND NUMBERS.—NEW STAR IN CASSIOPEIA.—VENUS IN SUNSHINE.—VELOCITY OF LIGHT.—EVOLUTION.—RAINBOW.—SOLAR STORMS.—ANTIQUITY OF THE PYRAMIDS.—MENTAL PHYSIOLOGY.—THE ANTIQUITY OF MAN.—TOADS.

[138]—As no one, so far, appears to have replied to the Query (17) of "Astronomicus," on page 60, perhaps I may say, shortly, that the seeming retrogradation of a planet is a differential phenomenon, arising from the fact that the earth moves less rapidly in her orbit and describes a larger ellipse than the interior planets Mercury and Venus; and more rapidly than those exterior to her—Mars, Jupiter, Saturn, Uranus, and Neptune, whose orbits must obviously increase in size as they recede from the sun. If "Astronomicus" will describe a series of concentric circles to represent the paths of the planets, and suppose them to travel round such circles in a direction opposite to that of the hands of a watch, and at rates proportioned to their periodic times (to be obtained from any Primer of Astronomy whatever), he will soon see how, taking the case of Mars, for example, when the earth is between that planet and the sun, she, as it were, overtakes him. Evidently in doing so Mars will appear to go back, as it were, among the infinitely distant stars; as will, in a similar manner, the planets outside him when in and near opposition. So far the appearance of retrogradation may be called subjective. I may now add, what I abstained from saying in connection with Mercury and Venus, for fear of confusion, that they have also an objective movement of retrogradation, when they come between the sun and the earth, as your correspondent may see from his own figures. Mars is the planet which describes the largest retrograde arc, the reason for which will also be apparent from his diagram.

"Vulcan" (query 29, p. 80) may see an orrery at South Kensington.

If "Warmus" (query 30, p. 101) possesses a pair of compasses, he may clear up part of his difficulty by constructing a simple figure; or he may even do so by the aid of a bronze halfpenny. Let him, then, describe a circle one inch in diameter, and from the top and bottom of this draw two parallel straight lines, between which he may rule as many more as he likes strictly parallel to them. These he may take to represent the sun's rays. Now, let him get a strip of card one-inch long, and hold it square across his series of lines. Obviously they will all fall upon it. If, however, he holds it slantingly across them, he will see that fewer and fewer of them touch it as its obliquity increases. Now this is just what happens on the earth. Within the tropics, where the sun is always somewhere overhead, all his rays fall square to the observer's horizon. Where, however, as in high northern and southern latitudes, the sun never, even at noon, reaches any great elevation above the horizon, his rays necessarily fall obliquely, and we receive comparatively few of them. With reference to the concluding part of "Warmus's" question, the gentleman who gets tanned by the sun in a tropical country has his complexion spoilt by the direct and immediate action of the sun on the *rete mucosum*, or under layer of the skin. It is this that sunlight enters directly, and not the earth first!

If "C. J. S." (query 33, p. 101) only wants his slides for one night, he will find that patent plate glass, densely smoked by burning camphor, will give him an absolutely opaque ground, on which very effective diagrams may be made by the aid of etching and sewing needles and compasses with a needle point. He must gum a little bit of paper on before smoking his slide, as a centre for one leg of the compasses to rest on, as otherwise they slide about the glass and make undesirable lines and scratches.

Assuming that we are looking at the outline of the *solid body* of Neptune, then I may tell "S. S. S. S." (query 38, p. 101) that his density must be something like 0·96; that of water being 1. Only one satellite is known. Its period is 5 d. 21 h. 3 m.

In answer to "S. S." (query 41, p. 101), there is a practical concensus of opinion among astronomers that Vulcan has no existence whatever. I am not denying that there may be a planet, or planets, between Mercury and the Sun, but the pseudo-observation of Lescarbault was sufficiently definite to enable computers to calculate the orbit of the alleged body. This having been done, it *must* have reappeared on the sun's disc on several occasions since, when the most skilled observers, employing powerful instruments, have wholly failed to see anything. It is the "Mrs. Harris" of the solar system.

"Meter" (query 45, p. 101) appears to be unaware that scientific men pay about the same kind and amount of attention to the lucubrations of Sir Richard Phillips that they do to those of, say, "Parallax," or Mr. John Hampden.

The same correspondent (succeeding query) should buy and read "Saturn and its System," by the Editor of this journal.

Mr. St. Clair (query 57, p. 101) will find that the principal stars in the Great Bear all set in latitudes below 25° North. The second part of his query is, in one sense, meaningless; because in the case of a circum-polar constellation, what is east below the Pole, becomes west above it, and *vice-versâ*; but, in the sense that the right ascension of Benetnasch exceeds that of Dubhe by some 2 hours 47 minutes, of course the latter star is the westernmost, as by "longitude" your correspondent obviously means right ascension. I may say that Ursa Major straggles over six hours in the sky, as nearly as may be from *o* on one side to Σ 1830 on the other. I quite fail to understand the meaning of the constellation having "a cycle of 2,700 years;" nor am I in any better position to clear up the difficulty as to the supposed connection between Sirius and either Ursa Major or Minor.

In answer to query 58, p. 102, Sirius was one of Orion's hounds, but that it was ever placed on the "shoulder" of the giant is news to me.

The great comet spoken of by "S. C. H." (query 61, p. 102), has no other designation than comet *b*, 1881. Its orbit was seemingly parabolic, and the parabola—as "S. C. H." doubtless knows—is a curve which does not return into itself.

"S. C. H." (query 62, same page) will find Algol marked on the map on p. 97. It is in the head of Medusa.

"F. H. S." (query 63, p. 102) asks when Algol and Mira are at their brightest? In the case of the first-named star, he should rather ask of the date of its minimum, inasmuch as it shines as a star of the second magnitude for about 2d. 13h., diminishes to the fourth in three or four hours, remains as a fourth magnitude for about twenty minutes, and again increases in brightness until it regains the second magnitude. It passes through the entire cycle of its changes in 2d. 20h. 48m. 55s. For its next minimum, "F. H. S." must really watch for himself. Mira Ceti should attain its next maximum about June 16 or 17, 1882.

Stars, I may say, in answer to query 64 (p. 102), are both lettered and numbered in their order of right ascension.

By the periodical star, concerning which "F. H. S." puts his next query (65), his informant probably meant to imply that if the one which blazed out somewhere about RA 0h. 19m., and Dec 63° 24' N. in November, 1572, was identical with those which appeared in or near the same spot in 945 and 1264, it may possibly soon reappear now.

Next, I would tell him (query 66) that Venus is always visible to the naked eye in bright sunshine to anyone who knows where to look for her—at and about the time when the *Nautical Almanac* gives the intimation "♀ at greatest brilliancy."

It may be worth while to remark, in connection with letter 100 (p. 116), that the latest and best determination of the velocity of light, gives it as 186,380 miles a second. Hence, as the pace of the fastest express never exceeds sixty miles an hour, it must travel $\frac{1}{60}$th of a mile in a second, so that the velocity of light must be in reality about 1,118,000 times that of the train.

Mr. Mitchell (letter 107, p. 117) might advantageously study Professor Huxley's lecture on the convincing evidence, from fossil remains, of the direct descent of the horse from the Hipparion, delivered before the Zoological Society in December, 1880.

"G. S. M." (query 67, p. 122) should read Tyndall's "Six Lectures

on Light," published by Longmans, for an explanation of the rainbow. It is too long to give here. Unless the same correspondent (query 68) knows something of the theory and action of the spectroscope, I am afraid that he will not be much wiser when I tell him that the velocity of solar storms is measured by the displacement of certain lines in the spectrum of the sun's surroundings.

I am not familiar with Rawlinson's researches in Egyptian history, but "Actinolite" (query 72, p. 122) will find an exhaustive argument in Bunsen's "Egypt's Place in History," tending to fix the date 3620 B.C. as that of the Pyramids.

"S. S. S. S." (query 79, p. 122) cannot possibly do better than get Carpenter's most interesting and amusing "Mental Physiology."

The researches of Mr. Horner, concerning which "Clio" puts query 84 (p. 123), were undertaken between the years 1851 and 1854, partly at the cost of the Royal Society, but mainly at that of the Viceroy, Abbas Pacha. No less than ninety-five shafts were bored through the alluvium of the Nile Valley, through sediment which the French engineers calculate is formed at an average rate of 5 inches in a century. At depths varying from 16 to 24 feet, "jars, vases, pots, and a small human figure in burned clay, a copper knife, and other entire articles were dug up." "Pieces of burnt brick and pottery, Sir Charles Lyell moreover tells us, were extracted almost everywhere, and from all depths, even where they sank 60 feet below the surface." If then we divide 60 feet, *i.e.*, 720 inches, by 5, we get 144, and as the estimation of the French engineers appears entirely trustworthy, that 5 inches of Nile alluvium are deposited in a century, this shows that pottery and brickmaking were practised by the Egyptians at least 14,400 years ago.

In connection with query 87 (p. 123), I should like to put one myself. *Do* toads ever exist "for many years, enclosed in blocks of solid matter?" I fear that "Arachnida" is the victim of the "Great Gooseberry" column of some local newspaper.

A Fellow of the Royal Astronomical Society.

"THE COMMON STAR-FISH, CROSS-FISH, OR FIVE FINGERS (*URASTER RUBENS*, LIN., AG.), OCCASIONALLY THE FOOD OF THE SUN-STAR (*SOLASTER PAPPOSA*, LIN., FORBES)."

[139]—Sir John G. Dalyell, in his excellent work, "The Powers of the Creator displayed in the Creation" (Vol. i., p. 3), in speaking of the common sun-star, states that "the fishermen believe that this animal devours the *Asterias glacialis*" (*Uraster glacialis*, Ag., Lin., Spiny Cross-fish). I am able to confirm this assertion, so far, at least, as it relates to the closely-allied, but far more common species, the *Uraster rubens*, or common five-fingers. Whilst on a visit for some weeks at Colwyn Bay, North Wales, during the months of September, October, and November last, I had ample opportunities of observing some of the habits of the sun-star, great numbers of which I found amongst the sea-tangle (*Laminaria*) beds, which, forest-like, waived their fronds in the tidal waters close to the fishery weir at Rhos, in the possession of Mr. Parry Evans. At the time of the low equinoctial tides, this locality abounded in specimens of *Solaster papposa*; it was the commonest species present. I could have collected wheel-barrows full. Of course, the common star-fish, or five-fingers, was there also—it has "a finger in every pie"; but it did not abound to the same extent as the sun-star. Here and there I met with *Cribellæ*, both *Oculata* and *Rosea*, as well as other members the Asteroidean and Ophiuridean order of the Echinodermata. It was a very common thing to notice within the stomachs of the larger individuals of *Solaster*, rays of the five-fingers; sometimes there were two, but more generally one ray in a stomach. Now the ray was fresh, having been recently swallowed, and unaffected by any digestive process, now in a state more or less pulpy from the results of that process.

It has been long known that the food of star-fish consists, in a great measure, of the succulent portions of different kinds of molluscs, such as mussels, oysters, scallops, &c., small crustacea, and other animals, which they kill and devour; but so voracious are they, that they will sometimes make a meal of one of their own kind. It is difficult to keep sun-stars alive for any length of time in an artificial state; they soon die, so that I was unable to discover by experiment in what form of diet their propensities might be supposed to lie. Neither was I able to ascertain whether the sun-star attacks the whole living five-fingers, by first of all seizing the pointed part of the ray and gradually sucking in its whole portion, thus causing it to break off from the disc, or whether the remains found in the stomach consisted of rays which had been, either voluntarily or otherwise, detached from the body. The destruction which the five-fingers cause to mussel and oyster-beds is well known, and statements to this effect are corroborated by ample testimony. Fishermen and others practically interested in oyster fisheries, when examined before appointed Commissioners on this subject, bear testimony, one and all, to the havoc occasioned by these star-fish. Captain G. Austin, some time ago engaged in the oyster business at Whitstable, gave evidence before the Commissioners in the following words:—"They (the five-fingers) come like a flock of gulls, and, unless the beds were well dredged, they would soon destroy the spat. There is one kind that will eat an oyster itself, yet it is a singular thing with regard to them that after they have been dredged for a time, they roll themselves up and float away. So much is that the case, that in places where the fishermen have caught ten bushels of five-fingers one day, they will go out the next day and not catch one." (See Report of the Commissioners appointed to Inquire into the Sea Fisheries of the United Kingdom. Vol. II., 1865, p. 1,363.) There is every reason to believe that the sun-star is also destructive to oysters; if these asteroids are found, which is often the case, on oyster beds, it is presumable that they are there for some purpose, and when we know that other closely-allied members of this order possess in an eminent degree, and when opportunity offers gratify, oyster-eating proclivities, it is almost certain that their presence on the oyster or mussel beds has a gastronomical explanation. Sir J. G. Dalyell has recorded instances of sun-stars exhibiting cannibalism, and has been an eye-witness of larger specimens devouring their smaller brothers. The destructive agency of the sun-stars with respect to oysters must be small compared with that wrought by the ubiquitous five-fingers, for though the former are widely distributed round our coasts, they are not so generally abundant as the latter. That the sun-star frequently feeds upon the five-fingers I have lately had proof, but whether the good they do in this respect is outbalanced by the evil they cause to oysters, or whether the good has any appreciable effect on the natural increase of the five-fingers—these are questions I cannot answer.—Yours, W. Houghton, M.A., F.L.S.

WORD-CHOICE.

[140]—I hold that an Editor who amply lends his pages for the actual use of the public at large, as well as for delight and teaching, has a right to look for every aid that public can give him. Each writer offering matter for insertion should be asked to consider the *length* of every word he sets down. While thus sparing the printer's costly time, and leaving blank the space otherwise needlessly filled, he will at the same time be serving his own ends, since more space, more letters. Not only so, but in another way he will be a gainer. He will soon find that he is getting to write better Saxon English. Rather write *enough* than sufficient, for instance; *begin* than commence; as well as letting us have *using* instead of employing when the sense permits. You can *use* your time, though you must *employ* a workman. In the above few lines I had myself tripped. I was about to write "entertainment and instruction." Besides being shorter, "delight and teaching," are, I think, better.

Word-lover.

ARE WOMEN INFERIOR TO MEN?

[141]—I have just seen Knowledge for December 2, and have read with much regret a letter (numbered 61), signed "Susan G.," relating to your interesting article "Are women inferior to men?" If the writer is to be considered a representative of her sex, I fear she has injured the cause she wished to advance. In the first place, some of her statements are not accurate. She says "in a girl's education the brain is but slightly exercised." Now in point of fact, in the present day, girls' education is quite as comprehensive as boys', with less relaxation in the way of cricket, football, &c., to counterbalance the study. "Music and needlework," your correspondent thinks, "scarcely exercise it (the brain) at all." I wonder what Haydn, Handel, and Bach would say on that point? If music *is* music, and not mere mechanical "strumming," it cannot be called a brainless study. And yet it has to be worked at in the hours that boys devote to football.

As to "Susan G.'s" theory that whipping would develope brain, it appears to me that people with brain do not want whipping. The two great incentives to study are "interest in the work" and "love of the master," and if those who have the training of boys and girls can inspire these, as every good teacher can, the brain results will be much better than those shown by a girl of eighteen taken from her natural pursuit (?)—"husband-catching," and whipped into a course of study for which she has no inclination.

Having entered a protest against the whipping theory, may I ask you, for my own information and that of others, whether a comparison, to be quite fair, should not be between those whose surroundings are similar? Do you not think that as the mind of a man having the care of motherless children or of a sick wife, becomes insensibly domesticated, and almost womanly (as distinct from effeminate), so the mind of a woman called upon to enter a profession or manage a business becomes widened and strengthened by

contact with the outer world, for the work before it? But whilst the lot of most women (without being doomed to "suckle fools and chronicle small beer") is yet to fill, as intelligently and happily as may be, the domestic posts of daughter, sister, wife, and mother, would it not be unfair to call upon them to exhibit qualities for which they would have no exercise, and which, if ever needed, come with the need? The "Jack Sprat" story of our nursery days would be falsified if men and women were made exactly alike, and I fear the result would sometimes be that the domestic platter would not be "licked clean." I may be wrong, being

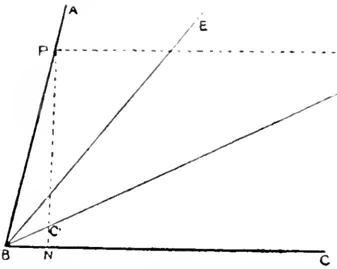
ONLY A WOMAN.

P.S. Let me add one word of grateful thanks for your paper. May it have the success it deserves.

Edinburgh, *Dec.* 9, 1881.

ANOTHER TRISECTION OF AN ANGLE.

[142]—I send you another method of trisecting an angle, more suitable for practical purposes. Of course it requires the ordinary mechanical contrivance, but as the point P is arbitrary, and CD is double BP, these measures can be permanently marked on the scale. To trisect any angle: ABC is the angle. Take any point



P in AB, draw PM parallel and PN perpendicular to BC; from B draw BD so that $C'D=2BP$; bisect PBD. The lines BD and BE trisect the angle. The proof I leave to the ingenuity of your readers. It is very simple.—Yours, &c., S. B.

15, Bessborough-street, St. George's-sq., S.W.

[This is the method invented by Pappus, of Alexandria. From it we can easily see that the hyperbola is a trisectrix.—Ed.]

VARIABILITY OF PENDULUM.

[143]—There is a misapprehension here founded on want of precision in ideas. The writer points out "a difference of velocity," but omits to specify to what point he refers as the standard. Apparently, however, the centre of the sun is intended, for which his statement is approximately correct; but the motions of the pendulum are controlled by the mass of the earth, generally reckoned as a force acting from its centre, and with reference to this latter point, no such inequality of velocity exists; so there is no ground for anticipation of any diurnal variation dependent on this (supposed) cause. COGITO.

ANTIQUITY OF THE PYRAMIDS.

[144]—It is impossible in the space which could be allowed in KNOWLEDGE to give adequate reasons for believing some of the Pyramids to be 6,000 years old. If "Actinolite" (query 72, p. 122) wishes to know the best authorities on the subject, he will find Brugsch's "History from the Monuments," Rawlinson's or Erasmus Wilson's "Egypt," and a work published by Macmillan, entitled "A Ride in Egypt," by Mr. Loftie, give him ample information.

If Egyptologists are correct in assigning the Pyramid of steps at Sakkara (which, by-the-way, differs from all others in *not* following the cardinal points of the compass) to Vanephes of the first dynasty, Sir J. Lubbock would probably be within the mark. The Pyramid of Senerferoo, eighth king of the third dynasty, is at Maydoum, and may well be as old as 6,000 years. For the date of Menes is fixed as 5702 B.C. by Boeckh, 5,000 B.C. by Prof. Owen, Marriette, and Manetho, 4,455 by Brugsch, for which he gives excellent reasons, 4,500 B.C. by Maspero, 4,000 B.C. by Chabas, and 3,892 B.C. by Lepsius. English authorities prefer a shorter chronology, Mr. Stuart Poole even favouring 2,717 B.C.

It may be said that all the accumulating discoveries go to prove, with slight exceptions, the validity of Manetho's list and dates. For instance, one of his supposed mythical assertions with regard to a King Apappus, that he was a giant, and reigned one hundred years, has recently been confirmed by a monument now at Boulaq, mentioning the one hundredth year of his reign, and his hieroglyphic name Papi means a giant. This longevity is surpassed by that of Assa and his son Ptah-hotep of the fifteenth dynasty, who, according to the Prisse papyrus, must have lived over 130 and 110 years respectively. See "Smith's Bible Dictionary," I., 322, where these facts are used as arguments in favour of the long lives of some of the patriarchs.

It is important to recollect that if the monuments are held to confirm the old supposed chronology of about 4,000 years from the creation to the time of Christ, they witness in favour of the plurality of the human race, because they show quite as great a divergence between the negro, Egyptian, and Asiatic types on the earliest monuments as at the prefent time, and so there could not possibly have been a sufficient period for such a differentiation from the progeny of a single pair.

A MEMBER OF THE SOCIETY OF BIBLICAL ARCHÆOLOGY.

SOME SUGGESTIONS RESPECTING "KNOWLEDGE."

[145]—1. I think it would be a great advantage to many of your readers if in your notices of books (which I hope to see soon) you stated the price as well as the publisher's name and address.

2. *Sale Column.*—Do not you think that a sale and exchange column (such as in the *English Mechanic*) would be a good addition to KNOWLEDGE? Through it subscribers could exchange and sell scientific works, telescopes, aquaria, &c.

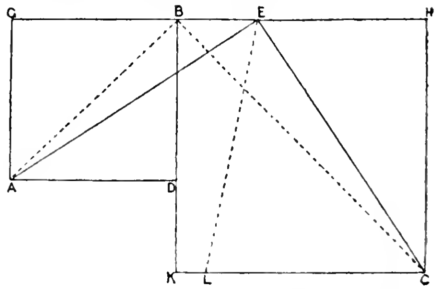
3. *Collections.*—Shall you have papers on making collections of all kinds of natural objects, such as a herbarium, butterfly collections, geological, bird and fish stuffing, skeletonising, insect taxidermy, &c.?—[Freshwater aquaria.—Ed.]

4. I hope you will foretell all natural phenomena, such as eclipses, meteoric showers, &c. (as far as you are able), and how best to be seen, by naked eye or telescope. E. R. C.

THE THREE-SQUARE PUZZLE.

[146]—Mr. Langley's note (No. 97) reminds me of an old puzzle which was set to me in Germany a good deal more than forty years ago. It is, in fact, a variant of his, and shows how his five pieces are obtained. It also always seemed to me to be the best proof of the celebrated 47th proposition of Euclid's first book.

Take any oblong piece of paper and fold down two corners, as along AB, BC in the figure; then, by cutting along AD and CK, you obtain two adjacent squares, AGBD and KBHC. Now, the puzzle is by one cut with a pair of scissors to cut these two squares into three pieces which will themselves form a square. Let those who are fond of puzzles attempt it without reading what follows.



Solution.—Fold the paper so that the point C lies on the point A. Then the fold will be along the line EF, giving the point E, where, of course, EH = GB. Cut with the scissors through both of the folded sides from A to E, and C to E, by one cut. Then you have the two triangles AGE, CHE, and the shapeless remainder. This done, I may leave any child to fit them into a square, and any young geometer to prove that that square must be that on the hypotenuse of a right-angled triangle of which the sides are also sides of the two squares. Observe, that if you also cut along BD, you get Mr. Stanley's five pieces.—Yours, &c., ALEXANDER J. ELLIS.

THE ORIGIN OF BUTTERCUPS.

[147]—I am sure that most of our readers could not fail but notice the clear and highly descriptive article upon "The Origin of Buttercups," a valuable treatise upon a botanical subject, without botanical technicalities, and rendered in such a manner that even the least unscientific person reading the article would have his knowledge considerably extended respecting buttercups.

I cannot, however, understand Mr. Grant Allen's theory of evolution respecting cut leaves. He says, "As a rule, just in proportion as vegetation is thick and matted, do the plants of which it is composed tend to develope minutely divided and attenuated foliage." I hold that the rule is the very reverse, for in traversing any waste piece of land where the struggle for existence is left to itself, one sees the very plants that predominate are those with entire leaves, viz., grasses, daisies, primroses, docks, &c., &c., and hold their own against the finely-cut leaved species; indeed, one scarcely sees the buttercup with its cut leaves growing in any profusion on uncultivated ground.

It is only in protected meadows that it flourishes in abundance; whereas the farmer carefully uproots those having entire leaves, knowing well that under their broad leaves no grass will grow.

Those plants having cut leaves are, as a rule, "tall growers," and have a weak and slender stem compared with the height of the plant. Have not these developed cut leaves in order that the wind may not break them down, but allow it to pass freely through? If, on the contrary, they had to develope entire leaves, they would be at a disadvantage in even an ordinary breeze. Upon the same principle many tall plants have entire leaves, but as they approach the top of the stem, the leaves are invariably smaller. Consequently, where the plant is weakest the leaves are smallest.

Again, many plants having entire leaves throw up a flowering skin entirely devoid of leaves, probably learning by experience that if they had to produce leaves there, snap would go their stems —viz., plantain, foxglove, hyacinth, grasses, &c.

It may be argued that few of our large forest trees have cut leaves, and that, therefore, my theory respecting the wind would fail. But I hold that they possess advantages equal to cut leaves in having their blades placed at the end of petioles, and articulated to the stem, so that they may bend and allow the wind to pass without injuring the tree. I hold that petioled leaves are merely a modification of cut leaves. Few of our radical leaved plants possess petioles to their leaves, not being required for such a "lowly" position. West Riding.

BEES AS FLOWER FERTILISERS.

[118]—In the suggestive article by Mr. Grant Allen in Knowledge No. 4, on the "Origin of Buttercups," an error has crept in with regard to bees. I am a bee-keeper on a somewhat large scale, and, consequently, interested in knowing from what flowers bees make their collections; but, though we have abundance of buttercups here, the hive bees do not visit them. Certainly buttercups are not included by bee-keepers among honey plants.

I do not, however, take exception to the assertions of scientific men, that bees are important aids in the cross fertilisation of flowers. When I say that the number of good honey-producing plants are comparatively few, and bees select the best yielders for the time being, I mean the probabilities appear to me to be very much against flowers being dependent upon bees for the fertility of their seeds.

Another circumstance is worth notice. When hive bees make collections of pollen from osiers, they fly straight to and from the tree, without passing from the male to the female flowers, a fact which may be easily verified in almost any district where bees are kept. It appears to me that bees might be of service as an aid in cross-fertilisation in this case; but it is fair to add that pollen is much needed in early spring when osiers bloom. This shows that the presence of honey in flowers is not the only attraction for the industrious bee.—Yours, &c., Alfred Donbavand.

Picton, Chester, *Dec.* 16, 1881.

Professor Nordenskjold is going to Russia, where the Government wishes to consult him on the best method of opening North Siberia to European navigation.

At the late Archæological Congress, held at Tiflis, Professor Samokvasoff gave an account of his discoveries in the graves near Pyatigorst. He excavated about 200 places of interment belonging to the stone, bronze, and iron periods. In the larger graves, bronze implements were found with stone ones. As there were in these graves, besides the bones of sheep, several split human bones not belonging to skeletons, he inferred that during the bronze-period the people in that part of the Caucasus were man-eaters.—*Frank Leslie's Magazine.*

Queries.

[104]—Moons of Mars and Saturn.—1. Can you inform me if Mars has any satellites? If so, how many? What is their period of revolution, and at what distance are they from the planet?—[Mars has two moons, discovered in August, 1877; periods of revolution, 30h. 14m., and 7h. 38m.; distances from the planet's centre, about 6,000 and 15,000 miles.—Ed.] 2. What are the names of Saturn's two outmost satellites?—[Hyperion and Japetus (the latter the outermost of all).—Ed.]

[105].—Fungi and Lichens.—How are specimens preserved, and which are the best books on the subject?—J. S.

[106]—Pneumatic Bell.—Will M. Tester (Letter 79, p. 100) kindly favour me with instructions, "plainly-worded, exactly-described," for making and fixing (down staircases, &c.) a pneumatic bell; taking for granted—as is really the case—that I have very little native ingenuity? Also stating the price of materials used. If he could possibly supply a simple diagram, where necessary, I should be greatly obliged.—E. R. C.

[107]—Name of Star.—How would you pronounce "Betelgeux," one of the stars (a) in the constellation of Orion. [The question is one for Arabic students. The name Betelgeux is, we believe, a corruption from *Ibt al Jauza*, the giant's shoulder.—Ed.]

[108]—After-Images.—These seem to be best obtained, not by closing the eyes and keeping them closed, but in the *act* of vigorous winking. When I do this after looking at the sun, I soon obtain an after-image of the following nature: An interior green disc; round that a narrow circle of red, and beyond, an undefined space of violet or dark blue. Has this been noted and sufficiently explained, and, if so, what is the explanation? Is there any significance in the fact that those three colours are the fundamental colours?—Max.

[109]—Railway Collisions.—From the history of these, are any practical rules deducible for the case of imminent collision (rules as to position and attitude in the carriage, &c.), the observance of which might somewhat limit the power of railway companies to maim and murder us?—Max.

[110]—The Coal Age and the Earth's Internal Heat.—As an ignoramus, may I ask you whether the earth's own internal heat had anything to do with the gigantic flora of the coal age, on the principle of a hothouse? Is it supposed that the earth was at one time in a state of intense heat, and will gradually cool like the moon has done? Does not the temperature increase the deeper you sink into the earth? What is a good text-book on this subject?—Ignoramus.

[111]—Axes of the Planets.—Will you inform me if the axes of the planets are all inclined the same way—that is to say, if the sun and all the planets could be placed in a line at their respective distances, would all the axes be inclined in the same general direction?—Orion.—[The axes of the planets have no community of direction. Our earth's axis points towards Ursa Minor, Jupiter's to a point in the constellation Draco, not far from Omega, Saturn's to a point near the northern extremity of Cepheus, and so on.—Ed.]

[112]—Optical Illusion.—A remarkable optical illusion is caused by holding the hand, with the fingers close together, near a gas flame. One seems to see through his fingers. What causes the illusion? Does the light shine through the skin at all?—G. P.

[113]—Illusory Figures of Transparent Solids.—How is it that in looking at the figures of transparent solids that it is possible for you to imagine the figure in two positions? And what adjustment takes place in the eye whilst so doing? For instance, in the case of the cube it is possible for you to see it as having a certain face as the front one, and without moving the eyes you can make the opposite face appear as the front one; or in the prism, the edge xy can be made to appear either at the back or front, just as you please; but no motion of the eyes need take place. Yet there is a slight effort felt as you change, so to speak, the position of the cube or prism.—P. B. S.—[Mr. Foster will discuss such illusions.—Ed.]

[114]—Marine Boiler.—What is the increasing temperature on the furnace crown of a marine boiler required to keep the steam at a pressure of 100 lb. per square inch; with the scale formed by the deposit of salt within the boiler increasing by sixteenths, from $\frac{1}{16}$ to $\frac{1}{2}$ in. thick? How can this be calculated?—Crankshaft.

[115]—Screw Propeller.—Is there a vacuum on the following side of a screw propeller blade when revolving? If so, does it materially affect the power of the engine? Any information on either of the above will greatly oblige.—Crankshaft.

[116]—John Bull.—Can any reader refer me to the origin and meaning of the term "John Bull."—G.

[117]—Parallelopipedon or Parallelepipedon.—Why do

English writers spell "Parallelopipedon?" Both in German and French this word is always spelt "Parallelepipedon" and *parallélépipède* (comp. Dictionnaire de l'Académie and Littré's Dictionnaire), and one of the greatest authorities in classical philology assures me that the *o* of "parallelos," being an un-essential termination, *must* yield to the initial *e* of "epi."—G. L.

[118]—How to Make Cotton Waterproof.—Will any of the readers of Knowledge be good enough to indicate a process by means of which raw cotton wool, just as the plant furnishes it, can be made impervious to water, without changing the fibre or colour of the cotton?—Cottonian.

[119]—Electro Plating.—By mistake, nearly six ounces of a cyanide of copper solution have been thrown in two gallons nearly of a double cyanide of silver solution. Would any of your readers be kind enough to tell me how to purify my silver solution?—W. Van Eys.

[120]—Transit of Venus, Dec., 1882.—As the above transit will take place in December next year, I should very much like to know how the calculations are made in order to ascertain the sun's distance from the earth. I have a slight knowledge of how the work is performed, but should like to understand the system properly.—Hesketh. [Will, before long, give a simple account of the matter.—Ed.]

[121]—Latitude and Longitude.—I am anxious to be able to determine the latitude and longitude in a practical manner. Will you kindly, at your earliest convenience, give me the necessary instructions in Knowledge?—Hesketh. [The best advice we can give "Hesketh" is to obtain Loomis's excellent treatise on "Practical Astronomy," in which the best methods of determining longitude and latitude are clearly and fully explained.—Ed.]

[122]—Blood Analysis—Is there any method by which the amount of the albumen, or, at least, of the saline constituents of blood, can be estimated quantitatively, in cases where only a small quantity can be obtained, say 5 c.c.? Can the spectroscope be applied to quantitative analyses in such cases?—*ἄιμα*.

[123]—Fermentation in Beer.—Will you kindly allow me to ask if any of the readers of Knowledge will explain to me the process of fermentation in beer?—In Re.

[124]—The Coffee Leaf.—Have you heard anything lately of any experiments made in this country to introduce the coffee leaf among us? My reason for asking is that I think our labourers would derive a great benefit from its use, if it could be introduced.—F. C. S.

[125]—Indigo.—Is it possible to prepare indigo on a large scale artificially, and at the same time profitably? I have heard rumours that there is a manufactory in France for doing so; but have looked through, as they have arrived, my society's journals to see if I could find an account of the experiment, if any has been made, but it has been without success. If you could enlighten me on the above you would oblige.—F. C. S.

[126]—Flora, and Plants, and Insects of the Channel Islands.—Why are the plants of the Channel Islands included in the British flora, while the insects are usually considered French?—B. J.

[127]—Double Refraction.—I should be very glad indeed of information upon the following points:—When a spot of light is viewed through a piece of Iceland spar, two spots are seen, as a consequence of the double refraction of the crystal; and if I understand rightly, one of them consists of vibrations, say, in vertical, and the other of vibrations in horizontal planes. Now, if we look at these through a second piece of spar, we see four spots of light, each of the former pair being doubled or "resolved." What I want to know is the meaning of "resolved." If one of the first pair consists of vertical vibrations, where do the horizontal ones come from to form its second image? and if the other consists of horizontal vibrations, how do we come by the second image? Each pair behaves, when the spars are revolved, in the same manner as the first pair would if seen through a Nicol prism.—Polar. [It depends how the second piece is held. If it is held with its principal section parallel to the other's, only two images are seen, one by ordinary, the other by extraordinary refraction. The same if the principal sections are 180° from each other, unless the crystals are of equal thickness, when there is but one image. If the principal sections are at right angles, only two images are seen, which are (1) the ordinary image after extraordinary, and (2) the extraordinary after ordinary refraction. In intermediate positions, four images are seen, because neither the ordinary nor the extraordinary refracted rays would have, in order to pass through, to turn through quite a right angle, which, and which alone, would involve total extinction.—Ed.]

[128]—The Eye as one of the Senses.—I wish to give an essay, or a reading on this subject at a Working Man's Mutual Improvement Society. I should be extremely obliged with any information that would enable me to get a cheap pamphlet, or anything that will help me to prepare such an essay on "The Eye, one of the Gateways of Wisdom."—T. T.

[129]—Medical Botany.—Will you kindly tell me through your valuable paper the name of the best medical botany, with diagrams. Henry Hawkes-Spink.

Replies to Queries.

[26]—Orrery.—In the Museum of Philosophical Apparatus, at University College, Gower-street, London, was, and probably now is, the Orrery made by the celebrated self-taught astronomer, James Ferguson.—W. H. Hardy.

[66]—Venus Casting Shadow.—In India I have repeatedly seen Venus at least two hours before sunset. In 1849 or 1850, while driving on a moonless night, we perceived on the road a distinct, though faint, shadow of a clump of trees, of two large poles, &c., cast by Venus. This was not far from Delhi, in a very dry, clear atmosphere.—Cogito.

[72]—Antiquity of the Pyramids.—Notwithstanding Sir John Lubbock's statement, there is no trustworthy evidence that the Pyramids "are at least 6,000 years old." The Great Pyramid of Geezeh is generally admitted to be not only the greatest, but also the oldest, and astronomical considerations based upon the position of its entrance-passage—which constitute evidence of a much more reliable character than that of ancient Egyptian traditions—indicate that its age does not exceed 4,051 years.—J. Baxendell.

[Mr. Baxendell fails to notice that the direction of the entrance-passage fulfilled the condition of pointing towards Alpha Draconis at its sub-polar passage, at two epochs during the last 25,000 years—one that which he mentions, the other some 6,000 years ago. Moreover, what no one seems to have noticed yet, the ascending passage, which 4,051 years ago would have been directed towards no important star, would have been directed towards the most interesting orb in the whole star-sphere—namely, Alpha Centauri—at its southern culmination, at the earlier epoch. It has been supposed by persons unacquainted with astronomy that the Pleiades occupied the corresponding position 4,000 years ago. But this is not the case. The relation indicated by Prof. Smyth was only a symbolical, not an observational one.—Ed.]

[83]—Chemical Queries.—In reply to "Theion" (*a*), there are several allotropic modifications of sulphur, as the following table shows (Valentin's "Introduction to Inorganic Chemistry, p. 53):—

	Sp. G.	Fusing Point.	Solubility in CS.2.
1. Octahedral.	2·05	115	Soluble.
2. Prismatic.	1·98	120	Insoluble before transformation.
3. Plastic.	1·95	Are converted into the octahedral modification.	Insoluble.
4. Amorphous.	1·95		Insoluble.

Another modification insoluble in CS_2 is contained in flowers of sulphur, and is of a light yellow colour (Roscoe and Schorlemmer's "Treatise on Chemistry," vol. i. p. 292). If "Theion" will carefully read Roscoe's "Lessons" again, he will find that the plastic modification, while *tenacious*, is insoluble in CS_2. When the tenacious form has become *hard* and *brittle*, a portion will dissolve in the CS_2, and leave a dark-brown powder ("Treatise," vol. i. p. 292). Miller and some other chemists call this a grey amorphous powder. This latter modification corresponds to No. 4 in the above table. (*b*.) The word *nitrous* should be *nitric*. It is stated correctly in the "Treatise on Chemistry," vol. i. p. 126.—C. W. D.

[84]—Ancient Man.—Mr. Horner's researches were published in the "Philos. Trans.," 1855 and 1858, and reviewed in the *Quarterly Review* in 1859. His argument for an extreme antiquity of Egyptian civilisation from finding fragments of pottery at considerable depths in the alluvial soil is now considered insufficient. Sir C. Lyell says, "it is not worth while to notice such absurdities." Other pieces of Greek origin have been exhumed at greater depths, and I believe the Greek honeysuckle ornament was found on some of Mr. Horner's. Stephenson turned up a brick of Mehemet Ali's, even at a lower level. Stone implements from Egypt have frequently been exhibited at the Anthropological Institute, by Sir J. Lubbock in 1874, Capt. Burton in 1875, and General Pitt Rivers in 1881, but with regard to many of these, there is great doubt as to whether they are hand-fashioned, and even those which are, do not prove the existence of a stone age in the Nile Valley, for Prof. Owen says, "Chert, chipped to an edge, or flint flakes struck off by percussion, being the ordained materials for circumcision and for the abdominal cut in mummifying, the finding of flint knives in Egypt requires evidence of the date when they were used, or of previous manufacture, before they can apply to the question of a

race anterior to the historical life of the country." Mariette says, "the use of stone and flint tools extended nearly 1,000 years, through thirty dynasties." Brugsch tells us, "Egyptian history throws scorn on the supposed periods of stone, bronze, and iron;" and Chabas shows that similar tools were in use at the latest historical period, and even now are not uncommon among the Arabs. —A Member of the Society of Biblical Archæology.

[84]—Antiquity of Man, as Shown by the Works of Art in Nile Mud.—Your correspondent "Clio" may find Mr. Horner's researches in the "Philosophical Transactions," 1855-8, or perhaps she will do better by consulting an admirable summary in Lyell's "Antiquity of Man," p. 35 and 41, 4th edition, 1873. The result is a simple rule of three sum. As is the thickness of Nile mud deposited by the annual inundations over certain historical monuments to their known age, so is the greatest depth at which the works of art occur in like mud hard by to their approximate age.—A Tramp.

[89]—Collodion Plates.—"Persevere" does not say whether the red stains appear after the plate is developed, or whether they are on the plates as received from the maker. In either case, it would be almost impossible to determine cause without inspection. The vagaries of gelatine plates are innumerable. If the negatives are not varnished, they are very liable to be spoiled by the silver from the paper; the gelatine readily absorbs moisture. The remedy is obvious. Evidently "Persevere" has not tried to answer his own question as to developing gelatine plates; let him try, and give his experience, if successful.—A. Brothers.

[91]—"Missing Link."—Dr. Andrew Wilson's article is on "Missing Links" (not on *the* "Missing Link"). It appeared in the *Gentleman's Magazine* for September, 1879.—Ed.

Notes on Art and Science.

Among recent finds at Pompeii were several amphoræ, on some of the largest of which was written the exact date of the extraction of the wine contained within, and on smaller ones the names of the wine.

It is announced that Dr. King, in charge of the Government cinchona factory at British Sikkim, has succeeded in manufacturing, for the first time in India, sulphate of quinine from local cinchona bark. The samples produced are said to bear comparison, on analysis, with the pure sulphate of quinine of commerce, and preparations are being made for undertaking the manufacture on a large scale.

The famous spring of boiling water in the middle basin of Hell's Half Acre, in the Yellowstone region, has lately become still more wonderful as a geyser. Four or five times every twenty-four hours it discharges a great column of water, freighted with stones and obscured by a dense volume of steam. The hollow formation for hundreds of yards around the orifice trembles under the upheaval, and the water is thrown to a height of a hundred feet.

The six healthiest cities of the United States are said to be in the order following:—Utica, Dayton, New Haven, Portland, San Francisco, and Lawrence. The unhealthiest are Charleston, Memphis, Cleveland, Chicago, and Lynn. St. Petersburg is the unhealthiest city in the world, and is followed by Charleston, Malaga, Alexandria, Warsaw, and Buda-Pesth.

M. Macagno, in *Les Mondes*, states that he has been making experiments on the influence of electricity upon the growth of the vine. An electric circuit was formed by copper wire between the extremity of a branch bearing fruit and its origin near the soil. More wood was formed in the branch, which contained less potash than the other parts, and the grapes ripened more readily, containing an excess of sugar.

It is said that a marked improvement has been noticed in the acoustic properties of the Grand Opera House, Paris, since the introduction of the electric light. A layer of heated gases acts as a screen for sound, hence the volumes of hot fumes arising from the old gas footlights obstructed and marred, to some extent, the voices of the singers. With the electric light, inclosed in air-tight bulbs, no fumes can be emitted, and very little heat is given off. Hence its benefits to the ear as well as to the eye.—*Frank Leslie's Magazine*.

The question of the existence of volcanoes in Central Asia, especially on the Kuldja frontier, has always been a matter of doubt and discussion among geologists and Russian explorers. The Governor of Semfretchinsk, General Kolpakofsky, had already fitted out expeditions to settle the question—one in 1878, and again in 1879; but owing to the difficulties of reaching the mountains, which the Chinese considered impassable, and also to disorders which were then taking place in Kashgar, both expeditions were unsuccessful. This year General Kolpakofsky again set himself to the task, and now reports that he has at last discovered the perpetual fires in the Thian Shan range of mountains. He telegraphs that the mountain Bai Shan has been found twelve miles north-east of the City of Kuldja, in a basin surrounded by the massive Ailak Mountains, and that the fires which have been burning there from time immemorial are not volcanic, but proceed from burning coal. On the sides of the mountain there are caves emitting smoke and sulphurous gas.—*Frank Leslie's Magazine*.

Our Mathematical Column.

THE USE OF LOGARITHMS.

In our last, we took a simple case of the multiplication of two numbers, each of six digits, and the division of the products by another number, also of six digits. Working this sum by logarithms seemed rather long, just as in practice nearly every one finds the first two or three sums he works by logarithms require more care and watchfulness than he afterwards finds necessary. We may now, however, proceed more freely.

Let us consider a few cases of taking powers, or extracting roots of numbers.

Take first the familiar problem of the horse with 24 shoe-nails, for which a price of $\frac{1}{4}$d. for first nail, $\frac{1}{2}$d. for second, 1d. for third, 2d. for fourth nail, and so on, doubling to the twenty-fourth nail, was to be paid: to find his price by the aid of logarithms. This is a case somewhat unlike those usually dealt with, where an answer exact to so many decimal places is required, not an answer absolutely exact. However, it can be readily solved by logarithms. Thus, for the first nail, amount is $\frac{1}{4}$d.; for first and second, $\frac{3}{4}$d.; for first three, $1\frac{3}{4}$d.; for first four, $3\frac{3}{4}$d. Start from the fifth, for which nail 4d., or a third of a shilling, was to be paid, and let the third of a shilling be our unit (the reason being that if we take pence or farthings, we should not be likely to get an exact result). Then there is to be paid for fifth nail 1, for the sixth 2, for the seventh 4, or 2 to power 2; for the eighth 8, or 2 to power 3; and so on: and for the twenty-fourth, 2 to the power 19, while we know that the total paid for all the nails from the fifth to the last is twice this, less 1, or $2^{20}-1$.

Now, turning to the tables we find—

log. 2 = 0·3010300
Multiply by 20 20

log. 2^{20} = 6·0206000 = log. 104856

log. 10485 = ·0205681
316
difference for 70 = 292 — This part of the calculation is simply working out the logarithm.
240
difference for 6 = 250

We know that 2^{20} must be a whole number, and can end only with one of the digits 2, 4, 6, or 8; so we take with confidence the number 1048576. This, less 1, is the number of 3rds of a shilling for the nails from 5th to 24th inclusive, and the first four give us one-third of a shilling, less a farthing. So the answer is 1048576 thirds of a shilling, less a farthing.

Or 349,525s. $3\frac{3}{4}$d.
Or £17,476. 5s. $3\frac{3}{4}$d.

This is an unfavourable example, because of the necessity for an exact instead of an approximate result. If we had only required to know the amount roughly, that is, within a shilling or two, we might have proceeded thus:—The amount in farthings is $2^{24}-1$, or in shillings the amount is $\frac{2^{24}}{48}$, neglecting the farthing.

Now log. 2 = ·3010300
log. 2^{24} = 7·2247200
log 48 = 1·6812412

log. ($2^{24} \div 48$) = 5·5434788

log. 34952 .... ·5434720
difference for 50 62
5 6

5·5434788 = log. 34952·5
Ans. = 34952·5 shillings.
= £17,476. 5s. 6d.; and the conditions of the problem show that the pence really amount only to $3\frac{3}{4}$d.

In nearly all problems requiring the use of logarithms, however, we do not require exact accuracy, but may be content with approximation to the third or fourth place of decimals.

Let us take a case not scientific, but practical.

Required the amount of £1,828 at compound interest, five per cent. per annum (payable yearly), at the end of ten years.

Any sum at the given rate of interest, is increased in the ratio $\frac{105}{100}$ at the end of the first year; therefore, at the end of two years, it is increased in the ratio $\left(\frac{105}{100}\right)^2$; and so on; and at the end of ten years it is increased in the ratio $\left(\frac{105}{100}\right)^{10}$. Thus we have to find the value of the following expression:—

$$1828\left(\frac{105}{100}\right)^{10}$$

Now log. 1828 = 3·2619762
Ten times log. 105 = 20·2118930
Sum 23·4728692
Ten times log. 100 = 20·
Log. (answer) = 3·4728692 = log. 2970·771
20
15,420
12
5,040

There is an error in the addition. log. (answer) = 3·4738692. True answer somewhat greater than stated.

Answer is £2,970. 15s. 5d.

Here is another question relating to compound interest:—In what time will a sum of money, say £100, be doubled at 5 per cent. per annum, payable yearly, compound interest?

If x be the required number of years, we have

$$(100)\left(\frac{105}{100}\right)^x = 200$$
$$\text{or } 105^x = 2 \times 100^x$$

This is the same as saying that

$$x \text{ log. } 105 = \text{log. } 2 + x \text{ log. } 100$$
$$\text{or } (2\cdot0211893)\,x = 0\cdot3010300 + 2x$$
$$\therefore \quad x = \frac{3010300}{211893}$$

We can again use logarithms to determine the value of this fraction.

We have log. 3010300 = 6·4786098
log. 211893 = 5·3251167

difference = 1·1524931 = log. 14·207
12

2·484

Answer is 14 years $2\frac{1}{2}$ months, very nearly.

For greater exactness, multiply ·207 by 365, giving 75·555, and making answer, 14 years, 75 days, 13 hours, 19 minutes.

The student of our subject is advised to go carefully through each computation. He will note that in taking out the logarithm of 211893, we put down for the first three figures not 325, but 326, though the logarithm is found in a section which seems to have 325 for its leading digits. In this section we find 325 followed by numbers continually increasing up to 9875; then on the same line comes $\overline{0}080$, which, of course, means that the logarithm has increased from 3259875 to 3260080. The student must be careful on this point, especially in the earlier part of the tables, where the changes are more rapid.

One other example illustrating an application of logarithms, in which great time is saved.

Suppose we want to find the cube-root of a number, say, 21,793, correct to the third or fourth decimal place. By the ordinary arithmetical process this would be a long job, and we should have carefully to test the result to insure accuracy. But by logarithms the process is very easy, thus:—

Log. 21793 = 4·3383170
Divide by 3 giving 1·4461057 = log 27·93221.

Thus the cube-root of 21793 is 27·93221.

Take a more complex case, the solution of which by ordinary arithmetical processes, with the same degree of accuracy, would take half-a-day at the very least, even in the case of an arithmetician knowing how to take out the fifteenth and seventh roots of numbers.

Find the value of the expression:—

$$\frac{(1828)^{\frac{2}{15}}(0\cdot1763)^{\frac{1}{3}}}{(745)^{\frac{1}{7}}(0\cdot0051)^{\frac{1}{5}}}$$

log. 1828 = 3·2619762
2-15ths or 1-30ths of this = 0·4349302
log. 0·1763 = $\overline{1}$·2462523
1 third of this, or of −3 + 2·2462523 = $\overline{1}$·7487508

0·1836810 (A)

log. 745 = 2·8721563
1-seventh of this = 0·4103080
log. 0·0051 = $\overline{3}$·7075702
1-fifth of this, or of −5 + 2·7075702 = $\overline{1}$·5415140

$\overline{1}$·9518220 (B)

A − B = 0·2318590
Answer = 1·705529

The student will notice how the negative characteristics are dealt with in such problems. We must always add enough to the negative characteristic to make it exactly divisible by our divisor, treating the number thus added as a positive characteristic for the rest of the division.

Our Chess Column.

GAME recently played at Simpson's Divan between Mr. A. P. Barnes, of New York, and Mr. Gunsberg.

Queen's Gambit declined.

	White. Mr. Barnes.	Black. Mr. Gunsberg.
1.	P. to Q.4.	P. to Q.4.
2.	P. to Q.B.4.	P. to K.3.
3.	P. to K.3.	Kt. to K.B.3.
4.	P. to Q.R.3. (a)	P. to Q.B.4. (b)
5.	P. takes P.	B. takes P.
6.	P. to Q.Kt.4.	B. to K.2. (c)
7.	P. to Q.B.5.	Castles. (d)
8.	Kt. to K.B.3.	P. to Q.R.4.
9.	B. to Q Kt.2.	P. to Q.Kt.3.
10.	P. takes Kt P. (e)	P. takes P.
11.	B. to K.2.	P. takes P.
12.	B. takes P.	B. takes B.
13.	R. takes B.	R. takes R.

18.	R. to Kt.sq.	R. to Kt.sq.
19.	Q. to R.3.	Kt. to Q.3. (h)
20.	Q to Kt.4.	B. takes Kt.
21.	B. takes B.	Q. takes B.

White resigns.

NOTES BY "MEPHISTO."

(a) This is preparatory to advancing the Pawns on the Queen's wing. We cannot approve of such a course with all the White pieces yet undeveloped.

(b) In most openings, where the first player opens up the Queen's wing first P. to Q.B.4 (to be followed, if feasible, by Kt. to Q.B.3) will be found effective, as it attacks the centre pawns, which threaten to domineer over Black's game.

(c) The Bishop is sometimes withdrawn to Q.B.2 *viâ* Kt.3, the idea being that on B.2 he is available for attack on the King's side (this is problematical). We prefer B. to K.2, for, in the first instance, it affords some protection against B. to Q. Kt.2. Secondly, we consider the hostile Queen's wing weakened, and from K.2 the Bishop will render assistance in attacking the White Pawns successfully (this is positive).

(d) Necessary before beginning the attack. Many good games are often thrown away through rashness in attack and insufficient regard for one's own safety.

(e) There is nothing better: if 10. P takes R.P., then 10. P. takes B. P., and the Rook's Pawn is lost; or if 10. $\frac{\text{Q. to B.2.}}{\text{P. takes B.P.}}$ 11. $\frac{\text{P. takes B. P.}}{\text{Kt. to K.5.}}$

(f) If B. takes Kt., then Q. to B.3. would win the piece back. White intended to bring his Knight to Q.4, but it would have been much simpler to have brought him *viâ* B.2.

(g) Taking the proper advantage of White's weak move. Black threatens to win a piece by B takes Kt., or, if the Knight retires, by Kt. to B.6.

(h) This ends the struggle. Black now wins the Knight, for if 20. Q. Kt. to B 3. then 20. Q. takes R., and the White Knight cannot take the Queen on pain of mate in 4 moves. If 20. K.Kt. to Q.4 then P. to K.4. wins.

Our problem No. 4 (wrongly numbered 3) in No. 5 is solved by R. to Q.R 8.

We have received correct solutions from Gamma, Arkansas, E. F. K., Caissa, A Young Player, Try Try Again, S. D. P., R. M., Afternoon, Worcester, Etoniensis, D. See. Others incorrect.

Edward Sargant points out that Mr. Healey's problem is unsound. If black Pawn becomes a Rook, white cannot win. This is so. The point appears to have been noted in "Westminster Papers" several months later. By putting the black Rook's Pawn one square further forward the flaw is corrected.

From the *Glasgow News*.
By Mr. C. R. Baxter, Dundee.

Black.

White.

White to play and mate in three moves.

This is the problem to which we referred in No. 6. Mr. Baxter tells us that he had never seen our older problem. We had not supposed he had. Next week, or later, we shall give an instance in which we were anticipated. He notes the resemblance of Carl Eggert's problem, in *Illustrated London News* for November 26, to his own, which appeared the same day.

Our Whist Column.

By "Five of Clubs."

H. P. H. points out a mistake in our discussion of this matter. Lord Y. should have wagered 1,827 to 1, not 1828 to 1, the chance being 1-1828th, and the odds, therefore, 1,827 to 1. Of course "H. P. H." is right. The numbers representing the odds and the chance are so nearly the same in such a case as this, that we were not careful about a point which in others of our papers on chance we have insisted on clearly and often. In dealing with another point, "H. P. H." misconstrues us. He says, "the chance that a Yarborough will not happen in any deal is *not* the same as the chance that it will not happen in a given hand in four successive deals; for in the former case one hand depends on the other to a certain degree, whereas in the latter, the chance of any combination happening is quite independent of any combination which may have preceded it. I agree that the chance of a Yarborough is $\frac{1}{1828}$, and consequently the chance of a Yarborough in four consecutive deals is $\frac{1}{1828^4}$. Following your principle, this would be the chance of four Yarboroughs in one deal, which is a manifest absurdity, for we ascribe" (thus) "a mathematical chance to a clear impossibility." The question we were really considering was what odds should be offered to each member of a party of four at whist that his hand would not be a Yarborough; and we (practically) affirmed that £1,827 to £1 should be offered to each. "H. P. H." seems to consider that this is the same as offering £457 to £1 (roughly) against the occurrence of a Yarborough in a single deal. But this is not the case. Take a simple case illustrating at once his difficulty and our position:—Suppose there are four cards marked respectively A, B, C, D, to be dealt, one to each of four persons. Then the chance that any particular card, as A, will be dealt to any given person of the party of four, is obviously one-fourth, or the odds 3 to 1 against that event, so that with that person any one might at once safely and honestly wager £3 to £1 against his getting that card. Now our position is that the same odds might be offered with each one of the four, although it is certain, in this case, that some one of the four must have card A. (In the Yarborough case it is not certain but more probable that one of the four will have a Yarborough than that any particular one will have such a hand.) Well, "H. P. H." might reason that this is not the case, for if the chance is $\frac{1}{4}$ that a particular person will have card A in any given deal it is $(\frac{1}{4})^4$ that he will have it in four successive deals, and on our principle the same is the chance that each one of the four persons will have the card A in a single deal, or, in other words, the odds are only 255 to 1 against the manifest impossibility that each member of the party of four shall have the same card dealt to him out of four. Yet it is perfectly clear that the just odds are 3 to 1 with each person of the four, and the proof is that if these odds are wagered with each the event can bring neither gain nor loss to the layer of the odds; he will have to pay £3 to one of the four, and receive £1 from each of the others. So, if a person wagered £1,827 to £1 with each of four persons, before an ordinary whist deal, that that person would not get a Yarborough, he would be laying the just odds. Now let us see what his wager really amounts to in this case. If he loses to one, he loses £1,827. One of the others might have a Yarborough, but the chance that this would happen is very small: it is really this, that out of thirty-nine cards dealt to three persons, one would only receive cards belonging to a particular group of nineteen—a chance very small indeed. Regarding it for the moment as zero, we may say that it is certain, or all but certain, that from each of the remaining three players the layer of the odds will receive £1. Therefore, the layer of the odds pays £1,827 and receives £3, or loses only £1,824. His case is, therefore, similar to that of one who had laid against a Yarborough occurring in each of four successive deals to one only of the four players, except that this one might have had to pay £1,827 for each of the four deals, whereas the other could only have to pay for two at the outside, and would most probably have had to pay for one only. The difference exactly makes up for the interdependence of the four hands in any given deal.

Take a simpler illustrative case to show what we mean. A person, P, wagers with another, X, one of four to whom four cards, A, B, C, D, are dealt four times running, that X will not receive a particular card A, offering £3 to £1 at each of four deals. Unquestionably each wager is fair. X may have A each time, in which case P will have to pay £12, or X may not draw A at all, in which case P will receive £4. There are other eventualities easily followed. But the wager is manifestly fair. Now take a single deal. P wagers with W, X, Y, Z severally £3 to £1 that they will not have card A. In this case, one of the four must have the card, and to him P must pay £3, receiving from each of the others £1, or neither losing nor gaining. Since each wager, or rather each set of wagers, is manifestly fair, we see that the possibility in such cases of having to pay the odds more than once when successive deals are considered, exactly counterbalances the certainty of winning in some cases (most probably in three when a Yarborough is in question, and certainly in three where four cards only are in question), in the case of wagers with the four parties to a single deal. We have, in fact, only to ask whether a certain wager with one party to the deal is fair or not. If it is fair, we may be well assured that there is no unfairness (either way) if the same wager is made with each of the four players.

However, although this, and this only, was what we were considering (as should be obvious from our remark beginning, "Supposing Lord Y. offered £1,000 to £1 to each member of a whist party for ten deals," &c.), "H. P. H." very naturally misunderstood us, seeing that we wrote carelessly, as if we were considering "the chance that a Yarborough will not occur in any given hand" (these are our very words, and naturally misled him). The chance of this is not to be inferred so simply, as our words might have suggested, from the true odds against the occurrence of a Yarborough in a single hand. To return to our simpler case. The odds against a card A being drawn by one of the four is $\frac{1}{4}$, and the true chance of its being dealt *once* to a given person in four successive deals is $(\frac{3}{4})^4$ or $\frac{81}{256}$; so that the odds in favour of its being dealt to him once in four deals are 175 to 81. Thus only £81 can be safely wagered against £175 that the card will not be dealt once, at least, in four trials to one of the four players; but the chance of the card being dealt to one of four persons in a single deal is, of course, certainty, or 1; so that no sum, however small, can be wagered against any sum, however large, that the card will not be so dealt.

Answers to Correspondents.

** * All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of* Knowledge, *the increasing circulation of which compels us to go to press early in the week.*

Hints to Correspondents. *1. No questions asking for scientific information can be answered through the post. 2. Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries. 3. No queries or replies savouring of the nature of advertisements can be inserted. 4. Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge. 5. Correspondents should write on one side only of the paper, and put drawings on a separate leaf. 6. Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

A "Paradox-Monger." Very likely you are right; with the kindest wishes and the best intentions men make enemies. It will be unfortunate if our evasion of any particular subject should be attributed to "prejudice"; but we *must* omit some things, and amongst those your letter.—S. H. Wright. You seem to me entirely to misunderstand Dr. Wilson's first letter—it was explanatory, not controversial. The spider's web is not a greater difficulty than the cell-making instinct in bees; the study of Darwin's reasoning on the latter subject would show you that there is no real objection in the arguments you consider valid against the Darwinian hypothesis. If you remember that of five letters received four *must* be omitted, you will see that you have no real reason to complain that your former letter was not inserted. It would seem that we are bound to offend four-fifths of our correspondents if we keep open a correspondence section at all.—Robert Kidd. The point has been corrected already.—Pascal. You are, of course, right; but is it worth while to reason back so carefully to the original equation?—G. B. Stubbs. Thanks. Our Chess Editor and "Mephisto" will analyse it.—J. Jeffares. In his reply to Archimedean, p. 61, "Mathematicus" took it for granted that the former would at once see what you have established, and what H. A. N. says the differential calculus is required to establish. As you say, the substance of the proof is to be found in books; we *must* not find space for it. F. S. Pilkington. The experiment proving that one part of the retina is insensible to visual impressions is well known. Must reserve space for newer matter.—Jas. H Symington. Letters relating to Vivisection will receive due attention, but the matter is hardly worth discussion; it seems so clear that those who hold extreme views on either side are mistaken. The editor of the paper you mention is well known to be an extreme opponent of vivisection, one who would not allow a tom-cat to have a hair plucked out if the lives of all his relatives depended on the experiment. On the other hand, there are some who would let a thousand dogs be tortured to death to establish a physiological law of no benefit to a living creature. Fanatics of the first sort consider all who approve of any experiments whatever on animals to be brutes, while those of the second sort consider all who oppose the wantonest cruelty, to be drivelling idiots. No amount of discussion will reconcile these, or either sort, with the moderate persons who hold that researches really directed to benefit the human race may be conducted at the expense of pain to animals, provided that every means be adopted to reduce such pain to a minimum. Your story hardly establishes the intelligence of that particular collie. What did he gain by taking the chop under the sofa, and returning it uneaten? Are we to assume that he was planning how to get the bone out without injuring the chop? If he had done this it would have shown intelligence; as it was he only showed the effect of craving.—R. S. Couch. You will find a reply to some of your questions in "Found Links," presently to appear in Knowledge.—H. D. General information on the subject of your letter will be given in numbers beginning December 30, or January 6, at latest, in a series of papers by a Fellow of the Royal Astronomical Society, on work with a 3-inch telescope. Most of the objects he will consider will be perfectly well suited to your telescope, though it is of only $2\frac{1}{4}$ inch aperture.—F. J. Brodie. We cannot at present make any arrangement: probably we may follow a plan which we pursued some eight years ago, when editing the natural science department of the *Mechanic* (not the *English Mechanic*, but the older paper, now merged in *Iron*).—John Bennett. Thanks. You will see that the "Witch of Agnesi" has been fully dealt with; the geometrical instructions being better suited to these pages than the analytical methods, though not so easily planned. The dotted curves in your figure, I see, correspond with the equation when $x-2a$ is written for $2a-x$.—A Constant Reader and Subscriber. It is not the case that the moon never sets in the polar regions and is never seen in the crescent form. The moon is only well seen as a full moon in the arctic winter months, and when so seen does not set. The crescent moon can be seen in the day time in the arctic summer months, not at all in the winter months.—J. A. R. I fancy I have seen your views respecting comets before. Was it not in the *English Mechanic?* They seemed to me unsound then, and I must confess I find no reason now to view them more favourably. They are inconsistent with many known facts.—Ron. Godfrey. Thanks. Have you heard the family anecdote about R. C.'s eleven reasons for not acknowledging the work?—Cogito. The trisection described by Mr. Warren may be extended to any angle by first bisecting, then trisecting the half angle. It is impossible by Euclidian geometry to draw from C a line CED such that DE shall be equal to OE.—J. Bacon. You are quite right. Sir D. Brewster wrote when the true nature of the spectrum was not understood.—J. M'Grigor Allan. Many thanks. Your interesting discussion of Section 3 shall presently appear.—C. T. B. Hardly room for Gems at present. G. M. The method of trisecting an angle described in Mr. Warren's letter will not do for angles above 120°, simply because when the angle 120° is reached, the point D comes up to the circumference of the semicircle.—A. J. You do not seem aware of the fact that the precession of the equinoxes is not explained empirically by the modern theory, but is shown to be an inevitable consequence, in measure and degree, of the action of gravity. It is one of the most beautiful of the proofs of the Newtonian theory. Your theory would be all right, if, first, it were certain that there would be no such effects as the law of gravity assures us there must be; and, secondly, if we knew that the sun were circling in a mighty orbit, such as you picture, in 25,900 years or thereabouts. As we are quite certain the sun is not so moving, and equally certain that the earth being spheroidal must reel precessionally precisely as she does, your theory cannot be satisfactorily maintained.—J. T. E. Mr. Foster has your illusion in his collection. It was published thirteen years ago in the *Intellectual Observer*. Mr. Foster complains that the increase of correspondence is destroying all his illusions.—K. Symons. Mere extravagance.—Edward Cox. You are quite right; but proving the earth not flat is killing the dead. The argument you use has been employed often—by myself among others,—but the Flat men cannot or will not see what to persons of average brain power is so obvious.—Thomas Bouttell. You misunderstand Dr. Wilson's reply to "Ignoramus," whose "frankness," you say, "brought down the wrath of his opponent." There is no trace of warmth, far less of wrath, in Dr. Wilson's letter. The tone of yours is, therefore (you will admit, I think, on consideration), unsuited to the occasion. Your letter is also not sufficiently condensed. If you had read Dr. Wilson's excellent essays on evolution, you would be aware that what you desire to "wisper in his tympanum," would be very far from being news to him. The evidence you adduce to "vanish the phantom touching those rudimentary members which puzzles so many of us," is precisely the evidence which the evolutionist quotes in support of his position. In any case the lecturer on Zoology and Comparative Anatomy in the Edinburgh Medical School, does not need to have such well-worn knowledge whispered in his ear.—T. Smithurst. We hope to give, before long, such articles on Time as you desire.—Cogito, C. E., Algol, &c. Thanks; questions already answered.—W. H. Jacob. The explanation is simple. Your right eye being very short-sighted, takes no part ordinarily in the vision of objects beyond its focal range. When you close it you see such objects (your finger and the distant light, for instance, in the experiment you describe) just as you did when it was open. But when you close the left eye the right eye is at once called into action. You see the distant object and your finger with this eye, though not well defined. Moreover, you see your finger to the left of the light, because the line from the right eye to the finger must obviously fall to the left of the line from the same eye to the more remote object (this object, the finger, and the left eye being in a straight line).—Thos. Hebden. Thanks. It shall appear early.—W. Ga. Rolfe. Your article on Seismology comes at an inconvenient time, when two papers on the subject are already in type.—H. Edmonds, B.Sc. We could hardly do so without apparently recommending that of which we have no personal knowledge.—Harris. Loomis's "Treatise on Practical Astronomy" is one of the best.—J. H. G. If there were any recognised connection between mild Novembers and the winters following we could ask your question, but there is not. J. Mitchell. Thanks; but no room. Clio's query already answered. Mariette, R. Lenormant, and Wilkinson quite out of date, Bunsen nearly so. Your question about first infant, and how it fed, reads like a joke.—Vega. Question 65 now sufficiently answered.—Excelsior. We were referring to another. Have no knowledge of the instrument you mention. Why not write to makers, asking what guarantees they can give as to performance, &c.—W. C. Blythe. Thanks; your interesting letter shall appear. Prof. Lunge. Thanks. Chas. Moulton. Your idea submitted to publishers; but it seem so easy for readers who prefer it to put the stitch through the paper for themselves.—D. K. Your idea that the sun-spots may be intra-mercurial planets was the first which Galileo, Fabricius, and Scheiner entertained (and disposed of) when the spots were discovered 271 years ago.—F. W. Dillon. The cat who put her paw on your knee when you were eating, so that she might receive a share of your attention and of your supper, showed intelligence, no doubt; but the case is not so unusual as you seem to think.—Ernest C. A. Axon. Thanks.—Thomas Newbitt. Thanks. Query now sufficiently answered.—T. R. Regret that we have no space at present for your sound discussion of the moon's rotation.—Cupidus Scientiæ. Puzzle marked for insertion early.—A. J. Martin. The eyepiece of a telescope is a microscope, by which the image formed at the focus of the object-glass is magnified.—Tentative. We cannot admit the ordinary stories of spiritualism, but anything tested by due experiments, properly conducted and vouched for, would, of course, be in our line.—Memb. Soc. Bibl. Arch. Many thanks for your interesting letter. We slightly alter one or two passages, lest they should lead to rejoinders of an undesirable kind.—Cæsar. The letters S. P. Q. R. were used on Roman banners, &c. They stood for Senatus Populusque Romanus (the Senate and People of Rome).—Wm. Young. Your suggestion is a good one, but at present something more than the name seems wanted.—A. A. Young. Questions sufficiently answered. D'Artagnan. "Engraver" wants more special instructions.—J. A. R. Letter on rainbow presently, if can make space, but the proof belongs to text-book matter.—J. F. Simpson. Many thanks. Correspondence occupies so much time and space that other matters, which I regard as more important, stand a chance of being neglected, unless a very strict hand is kept on our correspondence column.—Alpha. Certainly, "would" and "could," for "will" and "can," are suggestive of Mrs. Brown.—H. E. Parker. Chemical question answered sufficiently.—E. F. B. Harston. It is easier to explain than to name suitable book. You only get the force retardative by carrying the body outside the circle. So long as it moves in the circle, the force always act at right angles to the direction in which the body moves, and therefore neither hastens nor retards it.—A Haviland. Will see about it. —C. J. Shaw. Thanks. Queries already answered.—Sigma. The illusion not striking in the picture, which would cost a good deal to engrave.—Champion. The advertisement may or may not involve a reference to Knowledge. At any rate, we claim no rivalry in one of the subjects named. The last thing we should think of would be to assert any claim as to the other. We must let readers decide.—Orion. We cannot see that there is any difficulty, even now; later, the numbers will be widely different. Enough has been said about grammatical question, we cannot but think.—Sonnet. Our heart is hardening rapidly.—W. Arthur. How many have other knowledge than from books on the subject named; and if those who have are inarticulate, what good would they do our readers.—An Old Boy. We quite agree with you; Cassell's *Boy's Newspaper*, and S. Low & Co.'s *Union Jack* are capital.—F. C. S. Your proof shows how an angle of 135° may be trisected; but considering that such an angle is equal to the half of three right angles, or to three half right angles, this can hardly be regarded as the solution of the general problem, which is what is wanted. The other angle trisected in your proof is the complement of $22\frac{1}{2}$ degrees, or $67\frac{1}{2}$ degrees, the third of which is one-fourth of a right angle. Knowledge should reach Liverpool earlier than 1.30 p.m. on Saturday. —A. A. McMaster. You are certainly right. The length of the rope makes no difference if the action on the weight is along the rope. Great width between the axletrees would make a difference, because part of the strain on each side is parallel to the axle, and, of course, wasted.—F. J. D. Selbst. Will keep your remarks about water spheroids for further consideration.—M. D. P. Will try to find room for your question about worms. It seems clear your explanation is right. W. A. R. Should have put in note, but hoped to publish it ere this.—E. O. J. Thanks. Would insert your answer to Theta's paradox, had we space. A paradox is usually regarded as opposed to what is orthodox.—M. J. H. Impossible to answer your query without breaking through rules.—W. A. C. See reply above to J. H. Symington.—H. A. Bulley. Will repeat later on your lunar views. W. G. Rolfe. Alas! no room for reply. It is not a question of "may" and "might," but of "must not" and "cannot."—Philarist. You shall keep your "knowledge in a box," we keeping our five shillings "with no further trouble." Seriously, that is not the way we manage.—S. S. S. Do not know Cyples' book. We might reply to all queries if we knew how. But knowledge is very wide.—Freshman. The reverend doctor of medicine said much more than he could prove. A man who would say that "not a tittle of evidence could be found for evolution," would say anything.—J. P. F. You rather misunderstand the way in which, according to the theory of natural selection, leopards have become spotted. The case more nearly resembles modern breeding than the Jacobian system you refer to.

PLAINLY WORDED-EXACTLY DESCRIBED

LONDON: FRIDAY, DECEMBER 30, 1881.

CONTENTS OF No. 9.

CULTIVATED FIELDS.

BY E. W. PREVOST, PH.D.

IN a former number (No. V.) of KNOWLEDGE, the formation of the soil of a field was described as succinctly as possible, and it was then shown how a certain class of rock was caused to yield a loam fit for the growth of plants. It is now proposed to continue the subject, and to point out how, by the present methods of cultivation, soil can be brought into a higher condition of fertility than it would otherwise possess, if left only to the action of the weather.

It is generally found that there exists below the surface soil a layer of earth of a character somewhat different to that of the upper layer. This has been termed the *subsoil*, and we shall see later on that its composition may exert a considerable influence on the fertility of the surface soil. The methods of cultivation which we propose to consider (as also the reasons why they are employed), are draining, ploughing, and manuring. If water be poured upon some clay soil, placed in a suitable vessel, it will be noticed that some of it will pass through the soil, and that the rest will be retained; but, depending on the class of soil under examination, the amount of water retained will be greater or less, a clay soil retaining much, a sandy soil but little; this property of holding back some of the water which falls upon soil has been termed the retentive power, and it exerts a very great influence on the luxuriance of crops, for when a soil remains wet, its temperature cannot rise as high as if it were dry, and is consequently "cold." Such a "cold" land militates against the germination of seeds. On the other hand, if the retentive power is low, then the land dries quickly after a fall of rain, and the plants run the risk of being scorched by the heat of the sun. Now, it may occur that a soil is not naturally retentive of water to any great extent, yet an excess of water may be observed incapable of passing away from the surface; the cause of this stagnation may be found, on examination of the under-lying portion of the land, to arise from a bed of clay that will not admit of the downward passage of the water. This or another arrangement of the deeper portions of a field has given rise to the modern system of draining, which by causing the removal of the excess of water, and its more even distribution through the soil, permits of the entrance of air into its pores, whereby decomposition of the insoluble minerals is occasioned, and of a higher temperature being attained. Nor are these the sole advantages, but an excess of soluble saline matter, injurious to plants, such as stagnant water will deposit, is obviated, and the roots of plants are enabled to seek for their food at a greater depth than they otherwise could. Apart from these considerations affecting the well-being of the crops, there is also the great gain to the cultivator, in that the labour of tilling a soil sodden with water is far greater than when the land is fairly dry. The various methods in use for breaking up the surface of a field that pass under the name of tillage operations produce effects both physical and chemical: for by ploughing, the condition of the soil is improved, the soil being rendered less compact, dried from superfluous moisture, and exposed to the decomposing action of the air, whereby as before stated, solution of the minerals is facilitated. This decomposition has, however, been in progress but more slowly all the year round, and some of its products have been carried deep down by the rain; these the plough brings to the surface, thus adding to the stores requisite for the future crop. Sometimes, when the ploughing is carried too deep, the results are far from satisfactory, the land becoming for a short time less fertile than previously. When such an event as this happens, we may be nearly certain that the sub-oxide of iron has been brought to the surface, where it must remain until it becomes peroxide by exposure to the air, and after that the land may resume its original condition of fertility. Hence it is desirable on all accounts to allow a newly-ploughed field to remain untouched for some time, and the more so if the ploughing has been deep. It appears, then, that ploughing is in some measure supplementary to draining, and *vice versâ*, as without draining, a heavy wet soil can only be imperfectly ploughed; or, rather, the advantages following on ploughing are but in part gained.

By the removal of a heavy crop off a field, a considerable quantity of mineral matter is lost to the soil, which cannot be replaced under natural conditions in amount sufficient to produce a heavy crop in the succeeding season; to get rid of this difficulty it is customary to apply manure to the exhausted field, manures being substances which either of themselves supply food, or else by their action on the soil cause it to yield an increased quantity of available plant-food—at the same time improving its character. It would occupy far too much space to describe the properties, &c., of all the manures in use, so that we will confine our attention to two which are well known to the general public, namely, lime, and farm-yard manure. In the first of these two we have an example of a substance used not so much as a food—for, as a rule, all soils contain a sufficiency of lime for the plants—but as an agent whereby the stores in the soil are rendered accessible; but before being able to appreciate wholly the virtues of lime, we must call to mind what are the chief substances which are of value, and which are likely to be affected by the presence of such a manure; these substances are potash in combination with silica and alumina, and nitrogen contained in the organic matter or humus.

Lime may be applied as caustic or quick-lime, and as slaked lime (quick-lime to which water has been added), but as regards the action of either of these forms, there is no absolute difference, but only one of degree, in that quick lime is more energetic in its action than slaked lime; but to counterbalance the deficiency in energy of the latter, it is more capable of even distribution through the soil, by reason of its fine state of division. Rank and luxuriant herbage

is indicative of "sourness" of the soil. By this expression is to be understood the presence of an excess of acid humic matters; these acid matters on the application of lime are neutralised, and the nitrogen, held in combination in a state difficult of solution, is converted into ammonia, and finally into nitric acid which, combining with the lime, forms a most valuable manure, and one easily absorbed by the plants. The felspathic particles are likewise slowly acted on, the lime taking the place of the potash, which then becomes soluble in water, and fit for absorption by the plants. These, then, are the changes produced by lime; but there is considerable danger incurred if they are allowed to take place too often by repeated applications of the manure, for the organic matter will be reduced too much, as also the potash minerals, which in a poor soil may not be too abundantly present. But lime produces other as well as chemical changes, in that it lightens a heavy soil, and consolidates a light one, merely because it is a substance whose texture is opposed to a clay or to a sand. The lightening of heavy soil is, however, not to be ascribed wholly to the physical admixture of lime, but also to a somewhat complicated chemical change which occurs in the soil. To explain what actually does take place, it is necessary to know that when lime is exposed to the air, it gradually absorbs carbonic acid, and is transformed into carbonate of lime, or chalk; when, then, the acid humic matters of the soil come in contact with the chalk, carbonic acid is set free, but not being able easily to escape, it remains enclosed in the pores of the soil, causing the soil to swell and to become lighter, and, if the evolution of gas be not too great, much benefit is the result; but if, on the other hand, this porous condition is excessive, a loss of fertility ensues, in which case the land is said to be "over-limed." As a proof that this is one of the causes of "over-liming," it may be stated that rolling the land is found to be highly beneficial, as thereby the soil is rendered more compact, a portion of the imprisoned gas being forced out. To produce this porosity, it appears that we are not wholly dependent on lime, as the addition of carbonate of lime tends to produce the same result, and without such violence of action as is exerted by caustic lime.

Considering, next, farmyard manure, we see how different is its working, for by its application, actual food is given to the plant, though not in the form best suited for assimilation; hence the manure is slow in action, and produces its effects over a period of three years, as its constituents are but slowly brought into the soluble condition. Farmyard manure may be considered as consisting of nitrogenous matters, capable of conversion into ammonia, potash in a soluble state, and some phosphoric acid; and besides these compounds, there is a certain amount of organic or vegetable matter, such as straw, partly transformed into humus, and partly in its original condition. When this manure is applied to the fields, the soil retains all the valuable portions as they become soluble, handing them over to the plants seeking for food; but, at the same time, it is improved in character, for, if heavy, it is lightened. It is found that it is principally the straw which renders a heavy soil lighter; for, as it slowly decays, giving off carbonic acid gas, it leaves, as it were, its cast in the soil, thus forming passages which the air can readily traverse. In this decomposition of the straw, we have one of the sources of the carbonic acid which acts upon the lime, as referred to above, and which also aids in the destruction of the minerals, as previously stated in No. V.

According to an analysis of Professor Frankland, the water of the Holy Well of Zemzem, at Mecca, is sewage more than seven times as rich as the average sewage of London.

BABYLONIAN SUN-WORSHIP.

Nabupaliddina was the contemporary of the Assyrian kings, Assur-nazirpal and Shalmanesar, and the sculptured, inscribed memorial of his reign, which has been restored to us, is certainly one of the most important records that have rewarded the explorer in Babylonia. In the upper part of the tablet, the dimensions of which are 2 ft. long by 1 ft. broad, is a small sculptured panel representing the worship of the Sun-god by Nabupaliddina and attendant priests. The god is represented as seated on a throne beneath a baldacchino, or open canopy shrine. He has long beard and hair, like most conceptions of the Sun-god, and holds in his hand a ring, the emblem of revolving time, and a short stick; too small for a sceptre, we may, perhaps, see in this the fire-stick which was closely connected with the Sun-god. Before him, on a small table-altar, is a large disc, ornamented with four star-like limbs and four sets of wave-like rays. Above this group is cut the inscription: "The Disc of the Sun-god, and the rays (of his) eyes." The scene here depicted is clearly indicative of the fact that the priests of Sippara were worshippers of the solar disc and solar rays, and their creed seems to bear a close resemblance to that of the disc-worshippers of the eighteenth Egyptian dynasty, who, under Amenophis III. and his son Khunaten, for some time held their ground against the priests of Ammon. This heretical creed was introduced into Egypt by Thi, the Asiatic wife of Amenophis III., and its tenets have been made the subject of a special memoir by Sir Charles Nicholson. The discovery of this sculpture and inscription from the ruins of the temple of the Sun-god at Sippara tends very strongly to place the origin of the creed in Babylonia. The inscription on the back and front of this memorial tablet is a valuable record of the religious life and ceremonial of the Babylonian temples, and the list of the solar festivals in the fifth and sixth columns shows how far back into the remote past we must place the rise of Babylonian sun-worship. Astronomers will welcome this ancient list of festivals, as it proves very clearly the high character of the astronomical knowledge of the Babylonian priests. The six fixed festivals recorded in this inscription are:—

1. Nisan, seventh day, Festival of the Rays (vernal equinox).
2. Airu, tenth day, Festival of the Rays.
3. Ulul, third day, Festival of the Illumination of the Temple.
4. Tasrituv, seventh day, Festival of the Illumination of the Palace (autumnal equinox).
5. Marchesvan, fourteenth day, Festival of the Rays.
6. Adar, fifteenth day, Festival of Illumination of Palace.

The discovery of an important list of solar festivals such as we have here is an important addition to our knowledge of Babylonian astro-theology. The first month of the Babylonian calendar was the "month of sacrifice," or "the altar," and its position was fixed by the vernal equinox, which was in the time of Nabupaliddina, in the sign of Aries—the ram being the chief object of sacrifice. Students of Biblical archæology will find an abundant fund of matter in the carefully compiled rules as to the distribution of the sacrificial victims. "Sheep," "oxen," "rams," "fruits of the earth," were objects of sacrifice, and portions of each offering were set aside for the priests. These offerings were burned on the great altar of the temple discovered by Mr. Rassam in the chamber adjoining the record room. The great central court of this temple seems to have been styled "the court of the Sun-god," and there was also an outer court "called the court of Bel."—*Times.*

BRAIN TROUBLES.

Part III.—Distracted Attention.

THE next of these signs—one, indeed, which many mental physiologists set first—is an inability to fix the attention on any subject till the mind has done with it. We have taken the failure of memory first, simply because we believe that this symptom can ordinarily be recognised earlier than inability to fix the attention. The fact would seem to be that, since in ordinary processes of thought, we first recognise or ascertain particular facts, and then commit them to the keeping of the memory, the latter process is naturally the one which first fails us. That it should be taken first is indicated, too, by the circumstance that although many cases can be cited of persons who, although able to direct their attention to a subject, are unable to retain in their memory what has been suggested to their thoughts while thus directed, no case is on record in which this state of things has been reversed, and a person has been able to remember recent facts distinctly after he has lost the power of arriving at fresh ideas by efforts of attention. To mention only one case of the former kind, Dr. Winslow tells of one patient whose memory as to recent events was seriously damaged, while yet his perceptive faculties and reasoning powers were not at all affected. "He conversed with great sagacity, fluency, and acuteness on every subject, but if I permitted a second to elapse in the conversation, he entirely forgot what he had been previously talking of." From the time when his memory thus failed him, he retained his former power of reasoning. "He could discuss at short intervals the most subtle and abstruse political, professional, and literary matters with apparently unimpaired mental vigour; but his memory never recovered its healthy tenacity." It may hence be inferred that temporary loss of the power of fixing the attention (which must be carefully distinguished from mere forgetfulness, that is the habit of being inattentive), is more likely to be a sign of serious mental mischief, than failure of the power of memory. Yet the former, like the latter symptom, indicates in the great majority of cases no serious mischief, though it would be exceedingly unwise to overlook it.

The failure of the power of directing the attention to a subject may show itself in several ways. Thus the mind may be unable even to begin the study of a subject; or it may begin the study and presently wander off to other subjects, despite the most anxious efforts to restrain it from so doing; or suddenly it will seem to cease its action, remaining for a short time confused and, as it were, lost, and then resuming the consideration of the same subject at the point where it had left it, and apparently as acutely and attentively as before. These three forms of distraction are of different significance as symptoms of mental trouble. The first, though undoubtedly it would be very serious in this respect, if persistent, nearly always indicates only that the mind wants rest, and no one who is wise will neglect the warning. The second equally implies that the mind wants rest, though not in equal degree. But the third is usually a sign of serious mischief. We consider it here, not as belonging to those indications of mental disturbance which, without being alarming, should be attended to by all who wish to keep their brains in good working order, but because the nature of the cerebral mischief indicated by such symptoms has been ascertained, and we may hence infer the general nature of the mischief indicated when the less serious symptoms of distraction are recognised, and may so judge what is the appropriate remedy. For, unfortunately, several of the cases in which the mind has been observed suddenly to become confused or lost, resuming its activity and clearness after a short interval, have been followed by severe illness, which has proved eventually fatal.

Among the most remarkable and carefully-observed cases of this kind is that of King Oscar of Sweden, the circumstances of which were minutely detailed by Dr. P. O. Liljewalch, the king's first physician. King Oscar had enjoyed fairly good health during the greater part of his life; but before his last illness it had been noticed that occasionally the heart's action was irregular, oftener in spring than in other parts of the year. In 1851 the heart became very irregular in its movements, and the digestive functions were impaired. Although he soon after recovered to some degree, an attack of typhus fever, following the loss of a beloved son, severely tried his constitution, when, slowly recovering strength after this, he unwisely omitted his usual autumn rest and excursion, and devoted his mind to political matters requiring close and anxious attention. In 1857 his health again gave way, and it was at this time that the nervous mischief was first noticed which subsequently proved the characteristic feature of the king's illness, and, in Dr. Liljewalch's opinion, "brought him to his death." The first trace of this nervous disease, says Liljewalch, "manifested itself long since, although it was not until the last six or eight years of his life that, as we have seen, it occurred with more definite and at last with such threatening symptoms. No one who had an opportunity of observing him during a long period in his daily intercourse, could avoid being amazed at the very extraordinary power the king always exhibited of retaining in his memory the most varied details, or could cease admiring" (really one could imagine that some few could achieve this, however impossible it might seem to the courtly Liljewalch) "the rapid apprehension, the unerring judgment, and the singular clearness of statement which were exhibited whenever he spoke. But at the same time he could not fail to recollect how the king sometimes, in the middle of a conversation to which he was directing all his attention, would of a sudden appear to be abstracted, and would actually transfer his thoughts to some other subject on which unless he might be disturbed, he would allow them to rest, usually only for a few moments, but sometimes for many minutes, after which the conversation would be resumed as if it had not been interrupted. The peculiar expression of the king's features—particularly his look, assumed on such occasions, and the spasmodic state, or the involuntary movements which at the same time took place in one or other part of his muscular system—render it probable that this distraction, which at times was of frequent recurrence, was due to an incipient affection of the central organ of thought. This symptom, referable to the most important organ of the nervous system" (the care and ingenuity with which the court physician avoids any direct statement that the king's brain was affected is worthy of all praise) "was of late years accompanied, as has been already mentioned, with increasing weakness in the muscles of the lower extremities, and with uncertainty in the combination of movement, probably depending on a commencing organic change, either in the organ alone on which the power of motion depends or else in that by which the co-ordination of movements is effected." The king himself was not misled by the phraseology in which the court physicians endeavoured to cloak the fact that his brain was disordered. "Incapacity to discharge his royal functions now brought on a deep melancholy, and the king, even in the commencement of his illness, expressed his conviction of its incura-

bility." The strength of the body failed more and more as "the organ on which the power of motion depends" became more and more diseased. "The lower extremities, the muscles of which were always weak, began to totter under the weight of the body, and at the same time the power of combination for the motions of those parts was impaired, and the king was troubled with vertigo, particularly accompanying the movements of the head, and with vomiting, which symptoms, in combination with diminution of strength and the occurrence of involuntary muscular spasms, indicated the existence of a more deeply-seated affection, probably a softening in the central nervous system." (One could imagine that as, of old, Spanish courtiers adopted the conventional hypothesis that a Queen of Spain has no legs, Dr. Liljewalch held that the Kings of Sweden, and "royal personages" generally, have no brains). The means employed to combat the disease produced no good effects; "the paralysis, which commenced in the lower extremities, gradually increased, and after the king, feeling his inability any longer to fill the high position to which Providence had called him, transferred into the hands of the crown prince the government of the United Kingdoms, his deep melancholy gave way to a progressive indifference, even for those things which in his health he had regarded with the most lively interest." The rest of Dr. Liljewalch's account relates to the gradual failure of King Oscar's powers, mental and bodily, and is too technical to be quoted *verbatim*. It is noteworthy that the power of speech began to be affected early during the progress of the disorder, and later was lost altogether. From this we should be led to regard failure in the power of verbal expression as a later, and therefore a more alarming, symptom of cerebral mischief, than diminution of the power of fixing the attention. The *post-mortem* examination of King Oscar revealed extensive disorganisation of the brain.

A case somewhat similar to that of King Oscar is thus related by Dr. Forbes Winslow:—"A gentleman connected with the Stock Exchange was suspected to have disease of the brain. His symptoms were as follow: general muscular weakness, occasional paroxysms of severe headache, slight paralysis of the superior palpebræ and of the left eye, occasional sensation of numbness in the right foot. The mind was not apparently at all impaired. He continued, up to the period of my being consulted, fully competent to discharge all his commercial duties, attended to his accounts, and wrote letters of business with his usual ability and clearness. His brother informed me that at times he was greatly *ab*stracted and *dis*tracted; that whilst engaged in conversation, he would suddenly pause put his hand to his head, and appeared vexed with himself at having lost all consciousness of what he was saying. This symptom was observed *two* years before any question arose, or suspicion existed, as to the state of the brain! The family, judging from the subsequent progress of the case, were of opinion that the cerebral disorder was first exhibited by the sudden lapses of thought to which he was subject for many years previously to the manifestations of other and more unequivocal symptoms of brain disease. Such, also, was my opinion. . . . In about a year and a half he died, quite paralytic. Considerable organic disease of the brain was discovered after death."

In another case, which also ended fatally, an Irish barrister, three years before an attack of acute mania, was observed to stop occasionally whilst addressing the courts of law, as if for the moment lost. "So marked was this symptom, that a professional friend, often associated with him in the conduct of legal matters, considered it his duty to direct the attention of the gentleman's wife to the fact, considering that such attacks of mental distraction, on occasions when it was of essential importance for the mind to be in a state of continuous activity, looked suspicious, and, according to his judgment, were not consistent with a healthy state of the brain." About two years after this peculiarity had been noticed, this patient experienced a slight epileptiform seizure whilst at his chambers, during a very hot day in the month of July. "As this attack was considered to have been one of syncope, and to be caused by the then high state of the temperature, little or no notice was taken of it. Previously to travelling on the Continent, he had been working unusually hard, eating and drinking very sparingly, sitting up late at night, and rising early in the morning. In fact, he acted with great indiscretion and imprudence, and the result was an acute attack of brain disease, affecting the mind, a fortnight after his arrival in Paris." In this case, the *post-mortem* examination revealed the existence of chronic disease of the membranes of the brain—mischief which seemed to have lasted for a considerable time before death.

As we have already explained, it is not so easy to find illustrative cases of the less alarming forms of distraction. Even in cases where serious mischief has followed these slighter mind troubles, the symptoms immediately preceding such serious illness have commonly been of a more marked kind, and these alone have usually been regarded as really belonging to the case. Nevertheless, all who have given careful attention to mental maladies, can speak of instances in which the less serious forms of distraction have been noticed early in the progress of cerebral disorders; so that though they need not alarm those who note them in their own case, they should not be neglected. They are always signs that the mind wants rest, and they may be signs that some more specific remedy is required, which can be readily determined by noting whether rest brings relief. "I am anxious," says Dr. Forbes Winslow (and it could be wished that throughout his valuable work he had been similarly careful to avoid occasioning unnecessary alarm), "to attach no undue importance to this evidence of morbid intelligence, but I cannot close my eyes to the fact that a debilitated power of attention is a prominent symptom in the early stage of cerebral disorder. Cases of incipient brain disease have occurred in which patients have, previously to other symptoms, lost all ability to read continuously twenty lines of a book without a painful effort of thought." It will be noticed that Dr. Winslow here puts distraction as a phenomenon preceding, in cases of cerebral disorder, the loss of memory: albeit, we believe that had he had the means of ascertaining the precise progress of mental disorder, in cases where he supposed this to have been the case, he would have found that the memory had begun to go in the first instance. "If," he proceeds, "there be impairment of attention and debility of memory, it is illusory for the patient to imagine that he is able, until his *physical* condition of ill-health is attended to, by repeated and persevering efforts, to resuscitate these prostrated powers. In his attempt to do so he still further taxes the morbid state of these faculties" (meaning, apparently, that he overtaxes the faculties and makes their state still more morbid), "and, instead of invigorating, still further debilitates, and often entirely extinguishes his intelligence." This caution cannot be too carefully attended to. Returning to the analogy between bodily and mental powers, which we touched upon at the outset, we may compare the power of attention to actual muscular strength,—as the power of memory may be compared to skill in mastering such and such feats of muscular dexterity, and acquired mental knowledge to the various athletic exercises which a man has learned to

achieve. Now if an athlete finds that his bodily strength is unequal to a task which has hitherto been well within his powers, he would not think (if he were wise) of trying repeatedly to achieve the muscular effort which he has found too much for him. Or (extending the analogy to other ways in which the power of attention may fail) if an athlete finds that he is unable to continue some muscular effort so long as usual, he does not compel Nature to achieve the task which for the nonce has become too great for him. In either case he perceives that for the time being he is not himself, and, by rest or change of some kind (diet, mode of training, or the like), he seeks to restore his powers. At any rate, if he is so unwise, in either case, as to endeavour to master Nature, he increases the mischief, and may entirely lose the powers which had been weakened, and might otherwise have been soon restored, or might at least have been saved from further weakening. So, remembering how close in reality is the analogy between the mental and bodily powers, we can well believe Dr. Forbes Winslow, when he tells us that when the attempt to fix and concentrate the thoughts requires a continuous, painful, and vigorous effort of the will, "serious and irreparable injury may be done to the delicate organisation of the brain and mind by injudicious attempts to exercise, stimulate, and *force* into activity the morbidly flagging and sluggish mental faculties." These symptoms show that the brain is for the time being unfit for sustained action or for intense action, though not necessarily (or even probably) diseased, and that rest is essential to restore its enfeebled energies. Whether such rest should be long-continued or not, will depend on the question whether the symptoms of weakened powers of attention are marked or otherwise, and also in no slight degree on the length of time during which these symptoms, whatever they may be, have been neglected. If they are attended to so soon as they are noticed (in which case they will probably be slight), a very brief rest will generally restore to the mind its wonted energies. Many a man who, in the midst of prolonged and arduous mental exertion, has noticed signs of flagging in his power of attention, has found in even half-an-hour of sound sleep a remedy more effective than a three months' rest would be after such signs had been neglected during several successive weeks of mental labour.

Some physiologists assert that defective speech, the next symptom which we have to deal with, has been the first symptom noticed in cases of cerebral disorder. Dr. Forbes Winslow says :—"The first evidence of approaching apoplexy and paralysis is occasionally a sudden loss of speech." This may have been the first symptom noticed, but we question very much whether it has ever been the first symptom which has existed.

We ought to distinguish, perhaps, here, between defective speech and defective power of expression (by words indicated otherwise than by actual articulation). In fact, an important distinction exists even between the loss of the power of articulation and the affection of the vocal organs indicative of cerebral disease. Here, however, we consider generally the impairment of the power of linguistic expression which usually precedes serious mental trouble, and is often enough noticed where rest only or change of diet is necessary as a remedy. Usually, however, this symptom is serious. Indeed, one writer on the subject of cerebral disease remarks that it is a most unusual circumstance for the symptom to exist without being followed by acute cerebral mischief. Possibly the remark refers only to the absolute loss, whether for a short or long period, of the power of expressing ideas by language, spoken or written. That the power of expression may be affected, and even for a time affected seriously, while nevertheless there is no serious cerebral mischief, is within the experience of most persons who have occasion to exercise this power freely. The symptom, like others we have dealt with here, is one to be noticed, and its warning voice should be heeded early. This done, there is usually little occasion for alarm, startling though some of the stories now to be related may appear.

Dr. Winslow relates that "a literary gentleman, whose vocation in life was that of a public lecturer, noticed for nearly eight weeks before he was seized with paralysis, that occasionally whilst speaking he lost for a second or two all power of articulation. This occurred on five or six occasions previously to an attack of decided hemiplegia. This patient had taxed his powers of mind to their utmost by lecturing twice, and often thrice, a day*; but independently of this amount of literary labour, he had been exposed to much anxiety respecting family matters, and this had produced restless, and, in some instances, sleepless nights."

INTELLIGENCE IN ANIMALS.

LET us next examine a few cases in which animals have done things which they have seen done by the persons with whom they live, and more or less obviously with the object of obtaining the result which they had observed to follow from such actions. For this would seem, if the animal can be clearly shown to have had such a purpose, to be distinctly the result of reasoning. Monkeys may or may not reason when they imitate actions which, when performed by themselves, are of no advantage to them, or are even mischievous. Indeed, it is not improbable that they suppose their human fellow-creatures would not perform such actions except for a useful purpose, though what that purpose may be they may have no conception. But whatever opinion we may form on this point, we can have, it would seem, no room for rejecting the belief that an animal has reasoned who performs an act demonstrably for the purpose of producing a certain effect, such as he has observed to follow when human beings have so acted. Now in some of the cases which follow, this does seem to be most clearly made out.

A writer in *Nature* gives the following case :—"My sister, who lives just opposite to my own house, possesses a cat (now about thirteen years old), whose intelligence is very remarkable. He has a habit of making use of the knocker of a side door, which is just within his reach as he stands on his hind legs, whenever he desires admission. A single knock is tried in the first instance; but if this is not answered promptly, it is followed by what is known as the 'postman's knock;' if this is not successful, trial is then made of a scientific 'rat-tat' that would not disgrace a west-end footman. I should say that 'Minnie' holds the knocker in his paw as we should hold it in our fingers, and not by simply tipping it up. How far this practice involves 'abstract reasoning,' I will not say, but something like an approach to it is suggested, for he was never taught to knock at the door, and adopted the habit some three years ago, evidently to gain admittance, very often to the annoy-

* The writer of these lines has lectured twice a day for a week, filling up four or five hours of each day with literary work, without feeling any effects which seemed to suggest that he had taxed his powers of mind to their utmost. But, on the other hand, he has noticed that after lecturing only once a day, or even only four times a week, while travelling great distances each day, several of the symptoms of incipient cerebral mischief have appeared; and even less lecturing, accompanied by much mental anxiety, has caused such symptoms to appear.

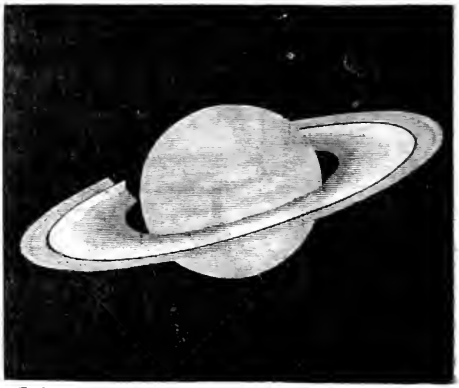
ance of my sister's family, who have occasionally been disturbed in this way at unseemly hours." The rest of the letter has no bearing on the subject we are upon, but it is too amusing to be omitted. "I should be sorry," says the writer, "in thus referring to the sagacity of poor pussy (who is now also somewhat feeble), to reflect upon him by noticing some other of his peculiarities, one of which is his fondness for a little brandy-and-water, and other alcoholic stimulants." It would be, perhaps, to inquire somewhat too curiously to ask whether this story shows that the fondness for stimulants is associated with an advance in reasoning power, or whether, perhaps, Minnie's brain was aroused to abnormal activity by the tippling in which alone (we may assume) he was indulged by his mistress. The point established by the story is that in some cases—at any rate, as in animals so low in cerebral development as cats—the consequences of a certain action are observed and remembered, the action being repeated by the animal when he wants those particular consequences to follow. This cannot be explained by any theory of mere instinct.

In the last story, the cat was an old one, and though this does not modify the conclusion to be deduced from the animal's behaviour, yet it in some degree diminishes our estimate of the activity of Minnie's reasoning power. In the following case, a young cat showed equal intelligence :—"I may mention a case," says the writer, "of a kitten about half-grown, having mental reflection of some sort. I was sitting in one of the rooms at a house where I was stopping in Somersetshire, and hearing a knock at the front door, was told not to heed it, as it was only this kitten asking admittance. Not believing it, I watched for myself, and very soon saw this kitten jump on to the door, hang on by one leg, and put the other fore paw right through the knocker and rap twice. The knocker was an ordinary shaped one, fixed in the centre of the door half way up; the top part of the door was glazed. I saw this performance dozens of times afterwards, and often used to put the kitten outside to see it done. It was never known to knock when anyone stood in the garden, but if one went indoors and shut it outside, in a few minutes came the usual knock. A sister kitten to this one was never known to knock, but sat on the doorstep and entered when the door was opened, and in nine cases out of ten the knock was successful. The kitten was never taught in any way: it would knock at both front and back door."

In the following case, the object of an animal's action in such cases was tested by an experiment, but the evidence is less satisfactory in one respect than that afforded by the two previous cases, the animal having been taught the action :—"A small English terrier belonging to a friend," says the narrator of the story, "has been taught to ring for the servant. To try if the dog knew *why* it rang the bell, he was told to do so while the girl was in the room. The little fellow looked up in the most intelligent manner at the person giving the order (his master or mistress, I forget which), then at the servant, and refused to obey, although the order was repeated more than once. The servant left the room, and a few minutes afterwards the dog rang the bell immediately on being told to do so." Here it is to be noticed that the dog did not ring the bell (as, in each of the preceding stories, the cat knocked at the door) to get some end of his own accomplished. He rang to save his master or mistress trouble. And the fact that he had been taught to ring for this purpose, although making the act itself less obviously a sign of reasoning power than the cat's action in knocking at the door, makes his refusal to ring when told to do so a more manifest evidence of reasoning than it would otherwise have been. If the dog rang for the servant because of some advantage he always gained from the servant's coming, it would have been natural enough that he should refrain from ringing when the servant was in the room. But his refusing to do what he had been taught to do, at the risk of offending his master or mistress by such refusal, makes it absolutely certain that he had clearly recognised the object which was to be attained by ringing the bell.

THE PLANET SATURN.

Although the ringed planet is passing away from the position where it shines most brightly, and being nearest to the earth, is, on the whole, most favourably situated for observation, yet, as he passes away from this position he shows certain features of interest which are either less favourably seen, or not seen at all when he is nearest to us. Just as the full moon shows no shadows, being seen from the earth when it is between the moon and the sun, so the shadow of the planet Saturn on his rings is less invisible when Saturn is in opposition (as it is called) to the sun, that is, when the earth lies on, or very near, a line drawn from the sun to Saturn. But when the earth has, by her more rapid motion, passed away from this position, the steadfast



shadow which, "as the planet whirls, sleeps on the luminous ring," is well seen. This shadow is an interesting object of telescopic study, because, instead of presenting at all times those uniform outlines which the laws of perspective teach us should be presented by the shadow of a spheroid on a plane, or nearly plane, surface, the outlines are often very cunningly distorted. Thus, in the accompanying picture, we have a view of the shadow as seen by Trouvelot, an excellent American observer, with the magnificent 26 in. telescope of the Washington Observatory, and this shadow is so distorted that one would say it was entirely "out of drawing" if one were not certain that Trouvelot depicted correctly what the perfectly trustworthy and most powerful telescope he employed, showed him. We would invite telescopists to examine the planet carefully during the next few weeks, and note any peculiarity of shape which the shadow on the ring may present. We shall be glad to indicate, for comparison with drawings which may be sent us, the true shape which, according to the laws of perspective, the shadow should have had at the epoch of the respective drawings.

THE MAGIC WHEEL.

WE had hoped to present our younger readers this week with a drawing of a trotting horse in the various positions successively assumed by the animal (as instantaneously photographed), for use with the ingenious instrument illustrated in the accompanying cut. But, on carefully examining the picture in the *Scientific American*, we found that there was an error which would have caused the picture to produce an imperfect illustration of the horse's action. Twelve positions had been taken from the photographer's series without its being noticed that the last two were almost exact repetitions of the first two (in other words, a complete double

step was illustrated in the first ten pictures). The delay caused by the corrections prevents us from giving the picture this week, but next week we shall have a set of ten positions of a trotting horse, arranged for use as in the accompanying figure, illustrating a highly ingenious method for avoiding the difficulties involved in the construction of a zoetrope. We shall later give a series of views of a galloping horse. In the meantime we leave our younger readers to puzzle out the meaning of the accompanying cut, and in particular to find out how it is that the various parts of a properly-constructed zoetrope are provided for here by so simple a construction.

PRIMARY COLOURS.

IT is impossible to construct a consistent theory based on three primary colours, whether the three be the older set—blue, yellow, and red, or violet, green, and red—the newer set of the theory considered by some to have been established by Clerk Maxwell in his paper to the Royal Society in 1860.

Clerk Maxwell's paper contains serious errors. He forms equations with different kinds of quantities, implicitly attributing to the units of those quantities values which, regarded relatively to each other, are purely accidental or arbitrary, and his results are, consequently, fallacious.

As is apparently recognised by Rood, in "Modern Chromatics,"—a correct and complete theory of colour vision ought to enable us to construct a circular diagram of colours, with complementary colours diametrically opposite to each other, and with the colours distributed with uniform gradation round the circle, and in accordance with their true relations to each other. Now, such a diagram cannot be constructed on the assumption that the primaries are three in number, without assuming certain colours, or combinations of colour, to be complementary, which are proved by actual experiment not to be so. The assumption also involves the absurdity that a colour can be (in a sense) complementary to itself; or in other words, that two diametrically opposite colours or combinations of colour which are complementary to each other may each contain the same colour as an ingredient.

When proceeding to arrange colours in a circular diagram, we have first to classify them. For this purpose I take so-called primaries and secondaries together, and for convenience call them simply distinct colours. To the blue-yellow-red theorists I say that to my eyes green and violet are as "distinct" as any of the three, but orange is not to the violet-green-red theorists. I say blue and yellow are as "distinct" as any of the three, but purple or crimson is not. How many "distinct" colours, then, are there to be assigned to equidistant points on the diagram? In my opinion the human mind cannot conceive of more than five colours which are as distinct from each other as red from yellow or from violet, or as blue from green or from violet, or as yellow from green. If, then, there are only five colours of the first class, or of the first and second classes together, it is impossible to construct a theory with three primaries, for such a theory implies three secondaries, or six colours of the first and second classes taken together.

With reference to seeing red in the violet of the solar spectrum, I may mention the case of a person who sees the violet of the spectrum as a dim grey only, and yet, when two spectra overlap, so that the red end of one combines with the blue part of the other, he apparently experiences the same sensations of violet and purple as normal-eyed persons.

It is held by Helmholtz and others, and I think there can be no doubt of the fact, that mentally we cannot really distinguish in any colour-sensation any components, but only a single resultant sensation. We may experience a sensation which may be called pure as regards its colouredness; for example, we may experience the sensation of a green, which inclines neither to yellow nor to blue, but it is quite certain that for a normal-eyed person it is impossible for light to act on the eye in a perfectly simple or pure manner. In this sense a perfectly pure colour is not obtainable even from the solar spectrum itself, however much it be dispersed, or however narrow a portion of it be taken. To explain my meaning, I will suppose separate nerve fibres of the retina are sensitive to the different primary colours, whatever they may be; then, what I assert, and can prove, is that no part of the spectrum, however small, acts on a single fibre (excepting, perhaps, at and near the extreme ends of the spectrum). Assuming this to be true, it follows that experiments, like those recently described by Lord Rayleigh, in which the green and red of the spectrum are combined and produce the sensation of yellow, do not in the least prove that the sensation of yellow is necessarily a compound sensation, or that yellow is not a primary colour. A great deal of the difficulty arising in the consideration of the effects of mixing colours disappears when it is understood that colours neutralise rather than combine with or add to each other, the resultant sensation being one which may be described as a mixture of more or less white or uncoloured light, with as much of the colouredness as is not neutralised. E. H.

Glasgow, *Dec.* 3, 1881.

Charles Brush, of Cleveland, Ohio, is declared to have perfected a new invention for storing electricity. The design consists of a battery in the same sense as in Planté's and Faure's, but the details are entirely different, and do not infringe upon the rights of either. Mr. Brush uses for his storage reservoir metal plates, so arranged that they are capable of receiving a very large charge of electricity and of holding it for an indefinite time. The storage reservoirs vary in size as desired, may be transported from place to place, and used as desired. Each citizen may then run his own electric light as he pleases; the plates can be put on street-cars, connected with the axles, and made to run the cars without horses, and steam-cars may be ultimately run in the same way. The practical character of the invention is said to be settled, and it is simply a matter of expense, but the details of the methods are not made public.—*Frank Leslie's Magazine.*

RIGHT-HANDEDNESS.

By James Shaw.

THERE is a difference both in structure and capacity between the left and the right lung. The former has two lobes, the latter has three. Suppose 240 inches of air have been inhaled, about 130 have been taken into the right lung, and 110 into the left. Watch at the same time the right side of the chest, and it will be seen to be more bulged out during inspiration. Meanwhile, the lower ribs, as they recede from an imaginary middle line, are firmly bound by a ligament, or short cord, to the liver. The liver, a heavy organ of about 4 lb. weight, inclines the centre of gravity to the side to which it swings, and the greater expansion of the right lung and the shifting of the liver to the right side tend to shift the centre of gravity to that side.

The heart, firmly attached to the spine and midriff, remains immoveable, but the stomach and spleen incline to follow the liver. They cannot follow the left ribs in a contrary direction, for they are not joined to them. The shifting of the line containing the centre of gravity towards the right has no countervailing-force opposed to it, for although the greater part of the heart and the spleen is on the left side, it is not enough to balance the part carried towards the right by the descent of the diaphragm, during nspiration.

It has been estimated that the viscera of the abdomen and the chest weigh heavier, by about a pound, on the right side than the left. Now it must be plain that if the right side be heavier naturally, and still heavier during the inspiration that precedes effort, the foot that supports it will be more leant upon; and if we lean more upon the right foot, it will afford a steadier basis of action for the right arm than for the left. According to this view, first clearly put forth by Professor Buchanan, there is a mechanical reason for right-handedness. The right leg is first preferred and utilised in action, and upon this preference the right hand and arm come more readily into use, and are then taken up consciously and educated as the skilled limb. No sooner is a beginning made of preference than the muscles oftenest or most strenuously used get stronger.

Violently exercise the right hand and arm, and you might expect that both lungs would inflate to their uttermost. But this is not the case. The right lung is better filled with air in proportion to its capacity than the left. If we exercise the left arm, the left lung is more inflated, according to capacity, than the right. We may even witness the right cheek of a man, violently engaged in lifting a load with the right hand and arm, inflating unconsciously. In some physical efforts, such as throwing a stone, in which the centre of gravity advances from the right, forward, and towards the left, the dilation of both cheek and lung has been observed, passing over from the right to the left. The temptation to prefer the right shoulder, the right arm and hand, in lifting a dead weight, because of the centre of gravity being more nearly over the right foot than over the left, is quite a natural one. So, when a carter puts his shoulder under the shaft of his cart, he prefers to hoist it up with the right shoulder, as having more power in raising it.

But the question may be urged, why are burdens generally carried on the left? Although portable loads are generally placed on the left shoulder, this, instead of being at variance with the mechanical theory, is really a proof of it. When a man has a heavy weight upon his left shoulder, the burden is, in reality, borne by the right rather than by the left lower limb. The body is inclined to the right, so that the mechanical axis passes from the left shoulder to the right foot, and the load is retained over it by the help of the right arm. In the case of burdens, such as fishwives' baskets, borne on the left side, it must be remembered that as the right side is the heavier, these burdens help to restore equilibrium with less of a bend towards the opposite side, and so leave the motion of the limbs less constrained. This is probably one of the causes why a nurse carries her child in her left arm, although we must recollect that, by doing so, she has another advantage, namely, the freedom of the right hand for work.

Professor Ferrier informs us that the brain has a cross action. The left hemisphere governs the right side, and the right hemisphere governs the left side. Therefore, when we see with our right eye, we see with the left side of our brain, and when we see with our left eye, we see with the right side. Now, not only has the right side a mechanical advantage; but it is strongly suspected that the left hemisphere of the brain, which governs the movement of the right side muscles, is, so to speak, a battery of greater power than the right hemisphere. Dr. Boyd made observations on the patients in St. Magdalen's Hospital, and he sets forward as a curious result, that, after weighing separately the hemispheres of 200 individuals, almost invariably the left hemisphere exceeded by an ounce the weight of the right hemisphere. To do so exactly, however, requires great nicety, as there is no definite division between the two hemispheres; and so we are not surprised that in Dr. Wagner's experience the proportion of cases having heavier left lobes was as five to two. In the Report of St. George's Hospital (1869), there is recorded a case of loss of speech and paralysis of the left arm of a left-handed lad, whose brain, after death, exhibited a softening of the right hemisphere. The question of how much the strength and dexterity of the right hand depends on the shape and nature of the brain substance is beset with difficulties; but the balance of the evidence is in favour of the constitution of the brain itself being a reason in favour of right-hand predominance. A reason founded on nature is much more satisfactory than the notion, somewhat prevalent, that right-handedness is a fashion. True, there is a percentage of our fellow-creatures left-handed; and there is a difficulty to account for this peculiarity. But it is not easy to account for many peculiarities equally striking; such as the want of beard in some men; the greater or less number of teeth, toes, and fingers; the heart being found occasionally on the right side; and the transposition of the viscera. Some men can shut one eye and keep the other open at the same time. Others can only do so with difficulty; and others, again, are quite unable to do so. From the evolutionist's point of view, it seems to me as if our destiny were to become more intensely and more generally right-handed than we are. If we go far enough back in infant biography, we arrive at a period when locomotion is chiefly performed by the aid of all four limbs. This is the case with adult apes and monkeys, who shamble along on a plain, or climb more gracefully in the woods, by the aid of all their limbs. With the infant, the difference of internal structure—throwing the centre of gravity to the right—is scarcely perceptible.

It is argued by some writers that it would be a great advantage were we ambidexter, using both hands with like skill. Now, no one doubts that the specialisation of hands for the purpose of grasping, and feet for locomotion, is of more advantage to man, than if he had four hands fitted for both functions. As the child grows older, the difference of hands appears; and this difference, in all civilised countries, is eagerly helped by precept and example. As in playing whist, it is better that partner should have many trump cards and self few, than that each should have an average number; so it is found that in a world where time is so valuable, where art is long and life is short, it is better one hand should be very well educated and the other comparatively neglected, than that each should have a moderate aptitude.

We can go back, in imagination, to the time when the grasping of a stick or stone was all the education received by a human hand. We can suppose the make of the body at that time more symmetrical, as an infant's is with us now. It is like going back to the time when the ancestors of our horses had more of a normal foot—three toes, instead of the one toe of our present steeds. Right-handedness would not be so regular nor so apparent then; just as it is said to be with Fijians at the present day, or, as it has been observed with the African elephant, which has a tusk called the "servant," with wh'ch it burrows more freely, but which is not so regularly the right tusk as the working hand is the right one with us. As soon, however, as man combined, either in labour or in war, the necessity for preferring one hand to the other would become apparent. Indeed, the evident advantage of shielding such a vital organ as the heart from wounds, and pushing forward the less vital right side, would incline men to place the shield in the left hand and the sword in the right. At all events, the thickening of complex circumstances would be unfavourable to a state of unstable equilibrium. When once the movement of preference began, everything would tend to strengthen it. Many of the implements by which man conquers nature would require to be made either to suit the supinating motion of the right hand or of the left.

The slightly stronger side would gain the day, and become the more apt and stronger after it had gained it. Now, since it has become an accomplished fact that screws, gimlets, scissors, scythes, &c., are all made for right-handed men, he who would educate us to the ambidexter must have two handles on every door, two methods of winding up every watch, Janus-shaped carpenters' benches and printcutters' gauges, duplicate sets of screw-nails, scissors and scythes.

Not only is the right hand the most dextrous, but, as far as I have extended my observations, in those cases in which there is a difference in the strength of vision between the right and the left eye, the advantage, more frequently, lies with the former. It may be thought that investigations of this kind are unpractical, but it will not appear so when it is stated that they have been the means of discovering serious differences in the organs of vision of the same individual, which drawbacks can be greatly modified by the spectacles of the optician. The relief, in reading, given to such a lop-eyed person when he has got a lens suited to either eye, is so great that, when once discovered, it is never forgotten. It is wonderful

how late in life some persons have been in detecting such inequality of vision. Indeed, there is a case mentioned by the younger Herschel, of an individual not knowing of complete blindness of one eye until advanced in years. When there is a weak one and a strong, it is generally the weak one that is most liable to disease, from its unconsciously straining to share the labour of reading, painting, or engraving with the other.

EARTH TREMORS.

(From the *Times*)

One day during the past summer, at the end of a long uphill beat after the partridges, I threw myself breathless on the ground, and on my back waited for the others to come up. As they drew near, five or six strong, tramping heavily through the turnips, I was struck by an apparent tremor of the earth beneath me. It was shivering like a jelly—or I was; for a moment I was in doubt which. Spreading out my hands upon the surface, and lying as close and flat as I could, I was soon made sure that the tremor was really in the earth and not in me. It grew more and more distinct, keeping time with the tramp of the walkers. When at last they reached me I told them of their Neptunian feat, and, making them jump altogether a few yards off was gratified to find that I could thus bring about a very respectable earthquake at will. The motion was very peculiar, and I can well believe that a queasier stomach than mine would soon be conscious of something very like a *mal de terre*. We examined the structure of this skipping hill, but found nothing that helped us much to an explanation. It was mainly made up of a thick cap of gravel on a base of red sandstone, and so was not likely to contain anything like a high-arched hollow or concealed morass within.

This vivid little experience made me readier, perhaps, than some to accept the striking statements about earth-shaking made by the brothers Darwin at the York meeting of the British Association. Especially was I prepared to give credit to what they quoted from the Astronomer Royal about Greenwich Hill and the Observatory. He wrote:—

"In the old times of Greenwich Fair, some twenty years ago, when crowds of people used to run down the hill, I find the observers could not take reflection observations for two or three hours after the crowd had been turned out. . . We do not have anything like such crowds now, even on Bank holidays, and I have not heard lately of any interference with the observations."

There is as little foundation for the calumnious hypothesis that the observers whose reflections were thus agitated had been visiting the fair themselves as for the suggestion that the above experience of my own took place after luncheon. No, the truth is, the solid earth is a very elastic solid after all, and Greenwich Hill and the Observatory and all that it contained were trembling like my Highland knoll. The *howdah* of the Atlas-elephant that stands on a tortoise is a rather ricketty structure, and quakes with every jog of the Titanic beast. But is it not being tugged at by every petty planetoid, pulled from its path by every planet, heaved all awry through its yielding bulk by sun and moon in their courses? It is; but over and above these longer, graver motions, there are incessant tremblings and quiverings in quick periods measured by seconds or less. This unlooked-for sensitiveness to small stresses, this incessant vibration when all obvious disturbing causes are eliminated, are the new facts that the Darwins have so strikingly brought out. How solid rock and massive piers of stone warp under heat and cold like unseasoned wood, how a wide stretch of ground may swell and rise for hours together after a little water has been poured on it, how the passage of a train miles away, or the pressing of a finger on the ground near at hand, may be enough to deflect the plumb-line to a visible degree—these and many other new phenomena are detailed in the full and most interesting preliminary report on the Lunar Disturbance of Gravity handed in to the Section of Physics by the ingenious brothers.

The title reminds us that, as so often in science, it was in looking for one thing that they found another. Every one knows that as the earth pulls the moon round in its monthly orbit, so, too, the moon pulls the earth and everything upon it. If a plummet be hung up right under the moon, so to speak, the earth is drawing the bob downwards, the moon very much more feebly pulls it upwards. The result is that the bob weighs a trifle lighter than if the moon were abolished. Thanks to the moon, the string is less severely strained. If the moon be not right overhead, but down a little towards its rising or its setting point, the bob will be a little drawn aside out of the straight and the plummet will no longer give a true plumb-line. As the moon rises, crosses the sky, and sets, then the direction of the plumb-line will change through a small angle. Of course, even when no moon is seen, its silent influence must be felt, and the plumb-line will return to its position by the time the moon is ready to rise again. How small the change really is we may gather from the fact that with a plummet 300 yards long the travel to and fro of the bob could scarcely in this country reach a thousandth of an inch. This is what is meant by the lunar disturbance of the direction of gravity; and there must, of course, be a solar disturbance also, the same in kind, but naturally very much smaller in amount. To investigate these disturbances experimentally clearly calls for refined skill and very delicate apparatus; but Sir William Thompson, to whom instrumental difficulties are always but child's play, in suggesting the investigation three years ago, had in view the detection of an influence still more recondite and refined.

I have said that the moon, in pulling aside the bob of the plummet, pulls also on the earth beneath it. If the earth were perfectly stiff and unyielding, this pull could have no effect on the deflection of the plumb-line. But if, as we have reason to believe, the earth yields like a great viscous mass to great stresses as well as to small ones, a hump of solid earth—a land-tide—will travel round the globe in obedience to the moon's attraction. This hump in its course will pass under the suspended plummet, and the actual deflections of the plumb-line as observed will no longer agree with those reckoned on the supposition that the earth is rigid. If we had an instrument, then, by which the minute aberrations of a carefully-suspended pendulum, isolated as far as possible from all local disturbance, could be magnified up to the point of visibility, we should have it in our power to settle some very pretty points in the physical theory of the world. Such an instrument, after various trials and failures, the Darwins have erected in the Cavendish Laboratory at Cambridge.

A massive stone, weighing three-quarters of a ton, is bedded in a pit upon the native gravel. It is surrounded by a trench, a foot wide, to isolate it completely from the floor and the building. The pendulum is a massive cylinder of pure copper, hung, by a brass wire about a yard long, inside a hollow cylindrical copper support, that rises from the stone. A tiny galvanometer mirror is hung by two fine threads, one of which is fastened to the bob, and the other to a projection of the fixed support. This suspension is so arranged that any movement of the bob displaces the mirror to a much greater degree. A ray of light is sent from a distant lamp on to the mirror, and thence reflected to a scale seven feet away. The magnification resulting from this double process is something like 50,000 times. To still and quench accidental tremors, the hollow copper cylinder is filled up with a mixture of spirits and water. It is a fact, made out by physicists that a boiled mixture of gin and water is much more viscous and clogs the motions of bodies immersed in it much more effectually than either the neat gin or the simple water. Further, to ward off the effects of external changes of temperature, the whole instrument is immersed in a tank of water resting on the stone; and lastly, after the precedent of the Tishbite, the surrounding trench is also filled up with water. Thus protected, the apparatus might seem sufficiently cut off from local influences, but as a fact its sensitiveness is now so great, that the observation has to be carried on in another room by means of a window and a telescope. Standing in the room itself 16 feet away, it is enough to shift your weight from one foot to the other to cause the speck of light to run along the scale. The same result follows if you press steadily with your fingers on the stone edge of the trench, but you may strike a good sharp blow even on the stone base without effect. It is the distortion of the soil by slight, steady pressure that is transmitted through solid gravel and stone, and shows itself as a microscopic deviation of the pendulum. Such being the case, the instrument should be delicate enough, in all conscience, to determine lunar and even solar disturbances in the direction of gravity; but, unfortunately, having got so far we seem almost to have done too much. When regular series of observations are made it is found that the pendulum is hardly ever steady. The image on the scale dances about incessantly. The ground is never really still. Some days it may be quieter than others and generally there is evidence of distinct diurnal periods, but the minor zigzags constantly interrupt, and at times reverse for an hour together, the slower march northwards or southwards. These tremors have been hitherto so persistent and so wildly irregular, that for the present, at least, the prospect of unravelling from them the perturbations due to the moon does not seem very near. Mr. George Darwin talks of the probable necessity of building a gravitation observatory at the bottom of a mine. There, it may be hoped, the railway train and the market cart will cease from troubling, and the plummet, save for the steady paces of the moon, will be at rest. The work of examining and observing these tremors of the surface is, however, still going on at Cambridge, and already several sharp seasons of microscopic earthquake unsuspected outside have been noted. Sometimes a very storm of tremor breaks out, for which no sufficient local cause can be traced.

Even so far the outcome of these experiments may prove of high value to practical astronomers. The piers on which their great telescopes turn are built of solid stone, hitherto regarded as the material most insusceptible to change or disturbance. The Darwins have shown that such piers are really most sensitive to inequalities of temperature and to small stresses. They yield and warp to a most unexpected degree. Their bad conducting power is responsible for this in part, and it is fruitfully suggested that it might be well to plate the piers with copper and to swathe them with flannel. Astronomers, who, to their vexation, have to redetermine the level of their instruments from hour to hour, and who have long suspected the occurrence of microscopic earthquakes, will take note of this practical hint. They will make ready use, too, of the observation here recorded as to the effect of the observer's own weight. They will think more of the drainage of the soil around their instruments after the observation on the irregular and long-continued swelling of the ground that results from the percolation of water. Meanwhile, the British Association and Cambridge may be congratulated on the new and valuable field of work thus opened out under their auspices, and especially on their having enlisted the services and energies of two workers who so worthily keep up the tradition of an honoured name.

BREATHING.

By Dr. J. Mortimer Granville.

(*Abstract.*)

Every act of life, every movement, every thought, involves the final use of some particles of the body. In the great majority of instances the material used cannot be used again, and must be disorganised and removed. This is effected through the agency of the blood, which brings the materials of food within reach of the living cells of which every tissue of the body is composed. These draw nourishment from the blood, just as the plant takes up material nourishment from the earth through its rootlets. Side by side with this process of feeding and growth, and an indispensable part of the process, is the interchange of elements—oxygen, hydrogen, carbon, nitrogen, and the like. In short, the vital process is in a large measure chemical, and the oxydising agent—oxygen derived from the atmosphere—is the most potent agent and factor in the production of the general result. If the supply of this agent is not sufficient for the vast purposes which it is required to effect, the animal must suffer a diminution of health, and in the end die. It is plain, therefore, that the phrase "breath of life" is full of the deepest significance. If the animal cannot breathe—using that term with its broad meaning—it must cease to live. It follows that the first concern of the living being, for himself and other living beings, should be to secure a full and fresh supply of pure air. In the case of children, this is especially necessary, for the obvious reason that the chemico-vital changes of structure in their organisms are more active and persistent than those which go on in the adult body. The child is growing in bulk, as well as constantly using up the materials of its body and requiring to replace them by new. The result is a large, continuous, and inexorable demand for copious supplies of fresh air. How is that demand complied with in the majority of cases? Growing children ought to live in the open air; but we mew them up in schoolrooms and confine them to the house on the smallest pretence of weather or indisposition. When a child is ill, its systemic demand for air is not diminished, but rather increased, as is plainly shown by the quickened pulse and breathing. Bad weather is no excuse for the confinement of children indoors. The danger of "cold" is increased by this treatment. Children are made delicate, and susceptible to the depressing effects of sudden or great changes of temperature, by the practice of calling or keeping them indoors for every shower of rain or cold wind. They are also rendered generally weakly by wrapping-up. Later on in years the requirement is very much in proportion to the activity. But, even in a state of rest, the need for oxygen is considerable. If health is to be maintained, it must be in excess of the actual chemical requirements. In truth, the more air of the purest description which can be taken into the lungs the better. Wind is, as a rule, an advantage, because there is less chance of the atmosphere we inhale having stood stagnant over bad soil, or around sources of poisonous or deleterious exhalations, and thus contracted pollution. Breathing bad air is disastrous. The "stifling feeling" and "headache" which are so commonly produced by sitting in a public meeting, are the immediate and more pronounced effects of breathing bad air; but, long before these inconveniences are consciously experienced, and even when they are entirely absent, harm is being done. The robust may not feel the effects, but they too are injured, while the weakly are enfeebled, and the seeds of disease are sown, and will probably spring up later on, and cause trouble of some kind. Nature's preventive remedy for disease, whether in the individual or in the multitude, is a bath of pure air. *The Estates Roll.*

MAN'S PROPER FOOD.

Long before reading Dr. Carpenter's articles in Knowledge, I had believed that, as a race, we are prone to eat more meat than is necessary. I must, however, protest against Miss Kingsford's argument, which, put baldly, is this:—

"Men and apes are closely akin; apes eat fruit and herbs only, therefore men ought to eat fruit and herbs only."

I cannot, however, see why it is desirable for men to go out of their way to assimilate themselves to apes, and I even think it possible that the divergence of the human from the ape stock began when men became omnivorous. I cannot assent either to the validity of the arguments derived from the animals mentioned by Miss Kingsford and in your article. I say that the wolf is incomparably superior to horse, mule, or camel in endurance, and I would myself gladly back either a lion or a tiger against a gorilla. There may be no flesh-fed animal equal in strength to the rhinoceros, and the other grass-fed animals mentioned are also grand specimens of bulk and strength (and often too of unwieldy inertness) but, *weight for weight*, they cannot compare in strength or activity with the carnivorous animals. Were the vegetarian Indians, who became intoxicated from eating meat, equal in stature, strength, or intellect to the omnivorous European? I guess not; it does not appear indeed that they were not South American Indians, some tribes of which are scarcely human. And that even a purely flesh diet may not be prejudicial is, I think, pretty well shown by the physique and strength of the Sioux and some of the other sufficiently fed tribes of North American Indians. I have lived with them in the buffalo-hunting season, when they and (after my biscuit was done) I too practically lived on buffalo meat only, and if I had not seen it in them, I could not have believed in man's having such wiry endurance; whilst for myself, I can say that, though blessed ordinarily with health and strength beyond the average, I have at no other time known either in anything like the perfection in which I enjoyed them then. Of course, the active life in the open air accounts for much of this, but the diet must, at least, have been wholesome. Personally, I believe in a mixed diet, but I also believe that man's capability of eating *anything* is one great element of his superiority to the beasts of the field. Certainly his adaptability to any climate is owing to that capability. Are the northern regions to be depopulated on the ground that, as there are no fruits and herbs there on which Miss Kingsford's apes can live, man also has no right to live there? Practical.

CALLAO "PAINTER."

On approaching Callao in a steamer, at a certain season in the year, the traveller suddenly becomes aware of an unbearable stench in the cabin and everywhere else on board; he naturally asks "what is the matter,"—he is informed "it is the 'Painter,'" the traveller, not yet knowing what really causes the vile smell, wishes "the painter would clear out with his smells." The next thing to be noticed is that the *white paint* on board becomes blackened. If the person who has observed the offensive smell for the first time, as well as the gradual blackening of the paint, has any knowledge of chemistry, he at once sees the cause of mischief, viz.: a great excess of Free Sulphuretted Hydrogen in the atmosphere—this is really the case, the air smelling abominably strong of "rotten eggs"—*i.e.*, H_2S.

If he now looks at the sea around him, he notices that the water has a yellowish milkish appearance, showing the presence of sulphur in the water—anyone who has seen Harrogate Sulphur Water will see what I mean, for the cases are similar.

His next thought is naturally what causes this singular phenomenon.

In answer to his question to those on board, "are you troubled with earthquakes at this time on land (Callao) and sea?" he is told that such is the case.

That earthquakes are felt at this time, the traveller, whether scientist or not, has rather a questionable gratification of finding out for himself before he has been long in the neighbourhood of the "Painter." That some of these earthquakes are serious occurrences our Geographies show us, though nothing is said about the "Painter."

The conclusion I have come to is one which anyone else would come to respecting this disagreeable local phenomenon, viz.:—that at a certain season of the year a submarine volcano breaks out impregnating the sea with its sulphurous vapours, then when the sea has absorbed its share, the air becomes filled with the gas.

It seems hardly necessary to explain why the white paint should become black. It is simply due to the action of the gas already alluded to above—on the white lead of the paint, sulphuretted, hydrogen having the property of changing the white lead or oxide into the sulphide of lead.

Bitumen is, I believe, thrown up onto the shores of Callao, just the same as it is on the shores of Mexico, where it soon becomes a hard mass. F. C. S.

COLOURS OF ANIMALS.

PERMIT me to reply to "B. Donbavand," [let. 130] that his remark concerning flounders being "concealed by *a covering of sand*" is entirely beside the question ventilated in my paper on colour in animals. If your correspondent has ever *seen* a sole or flounder, he must know how accurately the sandy hue is mimicked by the upper side of the animals.—If he had (as I doubt) ever seen a flounder lying motionless and uncovered in an aquarium tank, he would never have penned his sweeping statement above referred to. Permit me to say that I have repeatedly had the greatest possible difficulty, both in gazing into shallow water, and in aquaria, in distinguishing the outline of flounders of whose presence I was aware, from the sand on which they reposed. "B. Donbavand's" remarks on the "extreme tenuity" of scientific investigation (he might have used a plainer term than "tenuity") strike at the root of all scientific advance. Who, pray, is to decide what is important and what is insignificant in scientific research? Who can tell the bearing of even apparently the most trifling fact on future research? "B. Donbavand" arrogates to himself just a little too much authority, when he writes cynically of "extreme tenuity" in such a case as Mr. Darwin's observations on "Worms." The single sentence in "B. D.'s" letter, wherein he speaks of Darwin's work as a "huge paradox," is just a trifle too near silliness to warrant further remark.

In answer to "Ornithorhynchus" [100], who asks why the stings of bees and wasps do not affect a toad when it swallows the insects, I may simply refer him to the common-sense explanation of very plain differences between the constitution of a low vertebrate, such as a toad or frog, compared with the higher warmblooded vertebrates. Your correspondent is evidently thinking of the effects of the insects' sting on the human type when he puts his question concerning the immunity of the toad. But analogy reveals many examples of the fact that the powers of different quadrupeds to resist the evil effects of noxious foods, must be due to differences in the nervous sensibility, and to other features in the constitution of the animals in question. A donkey eats raw nettles, a dietary that would kill a man by producing severe throat inflammation. A secretary bird devours serpents, which may contain poisonous matter sufficient to kill a legion of birds; and man is in the same position as the bird, inasmuch as he can *swallow* safely poisons which only act when introduced directly into the blood-circulation. In a word, individual or race peculiarities serve to render innocuous to one animal what is a poison to another. The black races of men do not suffer from yellow fever, which kills off the white. A tropical sun burns and blisters a white skin, but leaves the black skin untouched.

The second Query [101] of "Ornithorhynchus," regarding "ants," will be best answered by referring him to Sir John Lubbock's "Scientific Lectures" for a full exposition of what is known about the habits of those insects.

ANDREW WILSON.

SCIENTIFIC GHOSTS.

THE following paragraphs are from the "Leaves from a Naturalist's Note Book,"* by our esteemed contributor, Professor Andrew Wilson, a work we can cordially recommend. It contains articles (some of which many of our readers may have seen in various magazines and journals) on many and very various subjects, Giants, Kangaroos, Food and Fasting, Jelly Fishes, Whales, Science and Crime, Leaves, &c., &c., all treated clearly and correctly, and all treated in a most attractive manner. The subject we select for extract is a good illustration of Professor Wilson's method :—

Modern science has made us aware that the old belief in apparitions rested on nothing more than illusive fancies caused by some kind of physical derangement of the person so affected. It is important that young persons should be made thoroughly aware of the fact that there never was and never will be any such fancy which is not capable of being explained upon natural grounds. A person in weak health, though in perfect possession of all his faculties, begins to be troubled by waking visions of persons with whom he may be familiar, or who may have been long dead, or who sometimes may appear as perfect strangers to him. The spectres who flit before him, "come like shadows" and "so depart." They represent, in the most perfect manner, the reproductions of things that are or were—utterly intangible creations. The subject of these visitations may hear the spectres converse, and they may even talk in turn to him. He is perfectly aware of their visionary nature, and is as convinced of their unreality as is the friend who sees them not, and to whom the phantoms are described. No suspicions of insane delusion as to these visitations can be entertained for a moment, and the question may therefore naturally be put to the man of science, "How can these illusions be accounted for?" The answer is to be found in one of the simplest studies in the physiology of nerves and of mind, and shows us that these illusions have a material basis, or that, in the words of the poet, the

"Shadow proves the substance true."

One of the most interesting cases of vision seeing by a person of culture and intelligence is that related in the *Athenæum* of January 10, 1880, by the Rev. Dr. Jessopp, who, in Lord Orford's library, when engaged in copying some literary notes, saw a large white hand, and then, as he tells us, perceived "the figure of a somewhat large man, with his back to the fire, bending slightly over the table, and apparently examining the pile of books I had been at work upon." The figure was dressed in some antique ecclesiastical garb. The figure vanished when Dr. Jessopp made a movement with his arm, but reappeared, and again vanished when the reverend narrator threw down a book with which he had been engaged. Dr. Jessopp's recital called forth considerable comment, and amongst others a letter from the present writer, detailing the familiar theory based on the principles of subjective sensations, treated of in the present paper. After noticing the fashion in which subjective sensations become projected forwards, the author says (*Athenæum*, January 17, 1880): "The only point concerning which any dubiety exists, concerns the exact *origin* of the specific images which appear as the result of subjective sensory action. My own idea is that almost invariably the projected image is that of a person we have seen and read about. . . . In Dr. Jessopp's case there is one fact which seems to weigh materially in favour of the idea that the vision which appeared to him in Lord Orford's library was an unconscious reproduction of some mental image or figure about which the Doctor may very likely have concerned himself in the way of antiquarian study." It is most interesting to observe that in the succeeding number of the *Athenæum*, Mr. Walter Rye writes: "Dr. A. Wilson's solution 'that the "spectre" . . . was an unconscious reproduction of some mental image or figure about which Dr. Jessopp may very likely have concerned himself in the way of antiquarian study,' seems the right one, and I think I can identify the 'ghost' The ecclesiastically dressed large man, with closely cut reddish-brown hair, and shaved cheek, appears to me the Doctor's remembrance of the portrait of Parsons, the Jesuit Father, whom he calls in his 'One Generation of a Norfolk House,' 'the manager and moving spirit' of the Jesuit mission in England. . . . Dr. Jessopp when he thought he saw the figure, was alone in an old library, belonging to a Walpole, and Father Parsons was the leader of Henry Walpole, the hero of his just-cited book. Small wonder, therefore, if the association of ideas made him think of Parsons."

All such illusive visions are thus readily explained as the creatures of an imagination which, through some brain-disturbance, is enabled to project its visions forward, on the seats of sense, as the "ringing" in our ears is produced by some irritation of hearing-centre of the brain. The known vision is a reproduction of a present memory, and the unknown vision is the reproduction of a forgotten figure which has nevertheless been stored away in some nook or cranny of the memory chamber.

We may thus dispel the illusion by its free explanation; and science has no higher function or nobler use than when, by its aid, a subject like the present is rescued from the domain of the mysterious, and brought within the sphere of ordinary knowledge.

* "Leaves from a Naturalist's Note Book." By Andrew Wilson, F.R.S.E., &c. (Chatto & Windus, London.) Price 2s. 6d.

A VERY IMPORTANT GIFT has been made to the New York Museum of Art by its President, John Taylor Johnston. It consists of a collection of 331 engraved gems made by the Rev. C. W. King, of Cambridge, England, a connoisseur and authority on glyptic art. For the most part these antique gems follow in chronological order the Di Cesnola collection, which Mr. King, in a treatise, called "a true revelation in the history of glyptic art." Speaking of this addition to the museum, General di Cesnola said that with it two more departments were now unsurpassed by any similar ones in the great European Museums. Each of the pieces is accompanied by a plaster cast. The catalogue is in Mr. King's handwriting, and a treatise on glyptic art, by Mr. King, accompanies the collection.—*Frank Leslie's Magazine.*

Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of Knowledge*; all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of Knowledge*, should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

THE PRIMARY COLOURS.—RED AT THE BLUE END OF THE SPECTRUM.

[149]—I venture to suggest the following explanation of the difficulty raised by M. W. Laing, letter 71, p. 96. The sensitive ends of the optic nerve take the form of cones; each cone is divided into three parts, and each part is able to vibrate independently of the others. As a violin string of a certain length, thickness, density, and tension is only able to vibrate a certain number of times in a second, and is set vibrating by those vibrations of air only which synchronise or keep time with the string's periods of vibration, vibration for vibration, or every second, third, fourth, &c., air vibration to each string vibration, so each part of the cone is set vibrating by those vibrations of ether which synchronise with its periods of vibrations, and by those only. The sensation of red colour is produced by the vibrating of the thick end of the cone, green, not yellow, by the middle, and blue by the thin end, these three being the primary colours; about 392 billions of ether vibrations in a second synchronise, vibration for vibration, with the periods of vibration of the thick end of the cone, and about 757 billions with the thin end of the cone. Now, it is evident that with 784 (twice 392) billions of ether vibrations in a second, every *alternate* ether vibration would synchronise with *each* vibration of the thick end of the cone, and the result would be a weak red, contiguous to and beyond the blue of the spectrum. Thus we should have *about*

392 billions of ether vibrations in a second, represented by					red.
575	,,	,,	,,	,,	green.
757	,,	,,	,,	,,	blue.
784	,,	,,	,,	,,	red.

Higher numbers of vibrations are probably absorbed or reflected by the refracting media of the eye (*i.e.*, the conjunctiva, cornea, aqueous humour, crystalline lens, and vitreous humour).

In giving yellow as a primary colour, the "commissioners" were probably guided by their knowledge of pigments and their compounds, which knowledge only misleads in the matter of coloured lights.

I trust that my explanation, be it right or wrong, is "plainly worded," and the assumed facts "exactly described"; but I cannot hope to rival "M. W. L." in these matters.

W. Rayment, Amateur of Sc.

THE MOON'S ROTATION.

[150]—C. O. K.- [39] Newcomb, in his "Popular Astronomy," says:—"The most remarkable feature of the motion of the moon is that she makes one revolution on her axis in the same time that she revolves round the earth. . . . The reason of this peculiarity is to be found in the ellipticity of her globe. That she should originally have been set in revolution on her axis with precisely the same velocity with which she revolved around the earth, so that not the slightest variation in the relation of the two motions should ever occur in the course of ages, is highly improbable. . . . The effect of the attraction of the earth upon the slightly elongated lunar globe is such that if the two motions are in the beginning very near together, not only will the axial rotation accommodate itself to the orbital revolution around the earth, but, as the latter varies, the former will vary with it, and thus the correspondence will be kept up."

Herschel, "Outlines of Astronomy" (S. 436ª), refers to a remark made by Professor Hansen, viz., "that the fact of the moon turning always the same face towards the earth is in all probability the result of an elongation of its figure in the direction of a line joining the centres of both the bodies acting conjointly with a non-coincidence of its centre of gravity with its centre of symmetry." He then gives a practical illustration.

"Suppose, then, its (the moon's) globe made up of materials not homogeneous, and so disposed in its interior that some considerable preponderance of weight should exist eccentrically situated, then it will be easily apprehended that the portion of its surface nearer to that heavier portion of its solid content under all the circumstances of a rotation so adjusted will permanently occupy the situation most remote from earth."—A. T. C.

FOUR FOURS, SINGULAR NUMERICAL RELATION.

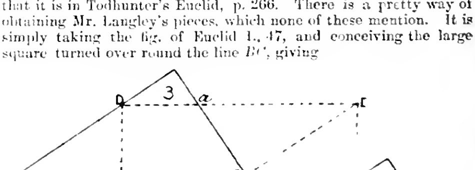
[151]—It may be as new to some of the readers of Knowledge as it was to myself when first shown the other day that all the numbers to twenty inclusive (and many upwards), with the single exception of nineteen, may be expressed by four fours, using any signs necessary except those of squaring and cubing, in which figures are required. Only four, but at the same time, the whole of the four figures are to be used. I do not say that it is impossible to obtain the number 19 in this way, but neither myself nor the gentleman who showed me the above has been able to do so. With the hope that this may prove interesting to at least some of the readers of your valuable paper.—Yours, &c., Cupidus Scientiæ.

[Our correspondent gives the solutions for all numbers from 1 to 20, except 19. These shall appear next week. In the meantime we leave the problem as an exercise to our readers.—Ed.]

THREE SQUARE PUZZLE.

[152]—A great number of letters relating to this puzzle have been received, nearly all of which we should like to print, but we have nearly twenty pages of correspondence already in type, besides the correspondence received since No. 8 appeared. We have, therefore, absolutely no choice but to omit matter which otherwise would suit our pages exceedingly well.

Mr. Langley's puzzle has been solved and explained fully and exactly by J. O. M., W. T. Y., Mathematicus, F. F., J. S., and others. T. Turner, Thomas Mactaggart, and J. T. E. point out that it is in Todhunter's Euclid, p. 266. There is a pretty way of obtaining Mr. Langley's pieces, which none of these mention. It is simply taking the fig. of Euclid I., 47, and conceiving the large square turned over round the line *BC*, giving



We thus have the five pieces of Mr. Langley's figure, and, at the same time, see how they are to be arranged to fill the square *BE*. We leave 2 where it is; put 1 where *BAC* is, 4 on *Eab*, and then 5 and 3 together cover the triangle *bEc*, divided as shown by the line *cd*. R. A. Proctor.

THE QUERIES IN "KNOWLEDGE" (*Abstract*).

[153]—Perhaps you will forgive my making a few observations on Knowledge. Like many, doubtless, I have profited very much by such essays as those in the first half of each number. But, Sir,

t is very hard that space should be taken up with questions, the answers to which are in well-known text-books. May I suggest that such questions be not inserted, but answered shortly in the small print "Answers to Correspondents."

I also thought it very hard that so much room was given for "that the sun is cold," to men whom you say cannot comprehend an argument derived from the solar dark lines.—Yours, &c.,

Anti-Paradox.

[Anti-Paradox's letter is allowed to appear as a rather remarkable specimen of the class to which it belongs. Among some twenty or thirty kindly letter, recognising what we are trying to do in Knowledge, and, indeed, giving us credit for a degree of success which we ourselves would hardly claim, will come a letter or two such as the above. Anti-Paradox's complaint reminds us of a remark of a theatrical agent we met in New York, who said there were some who would not go to the theatre "unless they had orders given for all their family, and *then* they complained unless first-class carriages were sent to take them along." Putting aside the question whether those who have queries to ask have not a right to expect some space, and noting that many primers and text-books are not simply worded, even when (which is not always the case) they are exactly described, we would invite "Anti-Paradox," and the small proportion of our readers who view matters like him, to consider things from the point of view of the proprietors of such a journal as this. "Anti-Paradox" pays twopence for each copy, of which sum more nearly the half than three-fourths reaches the proprietors of Knowledge. Let "Paradox" inquire how much twelve, fourteen, or sixteen double leaves (as the case may be) of good paper is likely to cost, even at wholesale rate, and the probable expense per copy of such matters as composing, printing, folding, advertising, and so forth, to say nothing of editing. When he has done this, and notes the nature of the margin between a penny-farthing and such costs per copy, let him ask himself if it is quite reasonable for him to expect us to crowd queries, correspondence, &c., into "the small print 'Answers to Correspondents,' in order that he may have as nearly as possible the entire contents of Knowledge devoted to original matter. Observing that a page of small print in itself involves a loss (costing more than twice as much as a page of large print), let him notice that, on the average, we give him, as it is, as much original matter as would make the sixth part of such a work as my "Light Science" or Professor Wilson's "Leisure Hour Studies"—so that, for a shilling, he gets as much of such matter (fresh and fresh) as in such volumes costs six or seven shillings. It is "a very hard thing," he considers, "that we do not fill our entire space with matter so costly that if we did, the greater the sale, the greater would be the proprietors' loss. It would be, we venture to tell him, a "very hard thing" if our reward for giving six or seven pages of extra space to correspondence should be a claim for so much more original matter. It is "a very hard thing" to find room for so much original matter as we insert, and also to give space for correspondence, queries, &c., without making the proprietors cry out lustily at our extravagance (considering the price of Knowledge). If we had many such cheerful correspondents as "Anti-Paradox," this "very hard thing" would simply become impossible. We beg, on the proprietors behalf, to remind "Anti-Paradox" that the "very hard thing" which affects him is an infliction of his own choosing. He is not obliged to bring this terrible hardship on himself by expending the sum of twopence weekly on Knowledge, and then groaning because we answer queries in other than our smallest type, or admit inquiries from readers who do not fully appreciate the significance of the solar dark lines. To our more just and generous readers we say that we do the best we can to oblige all; we give to each class, correspondents, querists, mathematical students, chess and whist players, and original writers, more space than we can fairly afford. We feel satisfied that so long as we do so, the proportion disposed to be as unreasonable as "Anti-Paradox" and a few others have hown themselves, will be very small indeed.—The Editor.]

THE FIFTEEN PUZZLE.

[154]—The following is a solution to the Fifteen Puzzle, starting from the lost position :—

1	2	3	4
5	6	7	8
9	10	11	12
13	15	14	

Let R = right L = left U = up and D = down.

12. D.—11.10.9. R.—13. U.—15.14.12. L.—11. D.—10.9.13. R.—15. U.—14.L.—13.D.—9, &c., to L until the figures of the last two rows read.

9	10	11	12
15	14	13	

Then move: 15.14.13. R.—9.5.1. D.—2.3.4. L.—8.12.13. U.—14.15.9. R.—5.1.2. D.—3.4.8. L.—12.13.14. U.—15.9.5. R.—1.2.3 D.—4.8.12 L.

Then turn the box so that

4	8	12	
3	6	7	13
2	10	11	14
1	5	9	15

will be

1	2	3	4
5	10	6	8
9	11	7	12
15	14	13	

Then move: 14.13. R.—11.10. D.—6. L.—7. U.—14. U.—15.11 R.—9. D.—10.14. L.—11. U.—15. R.—14. D.—11.12. L.—13. U.—15.14.9. R.—10. D.—11.12.13. L.—15. U.—14. R.—13.D.—12.11. R.—10. U.—9.13.14. L.—15. D.—12.11.10. R.—9. up.—13.14.15. L.

Wishing success to your valuable paper,—I remain, yours truly,

Yawnups.

[The position attained by "Yawnups," which, of course, he does not regard as an actual solution of the problem, for which a money prize was offered in America, can be more readily reached; in fact, we do not see the plan of "Yawnups'" solution, many of the moves in which seem to be wasted. The actual number of moves in his solution, counting such a move as 9.13.14. L as three moves, is 102. By the following method the position is attained in 57 moves. It may, perhaps, be done in fewer, but the solution is straightforward, and its stages illustrate the method of dealing with such difficulties as occur in all "fifteen" problems :—4.8.12. D.—12.3. R.—13.9.5. U.—15.14.12. L.—3.4.8. D.—5.1.2. R.—15.13.9. U.—14.12.8. L.—2.3.4. D.—1. R. Now turn the box so that right hand runs

1	2	3	4

after 28 moves. We next get 5, 6, 7 right by the following moves:—7.11. L.—10. U.—6. L.—11. D.—7. R.—5. U.—6.11. L.—10. D.—7. R.—6. U. The two upper rows are now right, after 12 moves more, or 40 moves in all thus far. The last two lines now run thus :—

11		10	12
9	13	15	14

To get these right proceed thus :—11. R.—9. U.—13.15. L.—10. D. 11. R.—15. U.—10.14. L.—12. D.—11. L.—15. R.—10. D.—14. L.—15. D.—11. L.12.— U. The last two rows are now right, after 17

1	2	3	4
5	6	7	8
9	10	11	12
13	14	15	

more moves, or 57 moves in all. The blocks are now in the order which we may regard as one of the only possible forms of solution from the "lost position."—Ed.]

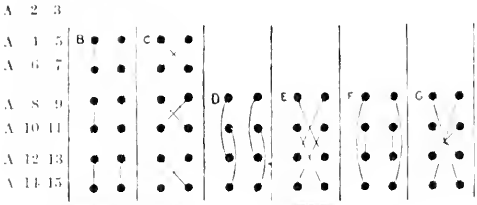
We have since received the following solution in 60 moves:—13.15.14. R.—1.5.9. D—2.3.4. L.—8.12.14. U.—9.13.15. R.—2.1.5 D.—3.4.8. L.—12.14.15. U.—5.9.13. R.—3.2.1. D.—4.8.12. R. One line is now right in 33 moves. Then: 14.15. U.—10.11 R.—6. D.—7. L. Two lines are now right in 39 moves. 15. R.—11. U.—13. U.—9. R.—10. D.—15. D.—11. L.—14. D.—12. R.—11. U.—15. U.—13. L.—14. D.—15. R.—11. D.—12. L.—15.14. U.—13. R.—10. U.—9. L.—or all the numbers right in 60 moves.

O. F. W.

THE FIFTEEN SCHOOLGIRLS.

[155]—In default of better, I enclose a sort of analysis and rule for doing the puzzle of fifteen, which is the simplest I have been able to find. Yours, &c. R. N.

The black dots stand for the numbers in the same line with them in the A column.



Otherwise—

A	b	c																		
A	d	e	B	d	f	C	d	g												
A	F	g	B	e	g	C	e	f												
A	H	i	B	H	J	C	H	K	D	h	l	E	h	m	F	h	n	G	h	o
A	J	K	B	i	K	C	i	J	D	i	m	E	i	L	F	i	o	G	i	n
A	L	m	B	L	n	C	L	o	D	J	n	E	J	o	F	J	L	G	J	m
A	n	o	B	m	o	C	m	n	D	K	o	E	K	n	F	K	m	G	K	L

The order of walking is then—

A B C	A D E	A F G	A H I	A J K	A L M	A N O
D I M	B L N	B M O	B E G	B D F	B H J	B I K
E J O	C H K	C I J	C L O	C M N	C E F	C D G
F H N	F I O	D H L	D J N	G H O	G I N	E H M
G K L	G J M	E K N	F K N	E I L	D K O	F J L

If the black dot formula is committed to memory, the puzzle can always be done nearly off-hand but, if not, a sure way of getting to the same result is to set down the 105 combinations of two letters from which the 35 combinations of three letters have to be formed side by side, and then amalgamate with *perfect regularity* from the top, cancelling all the used pairs.

A FOOD QUESTION.

[156]—If you think the following extracts have enough of general interest for your "Correspondence" columns, their insertion might lead to our getting some further useful information on the matter:—

In a recent number of *Chambers's Journal* (Nov. 12), under the head "Some Queer Dishes," it is said:—"In the West Indies, where meat becomes tainted very rapidly by the agencies of the damp motionless heat and abundance of insect life, it becomes necessary to cook it almost as soon as it is killed. To obviate the toughness which would result from this, it is wrapped in a large fleshy leaf, which has the curious property of softening the muscular fibre and rendering it tender. If left on too long, the juice permeates the meat and disintegrates it altogether, hastening its decay. I do not know the proper name of this leaf the black people call it "sangulo"—nor the nature of its action; there is a large tree in the market-place, near the King's Wharf, at St. Thomas."

This is probably the same plant or tree that is mentioned by Mr. H. Stonehewer Cooper, in his "Coral Lands," Vol. I., page 75. He says:—

"The one drawback to Fijian beef is that it is sometimes very tough, in consequence of being cooked the very day it is killed. The papau (*Carica papaya*) grows luxuriantly all over the Pacific, and according to Mr. Wittwach, a German naturalist, papau is the remedy. The juice of this is found to possess the property of rendering tough meat tender when boiled with it. If the unripe fruit be placed in the water in which the toughest meat is to be cooked, it is found to render it perfectly digestible, and the same results are observed if the meat be merely washed with the juice of the fruit. The thick, white, milky juice, when extracted from the unripe papau, in fact, contains properties similar to those of pepsine; and it is possible that it may be susceptible of chemical preservation, and become a valuable preparation. Tough meat is not unknown in England, and surely papau could be canned and sent over here, even if no mode of preservation is arrived at."

If this leaf or fruit has the virtues attributed to it, it is strange that we have not had it here in some form. "Coral Lands" was published last year.—Yours faithfully, F. C. M.

Nov. 28, 1881.

MAGIC SQUARES.

[157]—I am glad to see that your correspondent "H. S." has started the subject of magic squares in the last number of KNOWLEDGE; but though he gives examples of odd squares, he does not give the rules for making them. The subject is of great interest, and some squares are so very curious that I should like, if you will allow me, to bring it more fully before your readers.

Of magic squares there are two kinds: 1, those whose root is an odd number; 2, those whose root is an even number; the rules for the construction of each kind differing from each other.

The examples of odd squares given by "H. S." are made by Bachet's, or the Indian method; and the result is not capable of variation; but by the methods of M. Poignard and others, the resulting squares may be varied in many ways. I will now describe these methods for odd squares, and in a future paper will give the rules for squares with even roots and squares with borders, &c.

Bachet's Method.

Example: A square of 49 cells whose root is 7.

Fig. 1.

						1						
					8		2					
				15		9		3				
			22		16		10		4			
		29		23		17		11		5		
	36		30		24		18		12		6	
43		37		31		25		19		13		7
	44		38		32		26		20		14	
		45		39		33		27		21		
			46		40		34		28			
				47		41		35				
					48		42					
						49						

Fig. 2.

22	47	16	41	10	35	4
5	23	48	17	42	11	29
30	6	24	49	18	36	12
13	31	7	25	43	19	37
38	14	32	1	26	44	20
21	39	8	33	2	27	45
46	15	40	9	34	3	28

After having filled in Fig. 1 with the series, as shown above, proceed to transfer the figures in the cells outside the square into the

empty cells in the square directly opposite to them, as seen in Fig. 2—which will then be a magic square, whose root is 7—and the sum of the numbers in each vertical and horizontal band, and also of those on the two diagonals is 175.

Poignard's Method.

For a square whose root is 7.

In the square, Fig. 1, place in the top horizontal row the first seven numbers of the progression 1 to 7 in any order whatever, as 3, 7, 5, 1, 6, 4, 2. Then choose a number which is prime to the root 7, and which, when diminished by unity, does not measure it, say 3. Begin the second row with the third figure of the first. The third row with the third figure of the second, &c., and fill up the square.

Fig. 1.

1	6	4	2	3	7	5
4	2	3	7	5	1	6

In the top row of Fig. 2, place the multiples of the root 7, beginning with a cipher, viz., 0, 7, 14, 21, 28, 35, 42, in any order at pleasure; and fill up the square on the same principle as in Fig. 1, taking care not to assume the same number for varying the order of the figures. As 3 was taken for Fig. 1, we may take 4, or 5, or 6, for Fig. 2, say 4. Then the square will be filled up as in the margin. Now add the corresponding numbers in each cell of Figs. 1 and 2, and place the sum in Fig. 3, which will be a magic square.

Fig. 2.

28	7	42	0	14	35	21
0	14	35	21	28	7	42
21	28	7	42	0	14	35
42	0	14	35	21	28	7
35	21	28	7	42	0	14
7	42	0	14	35	21	28
14	35	21	28	7	42	0

It is easily seen that by this method the position of the numbers in the finished square may be varied greatly, and I leave it to the readers of Knowledge to say how many ways there are of varying the square of 7.

J. A. Miles.

Fig. 3.

31	14	47	1	20	39	23
5	15	41	25	30	10	49
27	32	9	45	7	19	36
44	3	21	40	22	34	11
42	26	29	13	46	2	17
8	48	4	16	38	28	33
18	37	24	35	12	43	6

INTELLIGENCE IN ANIMALS.

[158].—Referring to Mr. Henslow (p. 46, No. 3), is not his reasoning somewhat curious? He tells us that had the dog not been taught to ring the bell, his reasoning would have been abstract. As the fox was *not* taught to do what he did, why was not his reasoning abstract?

Another story is still more *apropos*. In this case the fox cut the line connecting the trigger with the bait, then went up deliberately (as seen by his track on the snow) and ate the latter. In this case the fox could not scrape a trench, so as to get safely at the bait, as there were only a few inches of snow on the ice where the bait lay.

In neither of these cases had the foxes been taught to do what they did, yet each in his own way used reasoning powers which enabled him to accomplish his object in the only way by which it could be safely attained by an individual fox (or man), ignorant of the mechanism of firearms. Was this abstract reasoning?

Mr. Henslow is rather hard upon brutes and boys. Every day we find what are supposed to be educated, reasonable, and, I presume, reasoning men and women, doing as silly things as the most stupid "boy or brute" could be guilty of."

Ask twenty persons what they would do if, whilst exposed to great cold, they found their faces freezing? Probably, nineteen of the twenty would reply, "rub with snow." This would be proper treatment if a person frozen was brought into a warm house, but is not right whilst he is exposed to the low temperature that is freezing him.

This snow application was improved upon by Major Burnaby, when, on his ride to Khiva, he thought his hands were freezing. He added brandy to the snow before rubbing it in, and thus made a sort of freezing mixture, as anyone can easily prove by trying it on some cold day, and exposing the part rubbed to the air. The brave lady who ascended Mont Blanc in winter adopted the same plan, and thought it successful. J. Rae.

[In a paragraph, which we have omitted, Mr. Rae appears to have misunderstood Mr. Henslow's remark about "pulling the string out of the line of fire." Mr. Henslow meant the fox being out of the line of fire while pulling, not the fox pulling the string away from the line of fire.—Ed.]

[159]—In favour of the lower animals possessing reasoning powers, I submit the following:

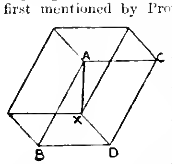
While living in Dublin, a few years ago, we had two female cats—one a "tabby," the other a "tortoiseshell." The tabby, my especial pet, was of rather fierce disposition, but an excellent mouser, and was in the habit of bringing her prey, generally alive, to show me before devouring it. The tortoiseshell—a feline beauty—passed the greater part of the day on the rug before the fire. One day "Tabby" brought no less than three mice, consecutively, into our sitting-room. The first two she ate; but the third, after playing with it for some time, she hid under a mat at the door, evidently meaning to reserve it till a hungrier moment. As soon as she left the room, the tortoiseshell, who had been sitting, as was her wont, with half-closed eyes before the fire, went to the mat, poked out the mouse, and gobbled it. This theft amused me so much that I resolved to watch the consequences. Tabby did not come in again till evening, when she proceeded instantly to fetch out her moose. She searched well under the mat, but not finding her *bonne bouche*, began growling ominously. At length her eyes fell upon the guilty tortoiseshell, upon whom she rushed, and beat and scratched her until in pity we rescued the culprit. Another time both cats were with kitten. The tortoiseshell disappeared for a few days, and returned looking very lean and miserable. Tabby, who had meanwhile brought forth her young, received her more amicably than usual, and after some rubbing of noses and purring, tho tortoiseshell took charge of the kittens, and suckled them. This was not the only time she was seen doing duty as wet-nurse, whilst the other was rambling somewhere round. A. F. R.

A BEAR'S MEMORY OF LANGUAGE.

[160]—The strategic shifts of Colonel Perkins' (Purtons'?) dog, Bully, at Bangalore, reminds me of another story connected with Bangalore. The late Rev. William Campbell, who was formerly a missionary there, on visiting Dublin, to advocate the claims of the London Missionary Society, went with some friends to see the Zoological Gardens in that city. While walking through the gardens, their attention was drawn to a particular den by the excitement of a small crowd before it. On approaching the place, they found it was the den of the Indian bear. Bruin was in a bad humour, and sat resolutely on his haunches, with his back to his visitors. Some tried to coax him with buns, others to startle him with shouts, and a few tried to stir him up with walking-sticks and umbrellas. All their efforts were in vain. At last it occurred to Mr. Campbell to address the bear in the language he was accustomed to in his youth, so he shouted "Cuddapah! Cuddapah!" (Get up! Get up!) To the surprise and amusement of the spectators, Bruin immediately turned round with a delighted grin.—Yours, &c. Cuddapah.

AN ILLUSION.—DURATION OF FLASH OF LIGHTNING.—RAINBOW.

[161]—Wheatstone calls attention to the following illusion first mentioned by Professor Necker, of Geneva. The rhomboid AX is drawn so that the solid angle A should be seen the nearest to the spectator, and the solid angle X the farthest from him. But in looking at the rhomboid, it will occasionally so change that the solid angle X will appear the nearest, and the solid angle A the farthest away. Necker attributed the alteration of appearance not to a mental operation, but to an involuntary change in the adjustment of the eye for obtaining distinct vision. Wheatstone, on the other hand, supposed the effect to depend entirely "on our mental contemplation of the figure intended to be represented, or of its converse."



I think Mr. Molloy (letter 116, p. 121) will find no account of any experiments of Wheatstone's on the duration of a flash of lightning in the collected volume of his papers issued by the Physical

Society of London. In the paper to which Mr. Molloy refers, "An Account of some Experiments to Measure the Velocity of Electricity and the Duration of Electric Light," Wheatstone gives an account of experiments made on the duration of the electric spark, as produced in the laboratory, and towards the conclusion of his paper he states that "the light of electricity in a state of high tension has a less duration than the millionth part of a second."

If "G. S. M." (query 67) could see a rainbow under perfect conditions, it would appear not semicircular, but circular. If, for example, he were up in a balloon, at a great height, with the sun overhead, and a rain-shower beneath, he would see a circular rainbow below, probably with the shadow of his car and its occupants fair in the centre. A rainbow being formed by those raindrops which are placed at a particular angle with regard to a line drawn from the sun through the head of the observer, it is apparent that as our balloon descended towards the earth the coloured ring would descend also, until finally it impinged on the earth's surface. Upon going lower still, the continuity of the ring would be broken, the earth having taken the place of some of the raindrops, and, probably by the time the observer had reached the ground, he would be only able to see a semicircular rainbow.

Wm. Ackroyd.

COMETS' TAILS.

[162] In reply to the query by F. C. S., p. 119, Mr. G. M. Seabrook, Temple Observatory, Rugby, writing to *Nature*, says:— "The comet (b. 1881) was examined spectroscopically here last night. The nucleus gave a bright, continuous spectrum, while the coma and brighter portions of the tail gave the three least refrangible hydrocarbon bands superposed on a faint continuous spectrum. On moving the slit of the spectroscope towards the fainter part of the tail the bands died out, leaving a faint continuous spectrum, which, again, gradually faded away as the end of the tail was approached. I have not measured the position of the bands, but they are sensibly the same as those from an alcohol flame."

Mr. Percy Smith, of the same Observatory, on July 1, writes:— "On the 27th (June), the bright jet extending from the nucleus was very plain, and gave the hydrocarbon spectrum very distinctly. No bands were seen in the tail, but only in the immediate proximity of the nucleus."

M. Wolf, in a paper read to the Paris Academy on July 11 (in regard to the same comet) says: ". . . "When the slit of the spectroscope is passed over the comet, starting from the head, one finds the three bands all round the nucleus at nearly the same distance from all the sides. They disappear in the tail properly so-called, the very pale spectrum of which seems to be continuous. Thus only the nebulosity surrounding the nucleus contains incandescent gases. The light of the tail comes to us from a pulverulent matter luminous or simply illuminated. Such are the data of spectroscopy."

A. T. C.

AN INSTANCE OF PRESSURE.

[163]—The readers of Knowledge have, doubtless, been interested in the scientific controversy on the subject of toads being enabled to live, enclosed by blocks of solid matter; probably the following fact will be unknown to many of them, and may afford additional proof of the frog's vital tenacity:—

A few years ago an experiment was made in the Arsenal at Woolwich, the particulars of which were published by the well-known Mr. Tegetmeier, of the *Field*. A frog was subjected to the enormous pressure of three tons to the square inch, for a period of thirty-six hours. At the end of the experiment the frog appeared prostrate, but recovered a perfectly normal condition in a few hours, and as a reward for his severe test, was taken back to his native marshes.

R. C. Fraser.

A geography of the almost unknown kingdom of Corea has been compiled by a member of the suite of the Japanese envoy to that country. Several valuable papers, containing accounts of travels in Corea, have been read before the Geographical Society of Tokio, and have appeared in its transactions. As they are written in Japanese, they are unfortunately all but inaccessible to European geographers. —*Frank Leslie's Magazine.*

The French Minister of Commerce has just issued a notice regarding the inspection of salted pork imported from abroad. Inspectors are to be appointed at the different ports to which the entry of this commodity will be confined. A course of lectures on the subject of micrography is to be instituted at the School of Pharmacy for the preparation of the experts who will be required for these posts. These measures foreshadow the eventual raising of the embargo on American pork.

Queries.

[130]—Known Languages.—I shall be glad if you, or any of the readers of Knowledge, can tell me the number of known languages spoken at the present day. J. A. L. R.

[131]—Creation.—Will any correspondent versed in this subject give his views as to what are the proofs of man having existed more than six thousand years?—R. I. P. [R. I. P. should read, amongst other works, "Quatrefages on Man," in the International Series, published by Kegan Paul & Co., London. Price 5s.—Ed.]

[132]—Fungi.—I shall be glad to have any information respecting the nature of fungi and truffles; how they are produced, and what their place is in the vegetable kingdom. Ignotus.

[133] Would you kindly inform me if you know of any works, articles in magazines, or anything whatever by the Rev. W. H. Dollinger, F.R.S.?—Querist.

[134]—The Stars in Northern and Southern Latitudes.—Would you oblige a boy by explaining the reason why we in northern latitudes do not see the whole of the southern constellations, as people in southern latitudes see all our northern constellations? Vide page 12 of "Easy Star Lessons." You state the fact, but do not give the reason. Quisquis.—[At the North Pole, the pole would be overhead, and the heavens turning around on upright or vertical axis, we should see only one half the star sphere, even if we watched through twenty-four hours of an arctic winter's day (really night). At the equator, the poles being on the horizon, we should see the whole star sphere, turning as it does round a horizontal axis, in the twelve hours of an equatorial night. In intermediate positions, more or less of the star-sphere would be seen the nearer the station to the equator. You must not confound latitudes south of ours with southern latitudes.—Ed.]

[135]—Cheap Telescope.—I am wishful to have a *cheap* telescope, such as would answer a beginner; say a $2\frac{1}{2}''$ or $3''$ object-lens. Would any reader give me a few hints as to construction, what would be probable cost, including tube, &c.?—R. I. P.

[136]—Sunlight on Fires.—Does bright sunlight interfere with ordinary combustion? If, as I believe, it does, I should be glad to have a scientific explanation of the fact. As evidence, let me quote the housemaid, who says she cannot get her fire to burn if the sun is shining upon it. And the smoker, who says that he cannot keep his cigar alight under the same circumstances.—N.

[137]—Humble Bees.—What success has attended the attempt to introduce humble bees (*Bombus terrestris*) into New Zealand, to fertilise the clover there? The first attempt was unsuccessful, but I have been unable to learn the fate of the second attempt.—Thomas Chandler.

[138]—The Gyroscope.—What particular laws of motion are illustrated by the gyroscope? Does it throw any light upon planetary motions? And what? Of what motions is the instrument capable, and can they be popularly explained? Is there any simple treatise on the subject? Can you give some easy papers upon it in Knowledge?—T. W. F. [Newton considered the movements of a rotating body under gravity among the most difficult problems which mathematics can deal with. We have tried elsewhere to make this difficult matter clear, and may try again soon in these pages. —Ed.]

[139]—Temperature of Interstellar Space.—What is the supposed temperature of interstellar space, and how has it been ascertained?—E. C. R.

[140]—Ice.—Does the volume of ice vary as other solids do with variation of temperature?—E. C. R.

[141]—Time of Glacial Epoch.—Is Dr. Croll's theory of the time at which the ice age existed in Britain probably correct? Are there other theories on the same subject?—E. C. R.

[142]—The Great Bear.—Will some reader of Knowledge inform me if it is possible to see the Great Bear $17\frac{1}{2}°$ south of the equator? I read in a book (and the author ought to have known) that it is so, but it seems hardly credible. Would some one state how far south it may be seen?—Marian. [Any star of the Great Bear can be seen just as many degrees south of the equator as that star is distant from the pole of the heavens.—Ed.]

The biggest thing yet in the way of plaster casts is the cast of a whale, taken at Provincetown by Mr. Palmer, modeller for the Smithsonian, at Washington. A papier-mâché fac-simile is to be moulded from the cast, the entire skeleton of the same whale is to be inserted, and the monster will be suspended in the museum. To show the arrangement of the skeleton, one side of the whale will be left open.

Replies to Queries.

[103]—HISTOLOGY.—Your correspondent may be glad to know of the following books on "Histology":—"1. Frey's, translated by Barker (expensive); 2. Rutherford's "Outlines of Practical Histology," is very good for students; 3. Klein's "Atlas" is a grand work on this subject, but too expensive.—B. TOM TINY.

[39]—MOON'S ROTATION.—I give a quotation from the lecture delivered by Dr. Ball, at the Midland Institute, Birmingham, Oct. 24, 1881:—"For many centuries it had been an enigma to astronomers why the moon should always turn the same face to the earth. It could be shown that there were many million chances to one in favour of this being due to some physical cause. The ordinary theory of gravitation failed to explain the cause. Every one had noticed this phenomenon, yet the explanation was never given till lately. It was Helmholtz who showed that this was a consequence of ancient tides, and this simple and most satisfactory explanation has been universally accepted."—A. T. C.

[88]—BRAIN TROUBLES.—The division of the brain into two parts will certainly not take in all the functions of the brain; at least one more must be added. The division into *a*, involuntary motion, *b*. centres of reasoning, higher emotions, &c., cuts out entirely the function of voluntary motion presided over by the brain. Also the function of the cerebellum, that of co-ordination of muscular actions, or muscular sense, is left out, and is certainly important; for a pigeon, having his cerebellum removed, cannot stand, but topples over, and although seeing a blow threatened, cannot avoid it. When lying down, it was not in a state of stupor.—P. H.

Notes on Art and Science.

AT Gnosso, in Crete, Professor Stilman has excavated the remains of what he believes to be the historical labyrinth famous from the story of Theseus and the Minotaur.

AT Honolulu, a signal station in communication with the United States Meteorological Bureau will be established on the volcano Kilanea, and a series of observations will be taken.

THE SUNDAY SOCIETY.—The twenty-sixth Sunday Art Exhibition of the society was opened on Sunday, Dec. 18, at the Hanover Gallery, from half-past one till four o'clock, when there was an attendance of 512, the admission being by ticket.

DR. SCHONDORFF has constructed a safety lamp which can only be opened with the help of a strong magnet. A lever presses against a toothed wheel, which allows or prevents the movement of the screw fastening the glass door-holder to the socket. The lever must be moved in order to open the lamp, and this is done by means of a strong magnet.

BRUGSCH PASHA has succeeded in deciphering the Ethiopic inscriptions of Meroe, the language of which resembles that of the Ethiopic *graffiti* on the walls of Philæ and other Nubian temples. He thinks that the language has some similarity to the pre-Semitic Sumerian dialect of Southern Babylonia, and quotes in support of this view words like *sher*, "King."

A MOST remarkable discovery has been made in the Sweetwater country, in Wyoming territory. It is a deposit of sulphuric acid in its natural state. The odour, chemical action, and general appearance of the stuff demonstrates it to be a pure quality of sulphuric acid. The ground is impregnated over a large area—100 acres or more—and parties have filed claims upon it.

A CONGRESS of experts has assembled at St. Petersburg to inquire into the evils caused by excessive drinking in Russia. By an overwhelming majority they have advised a diminution in the number of public-houses; while they also passed a resolution in favour of vesting in the communal authorities the right of opening liquor-shops under regulations to be determined by a sub-committee appointed for this purpose.—*Frank Leslie's Magazine.*

THE survey of Palestine east of the Jordan is proceeding rapidly under the superintendence of Lieut. Condor. When he last wrote, several hundreds of miles had been measured with accuracy, and a number of places having more or less modern names were identified as those mentioned under different titles in ancient history. He discovered a great many cromlechs, or flat stones, supported like a table by others set on end. Not less than fifty of these monuments were sketched in three days. Some of them had small chambers near them from 3 ft. to 5 ft. long, and 3 ft. high, excavated in detached cubes of rock 10 ft. to 15 ft. on each side. The interest in the work is increasing, and the result cannot fail to be of great archæological importance.—*Frank Leslie's Magazine.*

A SIMPLE ELECTRICAL MACHINE.—As a domestic electrical experiment, few are simpler or more demonstrative than that of first drying and warming a piece of paper, then smartly stroking it with india-rubber and placing it against a wall, to which it electrically adheres. Electric sparks may thus be obtained in the dark, and a variety of other experiments performed. When the wind is from the east, and dry, a small Leyden jar may be charged by using a long strip of paper, equal in width to the outer coating, and drawing this repeatedly, when excited, along the outside of the jar. An improvement on this simple electrical material has recently been made by Wiedemann. He takes Swedish filtering-paper (procurable wherever chemical apparatus is sold), steeps it in a mixture of equal volumes of nitric and sulphuric acid, then washes with abundance of water, and dries it—the same process as making gun-cotton, into which the fibres of the paper are thus converted. It is stated that with this gun-cotton paper, nearly all the stock experiments of the static electrical machine may be performed by laying a sheet of it on waxed paper for insulation, and rubbing it briskly. This was announced in the *Comptes rendus* of the French Academy about the beginning of the year, but I have heard no more of it since. As Christmas holidays are coming, I recommend it to my juvenile readers, who may possibly be able to improve upon the original suggestion by coating a fig-box, or other wooden cylinder, with a non-conducting surface of gutta-percha varnish, or shellac, or wax, then covering this with the prepared paper, and mounting it like an ordinary old-fashioned electrical machine; or by making an electrophorus of this material.—W. Mattieu Williams, in *Gentleman's Magazine.*

THE BURSTING OF WATER-PIPES.—In a country like England where the obstinate natives persist in the practice of burning their fuel in a hole made in the wall, with a shaft rising perpendicularly above it, in order that the greatest possible quantity of the heat of combustion shall be devoted to warming the clouds, and the smallest possible amount shall be radiated from only one side of the fire into the apartment, anything like a severe frost becomes a national calamity. Last winter, though far less severe than an average winter in Germany or the United States, is made miserably memorable by the domestic calamities connected with the bursting of water-pipes, and is recorded in the household accounts of expenditure for mending the same and repairing the damage done by the general house-and-furniture-soaking. If English houses were equally warmed *throughout*, as they are in other countries where domestic civilisation has made some progress, the freezing of any water-pipe inside would be impossible in any weather, and all outside water-conveyance can be made underground. But as the domestic fetish of the Englishman and Englishwoman, the hole-in-the-wall "cheerful" fireplace, must be worshipped: as the fire-worshippers must continue to scorch their noses while their backs are matriculating for lumbago; as the cheerfulness of the fetish must be maintained, and its devotees must demonstrate that cheerfulness by staring vacantly at the glowing coals which roast everything and everybody at one side of the room, while the rest of the house is at the mercy of the outside fluctuations of temperature; as all this must go on for a generation or so longer, in spite of Kyrle societies and smoke-abatement exhibitions—some adaptation of water-pipes to our existing domestic barbarism is very desirable. A very little geometry is required for understanding that if a pipe of circular section be flattened in any degree, its internal capacity must be proportionately lessened; and conversely, that a pipe thus flattened, or made of elliptical section, may have its internal capacity enlarged by simply squeezing it out towards the circular shape. Lead being flexible, a leaden pipe made of elliptical section and filled with freezing water will swell out towards circular shape, and thus allow room for the expanded ice without bursting. It is proposed that such pipes be made and used, and I think the idea an excellent one though plumbers are not likely to favour it, but their disapproval should be a strong recommendation to the householder who has to pay for mending ordinary pipes. I am told that a patent has been secured, but do not know by whom, and as I am going to suggest an infringement, he is entitled to any advertisement this note may afford. I recommend all householders to save their existing pipes by simply flattening them with a mallet, taking care to place behind the part which is struck a flat piece of wood, where the pipe rests upon rough brick-work. The freezing will simply reverse the work of the mallet, and lead of good quality will bear this double-bending. If freezing water were a rigid solid, the transverse expansion of the cylinder of ice within the tube would be proportionate to its diameter, and thus the elliptical form would be maintained; but freezing water is not a solid; it exerts an equal expansive pressure in all directions; and the walls of the pipe being equally pressed, give way in the direction of least resistance.—*Ibid.*

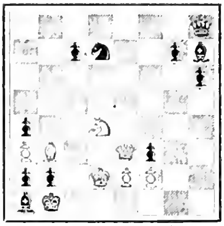
Our Chess Column.

In the *Illustrated London News* for Nov. 5 last, the following problem appeared:—

Problem, No. 6.

(By W. Grimshaw.)

Black.



White.

White to play and mate in three moves.

The solution, which appeared on Nov. 6, is—

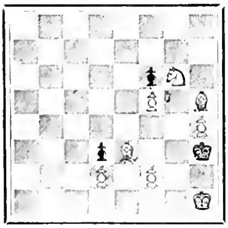
White.	Black.
1. Kt. to K.B 5.	2. B. takes Kt.
2. Q. to K.6.	3. Any move.
3. Q. or B. mates.	

The above problem, assuming this were the only solution, would be neat, but not particularly difficult. Its point, as thus solved, lies, not in the placing of the Knight on the Black Bishop's line of action, for that is an idea obvious enough; but in compelling the Black Bishop to occupy such a position that, when the White Queen goes to K.'s 6th, she will (though putting herself *en prise* by going there), threaten mate in two ways instead of one, as would be the case if she moved there at the outset.

There is, however, it so happens, a second solution, which involves a very pretty stratagem, one which hitherto we have not seen embodied in a problem. We leave our chess readers the next fortnight wherein to discover this second solution. They may suppose the other prevented by the addition of a Black Knight at Q.'s 8th, or simply that a second solution is required as a condition of the problem.

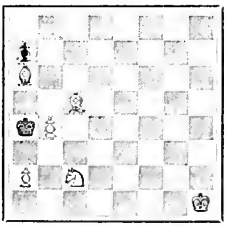
We mentioned last week a case in which a problem by the Editor (in chief) had been unmistakably anticipated, somewhat as a part of Mr. Baxter's idea in the problem of last week (No. 5, it should have been entitled) had been anticipated by the Editor. The case was on this wise. In the year 1858, the Editor sent several problems to the Chess Editor of the *Illustrated London News*, among which was the three-mover No. 7. The Chess Editor

Problem 7. By the Editor.



White to play and mate in three moves.

Problem 8. By D'Orville.



White to play and mate in three moves.

of the *Illustrated* remarked that he had seen something like this problem in the collection of D'Orville and Kling, and on the Editor writing that he had not seen that collection, the following pleasant remark appeared in the *Illustrated London News* for Oct. 9, 1858:—"R. A. P., St. John's College, Cambridge.—The following is the position by D'Orville, to which we referred [see Position 8 above]; we leave you to judge whether the resemblance is accidental." Mr. Staunton paid no attention to a disclaimer by the Editor of all knowledge of the position in question. We leave both problems as an exercise to our chess readers, leaving them to judge whether the resemblance is quite so close as to justify the remark above quoted, which followed (be it observed) a statement that the author of the later problem knew nothing of the collection by D'Orville and Kling. Strangely enough, the Editor's problem was published later (in August, 1859) in the chess column of the *Illustrated*. The Editor considers his problem so far superior to D'Orville's as to have justified him in claiming it as his own, even if he had known D'Orville's. But let others decide on that point. What the Editor would chiefly call attention to is that an experience such as his in this matter, makes him far readier than he might otherwise perhaps have been to see that even a close apparent resemblance in chess problems does not necessarily prove that there has been any borrowing.

The problem sent us by Mr. G. B. Stubbs is not quite up to publication standard. It is scarcely ever permissible for a three-mover to begin with a check, or capture (though a few instances are known of really strong problems so opening); but in the case of a two-mover like that by Mr. Stubbs, a check at the first move is quite inadmissible. There is a flaw still more serious in the existence of a dual solution, which, as Black has only one move, is a rather more serious matter than duals affecting only White's reply to moves by Black, which are not defensive. Thus there are duals in the Editor's Problem No. 4. If Black moves his Queen to Q.R.7, or 8, or to Q.B.8, or makes other purposeless moves, White can mate by moving his Rook from Q.5 to any free square; but that Black should have but one possible move, and White then be able to mate in more ways than one, is, of course, a fatal flaw in a two-mover.

Our Whist Column.

By "Five of Clubs."

When, having the original or first lead, we are obliged to lead from a short suit, as in the case considered in No. 4, p. 83, or when we have four trumps not very strong, and three of each of the other suits, we should, in general, select that suit which is least likely to injure our partner or to benefit the adversary. Of course, if your best short suit is very strong, as ace, king, queen, ace, queen, knave, ace, king, knave, or the like, you lead as from strength. Again, if you have to lead from ace, or king, or queen, and two small ones, you lead the smallest, so as not to throw away the command of the suit. You suggest, indeed, to your partner that you have led from numerical strength; but that is the misfortune of your position. It is better to do that than to give up the command in what may be a strong suit of one of the adversaries. When you have knave and two small ones, you should lead knave; because the card cannot help you against strength held by the adversary, and if your partner is strong it may help him.

But your best way of helping your partner, when you are obliged to lead from a short suit originally, is to play from a suit in which you have a strong sequence—such as queen, knave, ten; or queen, knave, and another; or knave, ten, and another. By leading the highest from such a sequence, you help your partner, if he is strong in the suit, without materially weakening yourself, if the enemy should be strong in it. Next to such hands come hands in which you have two honours and a small one. The proper leads from three-card suits, as well as from long suits, will be considered in detail later.

It can scarcely ever be advisable, no matter how your hand is constituted, to lead from ace, king, or queen, and one other. To lead from ace king, or king queen, or queen knave, alone may, in certain cases, be better than leading from a weak three-card suit. But in most cases of that kind it is better to lead from your four-card trump suit, even though it be weak.

In considering thus far the lead from a suit of three cards, we have dealt with the original lead. If you have not the original lead, then, even though only a single round has been played, you can generally form some idea of the suit you should select from among three weak non-trump suits. Thus, if your partner has led, and you have taken the trick, you should of course return his lead. Leading any other suit would imply that you had considerable strength in that suit.

If you are fourth in hand, you know at least one suit which you should not lead—viz., the one opened by your left-hand adversary. Unless, indeed, the fall of the cards in the first round showed that

he is not very strong in that suit, in which case, by leading through him, you put him at a disadvantage. Many players seem to think that the excellent general rule, lead *through* strength (that is, lead a suit in which your left-hand adversary has high cards), is a rule to be universally followed when you have no good suit of your own, and do not know which is your partner's best suit. But if your left-hand adversary leads from a suit both strong and long, and you, making first trick, lead through him in that suit, you are simply playing his game. Of the other two suits (outside trumps), you select that which you can lead with least chance of aiding the adversaries, and, as a rule, you play the best of the suit. It is an even chance that your partner is strong in it.

If you are second player, and take the first trick, you can hardly go wrong. Leading the suit your right-hand adversary had led would be doubly disadvantageous: you would be probably leading up to strength, and certainly helping to establish his suit. Of the other two suits, outside trumps, you select the best, and play the card most likely to help your partner. If you have thus led from a suit in which your left-hand adversary is strong, you at any rate lead through his strength. If your high card makes, and you then play a low one, your partner knows you have led from a short suit (or that you have made a forced lead), and infers that either you have four trumps, and no other four-card suit, or that your only four-card suit is very weak. His own hand will help to show which of the two explanations is the more probable.

With a five-card suit, however small the individual cards, it is scarcely ever wrong to lead from the long suit. Cavendish, in an amusing story in his "Card Essays," gives it as his opinion that the long suit should be led from, even with such a hand as this:—Ace, King, Queen of Spades; Eight of Clubs; Ace, King, Queen, and Three of Diamonds (trumps); Nine, Eight, Six, Four, Three of Hearts.

A YARBOROUGH HAND AT WHIST.

At the close of the letter to which we referred last week, "H. P. H." suggests a plan far calculating the odds that there will not be a Yarborough at a given deal. He says: "We must find the number of ways in which the pack must be dealt so as not to include a Yarborough. Suppose, for instance, one hand contains one of the high cards, another three of them, the third six, and the fourth ten. This arrangement may happen in

$$\frac{20 \;.\; 19 \;.\; 18 \;.\; 17 \;.\; 16 \;.\; 15 \;.\; 14 \;.\; 13 \;.\; 12 \;.\; 11}{2 \;.\; 3 \;.\; 6 \;.\; 5 \;.\; 4 \;.\; 3 \;.\; 2} \text{ ways.*}$$

By taking all such arrangements as these, and adding the number of ways, we get the number of different arrangements of the whole pack which will not include a Yarborough; the ratio of this number to the number of different arrangements of the pack, namely, $\frac{52}{(13)^4}$ is the chance against a Yarborough happening. This would give a long piece of work, but, perhaps, some of your readers may find a short method." H. P. H.

* The reasoning here is unsound. We leave the problem as an exercise for our readers (not proposing, however, to publish all solutions which may be sent to us).

Our Mathematical Column.

MATHEMATICAL QUERIES.

[8]—Are there any exact solutions of the equations:—

$$\frac{1+\sqrt{1-x}}{1+\sqrt{1+x}}=\sqrt{1-x^2} \text{ and } \frac{1+\sqrt{1+x}}{1+\sqrt{1-x}}=\sqrt{1-x^2}.$$

[The equations are really the same, so far as any difficulty in their solution is concerned, for they differ only in the sign of x, so that whatever root we find for one, the same quantity, taken negatively, is a root of the other. But it will be found on trial that 0 is the only value of x which satisfies either equation. The solution may run thus (taking first equation):—

$$\begin{array}{lll}
 & 1+\sqrt{1-x}=\sqrt{1-x^2}+(1+x)\sqrt{1-x} & \\
 & 1=\sqrt{1-x}(\sqrt{1+x}+x) & \text{(A)} \\
\text{But} & 1=(\sqrt{1+x}+x)(\sqrt{1+x}-x) & \text{(B)} \\
\text{Whence} & \sqrt{1-x}=\sqrt{1+x}-x & \text{(C)} \\
\text{and} & 2-2\sqrt{1-x^2}=x^2 & \\
\textit{i.e.} & 1-x^2-2\sqrt{1-x^2}+1=0 & \\
 & \sqrt{1-x^2}=1 & \\
\text{or} & x=0. &
\end{array}$$

It might seem that since, after obtaining (A) and (B), which give

$$(\sqrt{1+x}+x)(\sqrt{1+x}-x)=\sqrt{1-x}(\sqrt{1+x}+x)$$

we divide by $\sqrt{1+x}+x$ to get x, the equation should be satisfied by the roots of

$$\sqrt{1-x}+x=0$$

which are

$$\frac{1\pm\sqrt{5}}{2}$$

but this is not the case. Neither root will satisfy the original equation, whatever signs we give the quantities $\sqrt{1-x}$ and $\sqrt{1+x}$.—Ed.]

[9]—Arithmetical Problem.—Would any reader of Knowledge favour me with a solution of the following problem:—If twelve horses eat ten acres of grass in sixteen weeks, and eighteen horses eat ten acres in eight weeks, how many horses will eat forty acres in six weeks? The grass is supposed to grow uniformly.—G. H. Mapleton.

[10]—On base BC are triangles BAC, BDC, having equal perimeters, AB being equal to AC. If AC BD intersect in O, show that $AO>DO$. Mathematicus.—[Like most problems of the kind this is best dealt with indirectly. Thus, take at point G in OA (produced if necessary) such that $OG=OD$, and from OB the greater, cut off OF, equal to OC the less, and join FG. Then obviously

$$\begin{array}{ll}
 & FG=DC \text{ and } GC=FD \\
\text{Hence} & FG+GC=FD+DC \\
\text{But} & BF+FG+GC=BD+DC=BA+AC \\
 & \quad <BF+FA+AC \\
 & \therefore\ FG+GC<FA+AC \\
 & \text{or } FG+GO<FA+AO
\end{array}$$

whence it follows that G must lie between O and A. For if G were at A, $FG+GO$ would be the same as $FA+AO$; and if G were in OA produced $FG+GO$ would be greater than $FA+AO$. Therefore AO is greater than GO, that is, than DO.—Ed.]

[11]—Perimeter of Inscribed Triangles.—Show that the perimeter of an equilateral triangle inscribed in a circle is greater than the perimeter of any other isosceles triangle inscribed in the same circle.—Mathematicus.

[Prove as follows:—Let ABC be the greatest triangle with a given perimeter. Then, if it be not equilateral, there must be, at least, two sides not equal to each other. Let AB and BC be unequal. Through B draw KBL parallel to base AC, draw CM perpendicular to KL, and produce CM to N, making $MN=NC$. Join AN, cutting KL in D, and join DC, BN. Then $BN=BC$, and therefore $AB+BC=AB+BN>AN>AD+DC$, so that there must be same point P in DN, such that if PC be joined $AP+PC=AB+BC$, or there is a triangle greater than ABC, and having the same perimeter, contrary to our supposition. Hence, no two sides of the greatest triangle with the given perimeter can be unequal, or the triangle is equiangular.—Ed.]

[12]—I wish to prove that

$$\frac{2n\,(2n-1)\,(2n-2)\cdots(n+1)}{1\cdot 2\cdot 3\cdots n}.$$

The middle term in the expansion of 2^{2n} is equal to

$$1^2+n^2+\left(\frac{n\,(n-1)}{1\cdot 2}\right)^2+a\quad+n^2+1^2.$$

the sum of the squares of terms of the expansion of 2^n.

Proposing to do this by mathematical induction, I find, calling the first expression Σ, that when in it I write $\overline{n+1}$ for n, it becomes

$$\Sigma\left(1-\frac{n^2}{(n+1)^2}\right)$$

Can I, at this point, without more ado, conclude that since

$$\Sigma=1^2+n^2+a+n^2+1$$

(by hypothesis) when n becomes $\overline{n+1}$ that Σ will become

$$1^2+\overline{n+1}^2+\left(\frac{(n+1)n}{1\cdot 2}\right)^2+a+\overline{n+1}^2+1^2$$

which would prove what I want?—F. B.

[Your demonstration is beyond us. If you write $(n+1)$ in the first expression, calling it Σ before the change, it becomes—

$$\Sigma\left(\frac{2(2n+1)}{(n+1)}\right)$$

The best way to solve your problem is this:—

$$(1+x)^n=1+C_1x+C_2x^2+\&c.+C_2x^{n-2}+C_1x^{n-1}+x^n$$
$$(x+1)^n=x^n+C_1x^{n-1}+C_2x^{n-2}+\&c.+C_2x^2+C_1x+1$$

where C_1, C_2, C_3 are the well-known co-efficients, in the expansion of the triunial $(1+x)^n$. Multiplying—

$$\begin{array}{l}
(1+x)^{2n}=1+(C_1+1)x+(2C_2+C_1^2)x^2+\&c. \\
\quad+(1+C_1^2+C_2^2+C_3^2+\ldots\ldots\ldots+C_2^2+C_1^2+1)x^n \\
\quad+\&c. \qquad\qquad +(1+C_1)x^{2n-1}+x^{2n}
\end{array}$$

Hence, equating the coefficients of x^n, we have—

$$\frac{2n(2n-1)(2n-2)\ \ldots\ (n+1)}{1\cdot 2\cdot 3\ \ldots\ n} = 1^2 + \ldots$$

$$\left(\frac{n(n-1)}{1\cdot 2}\right)^2 + \ldots + n^2 + 1$$

[13]—Dividing an Ellipse. I wish to know how to divide an ellipse (1) that the radius vector may cut off equal parts of the periphery, and (2) that it may divide the ellipse into equal areas. J. A. L. R. [The latter problem is solved in my "Geometry of Cycloids," section vii. The construction for a given ellipse is sufficiently simple and can be supplied if "J. A. L. R." particularly requires it. The former problem cannot be solved by any geometrical method of construction.—Ed.

Answers to Correspondents.

⁎⁎ All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of Knowledge, *the increasing circulation of which compels us to go to press early in the week.*

Hints to Correspondents.—1. *No questions asking for scientific information can be answered through the post.* 2. *Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries.* 3. *No queries or replies savouring of the nature of advertisements can be inserted.* 4. *Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge.* 5. *Correspondents should write on one side only of the paper, and put drawings on a separate leaf.* 6. *Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

Newton Crosland. That would be your better course. It would please you, and everyone would understand why your letters could not appear here.—J. Belcher. Whewell's "Plurality of Worlds" is now very much out of date. It is full of suggestive matter, but even when Whewell wrote it the work was not regarded as of much scientific weight.—N. Railway noise next week; thanks.—M. E. Pendred. Having made no "certain statement against a certain body," nobody, certain or uncertain, has a right to space here in reply. You simply went out of your way to drag in the very subjects we had decided not to admit. The article you think we should not have published was practically a part of our programme. You go on to say that you would like to send us a letter anent the article on suicide, anent which, you ask us "this plain, straightforward, question: Is it or is it not our intention to publish correspondence anent any social question?" We answer, Not about any social questions, but about some such questions we should admit correspondence. Suicide is not an inviting subject by any means—though a review of a work recently published, on the statistics of suicide, suited our pages well enough. Whether any letter you might send on that subject appeared or not would depend on what you said in it.—J. M. Brown. Thanks for your kindly expressions about our chess. We were absolutely obliged to omit the column the week before last.—Young Stager. If phrenology has no absurdities, then "none have we offended," for we objected only to its absurdities. Thanks for the illusion, which has been submitted to Mr. Foster. We do not know who wrote the elegant lines you quote.—G. F. J. Thanks, your letter shall appear before long.—E. C. R. asks where an explanation has been offered of his query, 13, p. 60. He has searched in vain through Knowledge, he says, for any such explanation. If he will turn to query 13, p. 60, he will see, over the initials E. C. R., the explanation referred to.—Marian. "Oh, no; we never mention him" (in these columns).—A. B. Phrenology has been fairly tested, and the discrepancies between theory and observation are found to be far too numerous to be overlooked. There have been marked cases of agreement, of course, or the theory would never have had any adherents. Our readers would not care, we believe, for the article you suggest.—Ben Trovato. We understand: correspondents are to be wholly neglected, or they are to be left only a page or two of the smallest print, and we are to fill Knowledge with articles by "able individuals," preferably perhaps enlarging each number to twice the present size. We should displease correspondents, and each number would involve a heavy loss. But these are mere details. Ben Trovato "prefers such articles to the uncertain lucubrations of unknown individuals."—Jas. Green. Thanks. The illusion you illustrate had already been sent by Mr. Hodd, and before that Mr. Foster had had it in his collection. It shall appear soon, but *not*, as you suggest, at the back of a star map.—Chief Librarian. Thanks, but we are too modest to present Knowledge as published. We wait returningly till sought for.—J. E. Gore. We will try to find room for your note on the star in Cassiopeia. Thanks.—J. A. L. R. We know beforehand that no one can tell you the number of known languages; still we insert your query.—Jas. Green. Do not you think it would be better to study the theory of evolution a little before attacking it? If you had, you would know that the theory, as now understood, involves, as an absolute necessity, the "survival of the fittest" *only*. You ask why there are not, at the present moment, examples of every gradation from one extreme to the other (from monads to monkeys, and thence to men), this being precisely the question which you would refrain from asking if you had studied even superficially the views of Darwin, Wallace, Haeckel, Spencer, and the rest. They show that the fittest survive, and you ask, Where are the others? Understand, we are not saying that they of necessity are right, and believers in the doctrine of multiplied special creations of necessity wrong. We are not urging our own or any man's opinion against yours. We are simply saying that you do not as yet know what the doctrine is which you are attacking. If you did, you would not find the points you mention militating against it.—R. C. Thanks; but that particular solution of the magic square problem has been sufficiently discussed in letters received during the last four weeks.—Mrs. Dr. Kingford. The reviewer of the "Perfect Way in Diet" should have written Mrs. rather than Miss; but so long as our present manner of speaking English remains unchanged, "Dr. Anna Kingsford" will not be regarded as a legitimate expression. A gentleman may recognise to the full a lady's professional skill, and her title to a diploma, but he can no more address her as "Doctor" or "Professor," without smiling, than he could gravely address her as "sir." Even in America, where lady professors, doctors, &c., are more numerous than here, this is found to be the case. Miss Mitchell, for instance, at Vassar College, knows more astronomy than many professors of the science in her own country and this; she is also distinctly entitled to be called Professor, and she prefers to be so called. But no man has ever yet been able to address her in a perfectly natural manner, and the young ladies who attend her classes, though they try hard to do so, most certainly fail.—H. Fitz Hart. Ask yourself the usual question which science puts in such cases. Is there any possible relation of cause and effect in this case? And you will at once see that the hazel twig must have been held by someone who knew where water springs were. The trick is as old as the hills whence water-springs come.—W. A. We agree with you that there is a clear distinction between "I can but think" and "I cannot but think."—Bee. Some parts of the brain have been injured without any noticeable change, but certainly it is not "strictly true," as a general statement, that injury to the brain is not followed by any "noticeable injury."—Cumarrah. Thanks for interesting story, and for poetry, but we could not well offer a prize of £100 for a poem on knowledge.—F. Jukes. Propose to have some papers on the Arabic names of the stars shortly in Knowledge.—J. W. Chester. It is, we believe, out of print.—W. Kidd. Your solution is not correct. Will give the solution in the next number. The problem is not so simple as you seem to think. As an exercise try this. A body projected vertically upwards will not fall to the east, but to the west of the point whence it was projected; moreover, it will be travelling westwards not only when ascending, but when descending also.

This week being the Christmas holidays necessitates some slight changes of arrangement. We take the opportunity to publish matter which has been lying over for several weeks. More recent correspondents will understand the delay.

Later.—Christmas holidays, and in particular Bank Monday, cause sometimes rather inconvenient delays, increased by postal delays due to multitudinous Christmas greetings. We are prevented this week from giving our paper on the Pyramid, and a paper on the Telescope, by a Fellow of the Royal Astronomical Society, because the illustrations for both these papers were not in hand in good time. However, so far as the latter paper is concerned, it is fitting that it should appear in the first number of the New Year, in which also will be the first of our monthly Star Maps, in which some features have been introduced which, we believe, our readers will regard as decided improvements.

The Protective Effect of Vaccination. Dr. Henry Tomkins, medical superintendent of the fever hospital belonging to the Manchester Royal Infirmary at Monsall, in a paper which he read recently at Owens College, said: "The most striking of all evidence is, perhaps, that derived from the small-pox hospitals themselves. Here the protective influence of vaccination is seen and proved in a manner beyond all cavil. At Highgate, during an experience of forty years, no nurse or servant, having been re-vaccinated, has ever contracted the disease, and evidence of the same character I can myself bring forward, for during the whole time that I have had charge of the fever hospital, more than a thousand cases of small-pox have passed under my care, yet no servant, nurse, porter or other person engaged there has, after re-vaccination, ever taken it, though exposed daily to infection in its most concentrated form. One woman, a laundress, who escaped vaccination, took the disease and died; one nurse, who some years before had suffered from small-pox, and was then considered protected, had a very mild attack; and this summer a workman, who did not live on the premises, but came in to work as a painter, was not vaccinated, and had rather a severe attack; and still more recently a servant, who by an oversight was allowed to go about her work three days before being vaccinated, had, before the latter had run its course, a slight abortive attack. Again, among all the students who during the past two years have attended the hospital for clinical instruction, not one has suffered, all having been re-vaccinated before being permitted to enter the small-pox wards. And in their case the false argument which opponents of vaccination have brought forward to explain the immunity enjoyed by nurses and others in attendance on the sick, viz., that constant intercourse and exposure to infection renders them proof against it by the system becoming inured to the poison, cannot be applied, as these gentlemen attend the hospital only a few hours once a week. I defy the most enthusiastic or conscientious of anti-vaccinators to produce evidence like this on his side of the question, or to bring forward even half-a-dozen persons, choose them whence he may, who have not been protected against small-pox, and expose them as the students are exposed, without more or less of the number taking the disease. Facts such as these should convert the most ardent anti-vaccinator from his folly, and convince him that a weapon of defence so powerful as vaccination should not be left to the pleasure of the individual, but that the State has the right and duty to look after its most thorough performance." *Lancet.*

PLAINLY WORDED-EXACTLY DESCRIBED

LONDON: FRIDAY, JANUARY 6, 1882.

CONTENTS OF No. 10.

THE GREAT PYRAMID.

BY THE EDITOR.

IT seems to me a misfortune that the researches made by Professor Piazzi Smyth into the proportions, position, &c., of the Great Pyramid, should have their value and interest impaired by being associated with wild, visionary theories. As De Morgan said long since, Smyth's views are "paradox of a very high order, backed by a great quantity of useful labour, the results of which will be made available by those who do not receive the paradoxes."

But it has been said (the question has been asked me repeatedly, not only in this country, but in America and Australasia), how can the numerous coincidences which Professor Smyth has shown to exist between pyramid features and the most advanced astronomy of our day be explained without supposing that the builders of the Pyramid were acquainted with a number of astronomical facts, which yet could hardly have come to their knowledge unless they were divinely inspired? Or, if some higher civilisation existed before the building of the Pyramid, and the facts in question were discovered as they have been re-discovered by modern astronomers, how is it that we have no traces of such civilisation older than the Great Pyramid itself? To these questions another has been added, especially for my own benefit, viz., this:—How can the great number of the coincidences be regarded as an argument against their significance? How can they be said to prove too much?

It appears to me that if we carefully study what the features of the Great Pyramid may be regarded as certainly proving, we shall readily distinguish the difference between the wrong and the right way of using the argument from coincidence.

We find first, in all the Egyptian Pyramids, the evidence of an astronomical plan; and in the Great Pyramid we find evidence that such a plan was carried out with great skill, and with an attention to points of detail which shows that, for some reason or other, the edifice was required to be most carefully built in a special astronomical position. It matters little at this stage of the inquiry whether we suppose the Pyramid was erected for astronomical observation or not. It was certainly constructed in accordance with astronomical observations of great accuracy, and conducted with great skill. Moreover, it is obvious that to obtain such accuracy, the building was made to serve, while it was being built, the purpose of an astronomical observatory. Just as the astronomer in our own time uses the instrument he is setting up to adjust and make exact the position of the masonry on which it stands, so the builders of the Great Pyramid used the passages which they made within it to determine, with the greatest accuracy attainable by them, the proper position of each part of it, up to the so-called King's Chamber, at least, and probably higher.

So much is certain. Every feature thus far discovered in the Great Pyramid corresponds with this theory, and some features can be explained on no other.

I have shown at some length elsewhere—but the matter scarcely needs demonstration—that the only possible way in which the Pyramid could have been oriented so accurately as it has been, was by stellar observations. Of all observations for *that* purpose, those made on the Pole-star of the time would have been the most effective. If there is a star which the astronomer observes less than another when using his observatory for that chief of all purposes to which a great public observatory, at any rate, can be applied, it is the Pole-star, simply because that star moves so slowly round its small circle. But for determining the direction of the true north point (and also for determining latitude) the Pole-star is invaluable. No astronomer who thinks over the problem at all, can fail to see that the builder of the Great Pyramid would have been driven by the requirements of his case to make just such a slant descending passage as that which opens out (now that the casing-stones have been removed) on the northern side of the Pyramid, not far above its base. It is equally certain that such a descending passage would have been directed to the position of the Pole-star when it was due north and at its lowest. The position of the Pole-star when exactly above the pole would have been just as well suited for determining the direction of the true north, but the slant passage would have had to run deeper down into the solid rock to give the same degree of accuracy, and the extra labour would have been wasted.

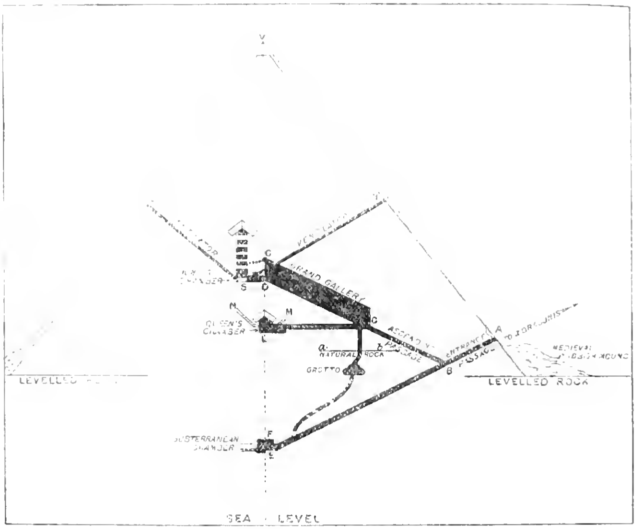
When, after marking the position of the base, the question of obtaining the true level came to be considered, only one method effective enough to give the required accuracy would have been available—viz., the use of water, flooding the squared space cut out in the solid rock. A difficult and costly task, doubtless, in itself, but a mere nothing considered with reference to the labour and cost to which the builders were prepared to go. For this purpose, the descending passage would have to be temporarily plugged; and as soon as the water-level had been marked at several stations on each side of the base, the plug could be removed, and the water run off into the pit which had been excavated underneath. A depth of a few inches of water all over the base would have sufficed for this purpose, but more probably a mere channel all round the base was prepared.

After thus orienting the base by aid of the Pole-star, and levelling it by using a property of liquids which was, of course, well known to them, the architects would place layer after layer, carrying towards the north the passage for observing the Pole-star, so that as each layer was placed, the work of orienting, and possibly of levelling, might be repeated, and an ever-increasing exactitude secured.

But they would know that ere long the direct pole-star observations would fail them; for the passage would pre-

sently reach the northern face of the Pyramid. By again using a well known property of liquids, however, combined with a well known property of light rays, they would continue the process of orienting to a much greater height. (When I say well-known, I mean well-known to them: they were manifestly skilful engineers and architects, and as surely as they were well acquainted with the properties of matter, so surely must they have been acquainted with the mathematical relations on which the simpler optical laws depend. Possibly they knew laws more recondite; but the simpler laws they certainly knew.) Now, the plan which would quickly suggest itself to anyone knowing these laws, would be to make use of the reflected rays from a star when the direct rays could no longer be employed. We know that when a ray from a luminous object is reflected at a plane surface, the reflected ray and the incident ray make equal angles with a line perpendicular to the surface at the point of incidence, and are also both in the same plane with that perpendicular. Now, what the Pyramid architects wanted was to have a constant means of determining the direction of north and south—in other words, a constant knowledge of the position of what modern astronomers call the plane of the meridian. They had this so long as they could observe the Pole-star when due north, through a passage opening out within the square layer they were adding to the Pyramid. When, as their work continued, this passage opened out in the part of the sloping side already completed, they could still detrmine the meridian plane if they carried up a passage through the masonry in such a direction as to contain the rays from the Pole-star after reflection at a horizontal surface, such as that of still water. For a perpendicular to the surface of still water is directed to the zenith, and the direct and reflected rays from the star (due north) lie, therefore, in the meridian plane which passes through the north and south points and through the zenith.

Now this is precisely what the Pyramid builders seem to have done, as the accompanying figure, the dimensions of which are taken from Smyth's book, "Our Inheritance in the Great Pyramid," shows. AE is the long, slant passage, which for convenience we may call the descending passage, BC is an ascending passage of exactly the same character, which, therefore, we might have presumed was intended for a similar purpose, even if the consideration of the natural course which intelligent builders would have pursued had not led us to expect to find precisely such an ascending passage here. But it may be asked how the reflected rays from the star were obtained? Nothing could have been simpler. The very same process which had been applied in levelling would be all that would be needed here. If the descending passage were for a time (a day, or even an hour would suffice) plugged at B, and water poured in so as to partially fill the angle thus formed at B, the surface of that water would reflect the rays of Alpha Draconis up the ascending passage BC. The direction for the south line thus indicated could be marked, and then the plug left to slide down to the subterranean chamber.



Once a year (supposing one layer of stones added each year, as Lepsius surmises) would have sufficed for this operation.

Not only do we thus find a natural and perfect explanation of the circumstance (hitherto unexplained) that the ascending passage is inclined at the same angle to the horizon as the descending passage, but precisely as we might expect from a true theory, we find that other points of difficulty have here their explanation. It is obvious that at B the casing stones of the descending passage would have to be very closely set and carefully cemented, so that the water used, year after year, in obtaining the reflected rays, might not percolate through and do mischief. Now, just here, we find the stones of the descending passage arranged with greater precision and made of better material. "Why," says Smyth—who notices everything, but seems always to insist on some forced explanation—"why did the builders change the rectangular joint at that point, and execute such unusual angle as they chose in place of it,

in a better material of stone than elsewhere, and yet with so little desire to call general attention to it, that they made the joints fine and close to that degree that they escaped the attention of all men until 1865 A.D. !" "The answer came from the diagonal joints themselves, in discovering that the stone between them was opposite to the butt end of the portcullis of the first ascending passage, or to the hole whence the prismatic stone of concealment through 3,000 years, had dropped out almost before Al Manoun's eyes. Here, therefore, was a secret sign in the pavement of the entrance passage, appreciable only to a careful eye and a measurement by angle, but made in such hard material that it was evidently intended to last to the end of human time with the Great Pyramid, and has done so thus far." In other words, the stones were thus carefully fitted that they might be a sign to Prof. Piazzi Smyth and the pyramidalists in 1865, just as the descending and ascending passages were all to be signs. It may show great want of taste to say that all these features indicate the builder's plan, and were in no sort intended for the benefit of remote generations of men belonging to an alien race; but it seems a long way more natural.

At any rate, it is certain that men having no knowledge of the telescope, and no means of securing accuracy of direction as our astronomers do by *magnifying*, would have adopted precisely such plans as thus far seem most clearly indicated in the Pyramid structure, making long passages in solid materials, and where necessary, changing the lines of sight by simple reflection. When we consider that this would be their natural course, and that even minute details of structure (some hitherto unexplained) correspond with the theory that they adopted this course, the conclusion seems fair that the theory is a sound one. Of course, it cannot be acceptable to pyramidalists, who prefer to believe that the labours of the Pyramid builders were directed by architects knowing all that is now known in science, and more; but we are, at least, saved from the incongruity of assuming that these wonderously-gifted architects were idiotic enough to adopt the blundering plan assigned to them—hiding away for preservation their sacred symbolisms and prophetic teachings, in a building so constructed that its interior could only be reached by being forcibly broken into, and would as a matter of fact be never properly measured until it had lost in great part the perfection of form on which its value for the supposed purpose depended.

This will appear still more clearly when we consider the great gallery, which to the astronomer is the most obviously astronomical part of the building, but to the pyramidalist is a sort of "Zadkiel's Almanac" in stone.

FOUND LINKS.

By Dr. Andrew Wilson, F.L.S., &c.

PART I.

As the question of "Missing Links" appears to be exciting a considerable amount of attention amongst the readers of Knowledge, I have thought that a paper or two on the general aspects of the beings that link together distinct groups of animals, may prove interesting and instructive to reflective minds. It is very necessary that in the first place we should remember the special form which the rational demand for such "links" should take. I have already shown, for example, that there exists no necessity or demand whatever for any theoretical link, either between man and any existing ape, or between man and any extinct ape. Such a demand is simply the outcome of an ignorance both of natural history at large, and of evolution also; and, as often as not, such ignorance is of the most prejudiced type. That which the evolutionist and naturalist desire to know, is the nature of the forms which, on the theory of "development," must have connected the human *root stock* with the pre-human *root*. The connection, or "link," cannot be sought in the existing world. It must be obtained, if ever it comes to light at all, from the world of fossil life, and from the stores of life-relics which the geologist is year by year adding to our stores of knowledge. It is true that Nature is not bound to furnish us with "links" because we see a logical necessity for their existence. But all analogy leads us to expect that such "links" once existed; and I will now to describe certain interesting examples of such *intermediate forms*, as they are called, culled from varied groups of the animal world. In a word, if I am able to show that we possess at present in the world around us certain animals which undoubtedly connect distinct groups, I may claim the strong support of such examples in favour of the idea that "links" that are now "missing" where we desire their presence, once did exist.

Lepidosiren annectens, or Mud-fish, showing the paired fins.

One of the most curious groups of fishes is that named by zoologists the *Dipnoi*. This name means "double breathers," and the significance of the name will become apparent later on. Of this order of fishes, there are two chief examples. The *Lepidosirens*, or "mud fishes," found in the rivers Amazon and Gambia, form the first of these examples; whilst a curious fish, occurring in Australian waters, and known as the *Ceratodus*, or "Barramunda," represents the second type. This latter fish is the "Jeevine" or "Teebine" of the Australian natives. Now, in looking at either of those fishes, the observer would never for a moment suppose that they presented any features out of the common. Yet a very slight acquaintance with natural history soon proves the singular nature of their position in the fish-class. Everyone knows that fishes breathe by gills; that they are cold-blooded; that their "limbs" are represented by certain of their fins (the "paired" fins); and that their bodies are covered with scales. If we add to these facts the declaration that fishes possess a heart consisting of only two chambers, we shall have nearly completed our definition of the fish type; and we might add, lastly, that the nostrils in fishes are typically closed pockets, and do not, as in higher animals, open backwards into the mouth. It is necessary for our present purpose to point out that most fishes possess a singular sac or bag, lying just beneath the spine, and called the *swimming-bladder*, *air-bladder*, or *sound*. From the "sound" of the sturgeon we obtain isinglass; and in a herring, for example, the "sound" may be seen as a silvery, glistening bag, which is removable along with the other organs of the fish when it is "gutted." This bag contains gas, and its use is that of serving to alter the specific gravity of the fish—that is, to render (by compression or expansion of the gas) the body of the fish heavier or lighter than the surrounding water. It thus enables its possessor to readily rise or sink in the medium in which it lives. The air-bladders of all fishes, as Dr. Günther tells us, at first open

into their digestive systems by means of a tube or duct. But in many fishes this tube disappears, leaving the air-bladder a closed sac (as in the cod); or the duct may persist, and place the sound in communication with the digestive tract, as in the sturgeon or herring. Again, the air-bladder may be a simple and single sac; or it may be variously divided, and its interior may be smooth or may be divided into cells. We shall presently see that in the mud-fishes and the "Jeevine," this structure assumes a form and function for which its variations in common fishes in some measure prepare us.

INTELLIGENCE IN ANIMALS.

IT may be objected that in cases such as those we considered last, the animal has merely imitated an action which it has seen performed by others, and has subsequently learned to associate the action with its ordinary consequence. Apart from the consideration, however, that although in any single case such an interpretation might possibly be correct, it would be most improbable that it should explain all cases in which cats or dogs have used knockers or rung bells in the usual way, cases may be cited in which animals have devised a way of their own for producing such signals. Thus Mr. E. L. Layard, of the British Consulate, Noumea, relates the following case in which a cat acted in a way which can hardly be explained, save by assuming that she reasoned :—"Many years ago," he says, "we lived in Cambridge, in Emmanuel House, at the back of Emmanuel College. The premises were partly cut off from the road by a high wall; the body of the house stood back some little distance. A high trellis, dividing off the garden, ran from the entrance door to the wall, in which was another door, or grate. A portion of the house, a gable, faced the trellis. . . . . We were, after some time of residence, extremely troubled by runaway rings, generally most prevalent at night, and in rainy, bad, or cold weather, which was a great annoyance to the servant girls, who had to cross the space between the house and the wall to open the outer door in the latter, and were thus exposed to wet and cold." The annoyance became so great, that Mr. Layard and a cousin watched behind the trees on 'Jesus' piece,' armed with stout ash saplings, wherewith to administer a sound thrashing to the ringer, whomsoever he might be. But though the rings continued, no one pulled the handle. Hence the theory of ghosts was naturally suggested, but Mr. Layard, having brains, rejected that interpretation. At length chance cleared up the mystery. "Being ill," he says, "I was confined to the wing facing the trellis, and one miserable, blowing, wet day, gazing disconsolately out of the window, espied my favourite cat—a singularly intelligent animal, much petted—coming along the path, wet, draggle-tailed, and miserable. Pussy marched up to the house-door, sniffed at it, pushed it, mewed, but, finding it fairly shut, clambered up to the top of the trellis, some eight or ten feet from the ground, reached a paw over the edge, scratched till she found the bell-wire which ran along the upper rail from the wall to the house, caught hold of it, gave it a hearty pull, then jumped down, and waited demurely at the door. Out came the maid; in rushed puss. The former, after gazing vaguely up and down the street, returned, muttering 'blessings,' no doubt, on the ghost, to be confronted by me in the hall. 'Well, Lydia, I have at last found out who rings the bell.' 'Lard, master, ye haven't, surely'—she was broad Zumersetsheer. 'I have; come and see. Look out of the breakfast-room window, but don't show yourself.' Meanwhile I went into the drawing-room, where Mrs. Puss was busy drying herself before the fire. Catching her up, I popped her outside of the door and ran round to my post of observation. Puss tried the door, and mewed, thinking, probably, someone must be near, and, after waiting two or three minutes in vain, again sprang up the trellis and renewed her attack on the bell-wire, of course, to be immediately admitted by the delighted maid, who this time did *not* cross the yard, nor ever again, I fear sometimes to the inconvenience of visitors, if puss was waiting for admission."

In this case it is possible that the cat may have only discovered by accident that the bell-wire could be reached in the way described. This is Mr. Layard's explanation. He considers that puss, in clambering up the trellis to the house-top, accidentally moved the wire and caused the bell to ring. It seems at least as likely that she noticed the wire moving when the bell was rung, and afterwards deliberately moved it to produce the desired effect. But in either case, it is clear that neither instinct nor mere imitative faculty can explain the cat's action in this case. In passing, I may remark that the imitative faculty, which some regard as a merely automatic quality, seems to me far better explained as the result of reasoning, though, of course, the reasoning is not of a very high order; an animal seeing a man perform some action, infers that some advantage is to be gained by the action, and repeats it in the expectation that some good result will follow, though without knowing what this may be. However, in the present case, there was no imitation, nor certainly could any instinct have been in question. Mr. Layard mentions other cases, of which the same may be said. "I have known dogs shake a door violently," he says, "to attract attention and be let in. A dear old spaniel of ours at the Cape used to rattle the empty bucket if he was thirsty, and then come and look in our faces. My horse will come up from his pasture to the pump in the yard, and whinny till someone gives him water. . . . . Surely all this is abstract reasoning." he proceeds. "These things are not taught them, and they do not do all of them even by imitation. I don't go to the pump and whinny if I want drink! nor rattle a bucket! No! they come by a process of mental reasoning, and I am convinced all animals have it to a certain degree, more or less."

There have been cases which have afforded opportunity of noting the behaviour of an animal when first some new experience has occurred to it, and (as it would seem) new ideas have been suggested. Such cases are of extreme importance in determining whether animals really reason or not; because it must be admitted that in some instances where animals have appeared to reason, the action noted may possibly have originated, in the first instance, by accident, and have been continued subsequently as a mere habit. It is rather unfortunate that the only animals which we can observe under favourable conditions—domestic animals, and those which, though not domestic, affect the neighbourhood of houses—are not those whose cerebral development is of the highest order among animals. If monkeys were commonly domesticated (which would, for other reasons, be by no means desirable), we should probably have a number of far more striking and convincing instances of animal reasoning than we at present possess, for nearly all monkeys are far higher in cerebral development than the most sagacious dogs, while horses, cats, rats, &c., are lower than dogs in this respect. Still, if we remember that whatever evidence we obtain from the behaviour of dogs and cats must be regarded as suggesting, for this very reason, a powerful argument *à fortiori* as to the reasoning faculties of monkeys, and especially of the higher orders of simians, we may be well satisfied with

such instances as have been adduced above. The following case, showing how a cat reasoned out the meaning of a phenomenon brought for the first time under its notice, seems to afford decisive evidence of the capacity of animals to deal with cases when neither instinct, habit, nor imitative faculty can afford them any assistance :—A household cat was observed to enter a bedroom which was being cleaned at spring-time : a looking-glass stood on the floor, and Tom, on entering, found himself confronted by an image which he naturally supposed to be another cat, an intruder on his domains. He made hostile demonstrations, which were presently followed up by a rush at his opponent, who, nothing loth, seemed to rush also at him. Finding an apparent obstacle to his vengeance, Tom ran round behind the glass, where he found no enemy ; so he came again to the front. Here he again found his foe, on whom he again made an onslaught, only to be similarly foiled. He repeated this two or three times, applying manifestly the inductive method to the problem before him. The result of these experiments was to suggest the theory that the cat in the looking-glass, if actually existent, was unlike those specimens of the feline race with whom Tom's experience had hitherto made him acquainted. These repeated failures must have a meaning, Tom seems to have reasoned. Either he was the victim of some illusion, or the cat behind the glass was of altogether exceptional activity. But, however active that cat may be, Tom proceeded to reason, he cannot be on the further side and yet not on the further side at the same moment of time. If, then, I look at him and see him to all appearance on the further side, while at the same time I feel for him there with my paws and find him not there, then the cat in the glass must be a mere fraud. No sooner was this *experimentum crucis* devised by the clever cat than it was put into execution. Tom deliberately walked up to the looking-glass, keeping his eyes fixed on the image ; then, when near enough to the edge, he reached out carefully with his paw behind the glass for the supposed intruder, whilst with his head twisted round to the front he assured himself of the persistence of the reflection. He also must have recognised, what the narrator of the story seems to have overlooked—that the looking-glass was not, as it seemed, transparent, for the paw with which he was feeling about for the other cat was not visible, though the supposed intruder remained in view all the time. The apparent presence of the feline foe, though the feeling paw could not be seen, satisfied Tom fully. "The result of his experiment," says the narrator, "satisfied the cat that he had been the victim of delusion, and never afterwards would he condescend to notice mere reflections, though the trap was more than once laid for him." It would, by the way, have been worth while to try whether a looking-glass without a frame deceived him after he had discovered the meaning of an ordinary mirror, or whether a cat placed on the other side of a transparent framed glass would be at first mistaken for a mere reflection—his conduct in either case being carefully watched. A cat which had shown such excellent capacity for reasoning was worth experimenting on.

Whether we suppose that the cat of the preceding narrative judged of the position of his supposed foe solely by sight, or may partly have been influenced by the sense of sound (very slightly, in any case), it must be admitted that he showed a fitness for original research which some amongst ourselves might be found wanting in, if we may judge from their actions in certain cases. But it is an interesting question how far an animal may really be deceived by the image of another animal, or of some object in which the animal observer takes interest. There are stories of birds pecking at painted fruit, and the like, of which some are unquestionably apocryphal. When we remember, too, that some savages fail utterly to understand the meaning of pictures,* even of the most familiar objects, we may well doubt whether animals can possibly mistake a painted figure for a real object. Yet there are some stories which seem to show that animals certainly recognise pictures of persons, animals, or objects familiar to them. It would almost seem as though such cases could only be explained as depending on the exercise of a certain amount of reasoning power, the animal inferring that, because a certain picture presents details of shape and colour corresponding to those belonging to a familiar object, the picture is in some way connected with that object, although other senses—as of sight, smell, hearing, &c.—must serve perfectly to prevent any possibility of actual deception. A letter in *Nature*, by one who remarks that "his own observations lead him to suppose that dogs very rarely take notice of a painting or any representation on the flat," seems to me especially interesting, as illustrating how the sense of sight may for a moment deceive an animal which usually trusts chiefly to other senses. "I only know of one instance," he says. "A bull-terrier of mine was lying asleep upon a chair in the house of a friend, and was suddenly aroused by some noise. On opening his eyes, the dog caught sight of a portrait of a gentleman on the wall not far from him, upon which the light was shining strongly. He growled, and for some little time kept his eyes fixed upon the portrait, but shortly satisfying himself that there was no danger to be apprehended, he resumed his nap. I have often," proceeds the narrator, "endeavoured since to induce him to pay some attention to portraits and pictures, but without success, though sometimes he will bark at his own reflection in a looking-glass. He knows it to be his own image that he sees, for he very soon tires of barking and looking."

The Health of Navvies.—In view of extensive canalisation soon to be done in France, the Minister of Commerce lately consulted the Academy as to measures that should be taken to preserve the health of workmen engaged. A report by M. Colin is the result. In it he notes the persistence of a depressed vital state in certain parts of the country, especially the coast departments, which are chiefly concerned in the works projected. Marshes, with their miasma, are not the sole cause of this "impaludism" (as he calls it) ; but virgin soil, newly turned, emits morbid germs, whence arise intermittent fevers, &c. With regard to precautionary measures, the report specifies the following :—1. Fragmentation of work, not attacking too many points at once, not entering on a piece of work before the piece next it, begun previously, is finished. 2. Choosing strong, vigorous navvies, by preference inhabitants of the region. 3. Diminishing the time of contact with the soil. The work should be stopped at times when it is known to be dangerous—viz., July, August, and September, and in the extreme morning and evening hours. Evening vapour on plains and low-lying parts is very dangerous. Large fires should be lit in the works morning and evening. 4. Lodging of the navvies in the neighbouring centres of habitation, as much as possible in the heart of towns and villages, and on high ground, or, where near the sea, in pontoons moored at some little distance from the shore. Fevers do much less injury among workmen who reach their homes at night, than among those who remain on the works. 5. A special diet—before his work the navvy should have a substantial hot meal ; preventive medications (such as arsenic, extract of nux vomica, and sulphate of quinine) have not yielded such results as recommend their use. 6. Immediate conveyance to the hospital of a navvy attacked by fever, and caution as to premature re-engagement of men discharged from hospital. 7. Early filling of the excavations, admitting water, in urgent cases, to parts which prove peculiarly infectious, and stimulating vegetation on ground newly upturned.—*Times*.

* There are some illustrations of this in the Editor's little book called "The Flowers of the Sky," in the article relating to "Fancied Figures among the Stars."

THE ELECTRIC TELEGRAPH.

BY W. LYND.

God has been bountiful to the human race in this age. He has given us to see Titans enslaved by man; steam harnessed to our carriages and ships; galvanism tamed into an alphabet—a gamut and its metal harp-strings stretched across the earth, *malgré* mountains and the sea, and so men's minds defying the twin monsters Time and Space." —CHARLES READE.

HALF A CENTURY ago railways were in their infancy, George Stephenson was bravely fighting against ignorance and prejudice, and founding his gigantic scheme which has revolutionised the world and proved one of the greatest blessings ever bestowed upon mankind.

Half a century ago there was not a single mile of telegraph wire in the universe.

Stephenson's name and fame have been trumpeted far and wide. Biographies without number of the great engineer have been written; only recently Dr. Smiles has given to the world his admirable "Lives" of the pioneers of railways, George and Robert Stephenson.

But, who has heard of that other Titan of the nineteenth century, William Fothergill Cooke?

The name of the man who introduced the first practical electric telegraph to this country is almost unknown outside scientific circles; yet, what a debt of gratitude we owe to the inventor of the instruments, by means of which that potent but mysterious agent we call electricity was first made to record intelligible signs which could be translated into human language! The first electro-magnetic telegraph was produced between 1820 and 1832 by Baron Schilling, of Lanstadt. Mr. Cooke was, in 1836, occupied in the Anatomical Museum at Heidelberg, preparing wax models for his father, who had been recently appointed Professor of Anatomy in the University of Durham.

It is a remarkable fact that he had no knowledge, or very little knowledge, of either physics or electricity. When Baron Schilling exhibited and explained his primitive telegraph, Mr. Cooke was so struck with the vast importance of an electric telegraph to the railways then progressing with such marvellous rapidity in the United Kingdom, that he immediately gave up modelling, and devoted all his time and energies to the realisation of his hopes. To be the means of establishing instantaneous communication by electricity between towns, particularly the great centres of commerce, was to become a benefactor of the human race. And Mr. Cooke was so sanguine of success, that he left Germany and came to England in April, 1836.

On Feb. 27, 1837, while engaged in perfecting a set of instruments to be tried on the Liverpool and Manchester Railway, he was introduced by Dr. Rogel to Professor Wheatstone, who had been devoting much of his time to the subject of electrical communication. The meeting was a happy one. The two electricians entered into partnership, and in a marvellously brief space of time the first really practicable electric telegraph was ready for trial.

There were, however, other claimants for the honour of having invented the electric telegraph as a practical reality, but there can be no question of Cooke and Wheatstone's priority in date over the other inventors, Alexander and Morse.

The first line of electric telegraph was constructed upon the Blackwall Railway in 1838. A sight of Cooke and Wheatstone's instrument, with its five needles, would surprise the telegraphists of the present day, who are used to duplex and quadruplex working!

The five needle instrument required five wires; now four messages can be shot along one wire!

The double needle instrument, which will be described later on, was the next improvement necessitating the employment of two wires only, and that form of apparatus can still be seen at work upon one or two of the railways in the United Kingdom.

Although Professor Wheatstone assisted Mr. Cooke, and, no doubt, contributed in no small degree to the perfection of the instruments, we are in duty bound to regard the latter as the father of practical telegraphy.

THE MAGIC WHEEL.

WE are able this week to give the series of views of a trotting-horse to which we referred last week; and to explain how the picture is to be arranged to produce a life-like effect, we repeat Fig. 1, as the two have to be considered together.

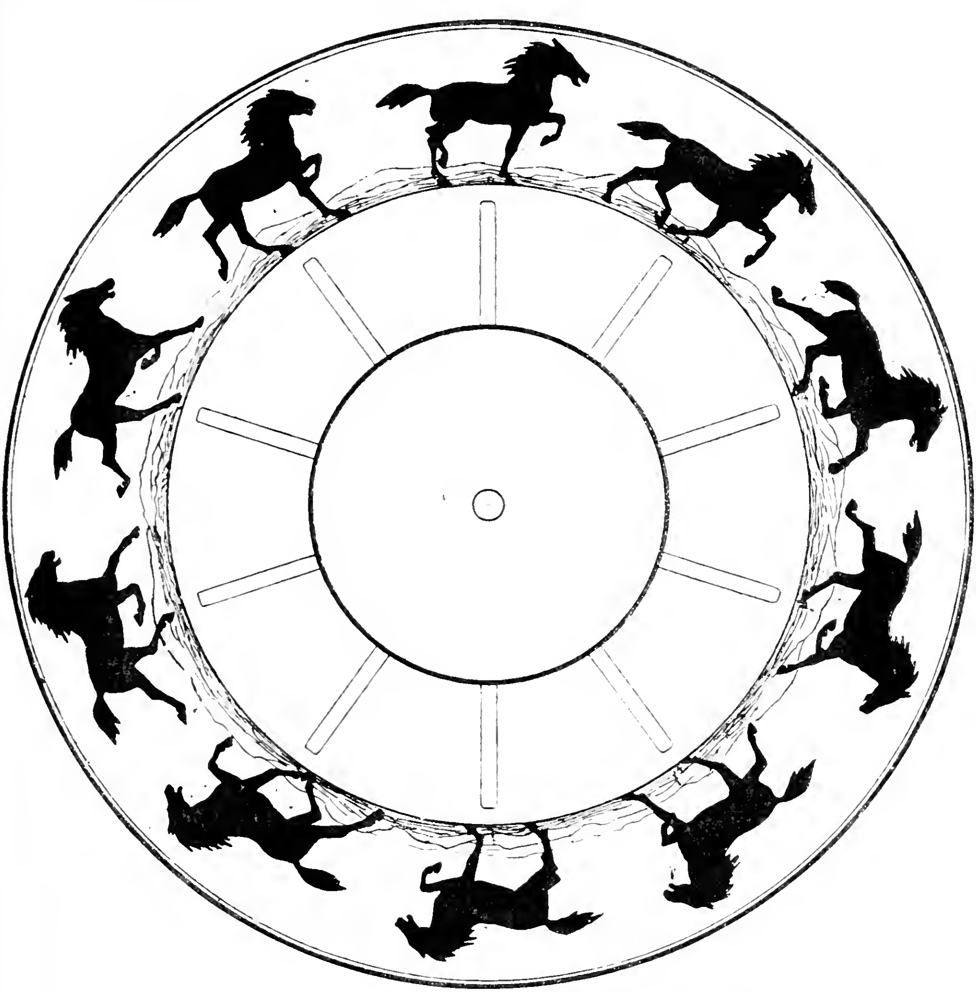
Fig. 1.

Cut out the series of views (following the outer circle) with the scissors, or carefully copy it on a separate piece of paper: and paste the circular disc thus obtained on a circular piece of cardboard. Cut out the oblong space under each figure, so as to make a series of oblong slits through the cardboard. Then fasten the wheel to a stick or handle, by means of a pin through the centre, on which it can freely turn. If now you stand opposite a mirror in the way shown in Fig. 1, and twirl round the disc before the eyes, looking through the upper slots, the horses will be seen to move as in life. The views have not been made by guess-work, as in most of the series used for zoetropes, but are from a series of actual photographs taken instantaneously at equal successive intervals of time during the trotting past of the celebrated racer, Abe Edgington. They were obtained by

Muybridge, of San Francisco. Next week, or the week after, we shall give a series showing a galloping horse.

The above views are from the *Scientific American;* but, as mentioned in our last, the series showing a trotting horse had to be modified before it could be used for the purpose of the magic wheel.

It is hardly necessary to say that the wheel can be readily made to turn uniformly by being put on a small axle, round which a string may be twined. But twirling with the hand will suffice to show how well worth while it is to provide for a more satisfactory method.



THE PLANETS AND SOLAR SPOTS.

M. DUPONCHEL considers that the maximum of solar spot frequency will not occur "as all the world, and M. Fagein particular," predict, in 1882, but not earlier than 1890. It may possibly occur as early as 1888, but far more probably will be as late as 1892. He bases this on the supposed relation between the sun spots and planetary movements, a relation which has not been established, but on the contrary, seems more and more unlikely the more the evidence is examined. Those who fondly imagine that the world is to come to an end in 1882 (the prediction of Mother Shipton—of fully equal value in our opinion—having failed for 1881) because of planetary perihelion passages, and resulting sun disturbances (also because the pyramid grand gallery is 1881·59 inches long, or ought to be), may breathe freely again, that is if they are disposed to prefer M. Duponchel as an authority to Professor Grimmer. For our own part we believe the world is quite as likely to come to an end in 1888, or 1890, or 1892, as in 1882. It has been coming to an end, at intervals of two or three years, for the last century, and probably, though we have no evidence as to details, ever since it seemed so certain to every one that the year 1,000 was to see the end of all things mundane. And so far as can be seen, one prediction in the past and for future dates has been as good as another—in other words, not one has been worth a straw.

NIGHTS WITH A THREE-INCH TELESCOPE.

UNDER the above heading we propose to furnish the beginner in astronomy with such directions as shall enable him to employ, to the greatest possible advantage, the kind of instrument with which he will, in all probability, at first provide himself. But, be it noted at the outset, that this series of papers is not intended for the possessors of telescopes of considerable aperture, equatorially mounted * or furnished with elaborate rackwork movements in altitude and azimuth.* For the owners of such, an abundant literature is already in existence; and they, at present, have such admirable works as Webb's "Celestial Objects for Common Telescopes," Crossley, Gledhill & Wilson's "Handbook of Double Stars," Chambers' one volume edition of Smyth's "Celestial Cycle," &c. We shall presuppose nothing on the part of our readers, then, beyond an ardent desire to become familiar with the beauties and glories of the celestial vault, and trust, if we can secure their attention, to put them fairly in the way of gratifying such a high and laudable aspiration. To this end, we shall use as our text the maps of the face of the sky which appear monthly in KNOWLEDGE, although we should strongly recommend the student to possess himself of the smaller "Star Atlas" by the editor of this journal, as well.

As it is of the first importance that the workman should be familiar with the tools he has to use, we shall devote this introductory essay to a description of the telescope itself, which we will imagine to be a 3-inch achromatic one, of about 42 in. focal length, mounted upon an ordinary "pillar and claw" stand. Such an instrument, as ordinarily sold, is shown in Fig. 1, which, however, represents it as furnished with a valuable little subsidiary contrivance (to be immediately described), which the observer will have to make, or get made, himself.

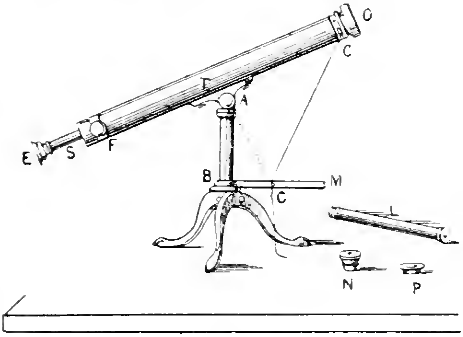


Fig. 1.

And here, albeit we are earnestly anxious to eliminate the commercial element altogether from our considerations, we are compelled to caution the student against supposing that a first-class 3-inch telescope for astronomical purposes can be made for £5, or, in fact, for any sum approaching it. The object-glass alone must cost the maker himself something like this amount. Hence, as we propose to deal with and describe celestial objects, as seen in an instrument of the highest class, we give this preliminary warning, lest the young observer should spend his money in a cheap glass, and then wonder at the discrepancy between our delineations of stars and planets and his own views of them. There is a vast amount of rubbish vended in the form of (so-called) cheap telescopes, and no tyro should ever purchase such a one without its previous examination and testing by a skilled expert. Makers like Cooke, Dallmeyer, and Wray will not imperil their great and deserved reputation by selling an inferior object glass, even to a total stranger; but instruments of unknown opticians require the most rigid trial before they can be safely bought. We shall give further on, a few tests by which the student himself may judge somewhat of the quality of his purchase. It is time, however, to turn to our figure. Here we see the brass tube T, into one end of which screws the cell containing the object glass O. Through a tube projecting from the brass disc which covers the other end of T, the smaller tube S is worked in and out by the milled head F, acting in a rack and pinion. This is for the purpose of focussing the telescope, and making the image of the object observed sharp and distinct. Into the tube S screw the eye-piece E, consisting of two lenses mounted in a short piece of tubing. Shortly, the action of the instrument is this. The object-glass forms in its focus an image of the object to which it is directed, and the eye-piece—which is really a microscope—magnifies this image before it enters the observer's eye. So much for the telescope itself. It is bolted, as will be seen, by two screws and nuts to a brass plate, which has a vertical motion, by means of the knuckle-joint at A, at the top of the stout brass pillar AB; and a horizontal one, furnished by the rotation of the whole of this top-fitting, inside the pillar. Three massive feet form its support. The arm BM shown in our drawing forms no part of the ordinary fitting of the instrument; it constitutes the subsidiary contrivance of which we spoke above, and we shall explain its use presently. L in the figure represents a terrestrial or four-lens eye-piece, which shows objects erect, and hence is used for land-purposes. It screws in at the extremity of S, just as E does. The ordinary astronomical, or so-called "Huyghenian" eye-piece contains, as we have previously said, only two lenses, and inverts, or turns objects upside-down. This, however, is obviously immaterial in a star, and this construction of the eye-piece enables us to obtain high power with comparatively small loss of light. N is another astronomical eye-piece, and P a dark cap or shade, screwing on to every eye-piece, for the purpose of observing the sun. The student is earnestly warned never to look at the sun through a telescope without first covering the eye-piece with one of these shades. When, however, we come, in a future paper, to speak of the sun, we shall describe how the solar details may be telescopically shown without looking through the instrument at all. The powers usually supplied with a telescope of the size we are describing are one terrestrial one, magnifying, perhaps, 45, and three astronomical ones, giving powers of something like 50, 100, and 180. If, however, the observer intends to devote his instrument wholly to the sky, we should advise him to replace the terrestrial eye-piece by two Huyghenian ones, magnifying 25 (for comets, nebulæ, and clusters), and 250 (for close double stars) respectively. For night use, too, a "Dew-cap" will be found indispensable. This may be made of a tin tube, bright outside and blackened within, about 8 inches long, and fitting over the object end of the telescope at O. This prevents direct radiation from the object-glass, and the consequent deposition of dew upon it. *Never wipe your object-glass if you can possibly help it.* Expose it to the heat of a fire (not too near) or of the sun, should it become heavily dewed.

A word may now be said as to the use of the bar BM shown in our sketch. It is a fact familiar to nearly everyone who has ever opened an astronomical primer (and, at any rate, to be established by a single winter night's observation of the sky from dusk to dawn), that the stars all seem to describe circles round a centre in the Northern sky, called the Pole, very close to which is situated the star we call the Pole-star. The farther we go from this centre, the larger these circles become, up to a distance of 90°, beyond which they begin to diminish again. Moreover, the point round which they turn is something over 50° above the Northern horizon (depending on the observer's latitude), so that they are all described obliquely to the horizon. Obviously, were the apparent axis of the concave celestial vault vertical, the Pole would be overhead, and the stars, seeming to describe circles parallel to the horizon, would neither rise nor set. In this imaginary condition of things (imaginary in England, for it really exists at the Poles), the mounting of the telescope shown in our figure above would enable the observer to follow a star by merely turning the telescope round the vertical axis, AB, when once that star was in the field; but a moment's thought will show that a simple movement round a vertical axis will by no means accomplish this when the star's path is described round an inclined one. The vertical movement of the telescope, we may here say, is spoken of as its motion in altitude; its horizontal motion as that in azimuth. It may require a little more attention to see that if we so tilted the axis AB that it became parallel to (or practically coincided) with the apparent axis of the sky; that then the simple motion round it would follow any star to which it was directed, from its rising to its setting. A telescope thus placed is said to be equatorially mounted. Now, the little device in our cut, for which, in its existing form, we are indebted to the Earl of Crawford and Balcarres, is intended to communicate an approximately equatorial motion to the ordinary altazimuth mounting of the instrument. It takes the form of a bar BM, extending from the base of the pillar AB. In it, at such a distance from the point B vertically under A that the angle ACB shall be = the latitude of the place, a hole is bored, and a thumbscrew (shown at C) inserted through the bar, so as to nip a light chain or thin wire tight when it is passed through the hole. The other end of this chain is fastened anywhere towards the end of the telescope at C', and sufficient weight is put on to the eye end of the telescope to keep

* These terms will be explained as we proceed.

the chain C C tight. Perhaps we may say that if the height from A to B is (as is very common) 11 in., the hole at C may be $8\frac{1}{4}$ in. from B. This will give a quasi-equatorial movement to the telescope for London and places not very far north and south of the same latitude. The use of this contrivance is very simple. The bar BM is placed due north and south (M, of course, towards the south). A star is got into the field, and the chain C,C′ stretched tight and made fast. Then the observer will find that on rotating the telescope horizontally round A, the end O will be so shackled as to constrain it to follow the given object. A few miscellaneous hints may conclude what we have to say on the telescope itself. First, the reader may wish to test it for its freedom from colour and aberration. For the first, let him turn the instrument on to the round edge (or "limb") of the moon, and first move the eye-piece within the focus by means of the milled head F, then a purple fringe should appear on the lunar limb. On moving the eye-piece outside the focus, this should give place to a green ring. A telescope that exhibits this sequence of phenomena is achromatic. For spherical aberration, focus the telescope on a tolerably bright star, with the whole aperture, and then put a diaphram of, say, $1\frac{1}{2}$ in. aperture over the object glass,

Fig. 2.

Fig. 3.

and see if the star remains accurately in focus. If it does, spherical aberration is cured too. A bright star in focus with a power of 150 should present the appearance of Fig. 2, by no means that of Fig. 3, which latter indicates a practically worthless object-glass; nor should any light *haze* appear about bright stars or planets. Next week we hope to set the young observer fairly to work.

THE SO-CALLED TUNNEL-WORM.

IN *La Nature*, for December 10, M. Maxime Hélène remarked that exaggerated ideas are prevalent respecting the defective ventilation of the great tunnel of St. Gothard, and in particular that the supposed development of a special parasite, the tunnel-worm, must be regarded as problematic. To this Professor F. A. Forel replies that the malady is perfectly authentic, and is due to a parasitic worm, the Duodenal Anchylostoma (the stiff-jaws of the first intestine, one might say), which attacks the mucus membrane of the jejunum and duodenum (the first parts of the small intestines), and sucks the blood like a leech. He says that Dr. Ed. Bugnion, a professor at Lausanne, has recently published a remarkable investigation, in which he has discussed the question thoroughly. He has examined forty-one well authenticated cases among the workmen in the Gothard tunnel, attacked by chloron and anæmia (ghastly paleness and bloodlessness). The presence of the tunnel-worm was established in these cases either by post-mortem examination or from the recognition of the eggs in voided matter. As for the origin of the disease, it is not, as has been thought, a new one, or produced by either the high temperature and bad ventilation of the tunnels. The worm is very common in Egypt, where it causes Egyptian chlorosis, and in Italy. Its appearance in the St. Gothard tunnel is easily explained, when we consider, on the one hand, the habits of the thousands of workmen employed there (all Italians, crowded in the villages of Airolo and de Goeshenen), and the migrations of the intestinal worm. It passes, says M. Bugnion, the first part of its existence in the mud and slime of water pools*, and it is from drinking dirty water containing young larvæ of the parasite that the infection is received. Since the nature of the disease has been known, worm medicines have been used, and the doctors of the St. Gothard tunnel have lost no more of the patients attacked by the ailment, which had been called provisionally the St. Gothard anæmia, and which should hereafter be called, Professor Forel thinks, by the pleasing name "Anchylostomasia."

* *Le limon et la vase des flaques d'eau*, amusingly mistranslated by a daily contemporary: "the lemon and vase, part of water flasks."

SCIENTIFIC PARADOX.

TIME was when itinerant lecturers made a great point of what was then called the "hydrostatic paradox," by which the weight of a pint of water might be made to burst asunder the strongest cask; but although that age has passed, yet we are not without some paradoxes which yet remain in the ordinary treatment of physics.

That steam at 100°C. should heat a bath of Calcium Chloride up to 115°C., is paradoxical at first sight; but it is an established fact, and well understood by those who are familiar with the laws of specific heat.

That getting nearer to the sun as a source of heat should result in perpetual ice, is paradoxical at first sight; but it is a fact, and well understood by those who are familiar with the complex conditions.

The following case may or may not enter this category; but after much trial, I have failed to understand the conditions.

(a.) *One Gas does not behave as a Vacuum to another.*—If I understand the books rightly, there is no difference between the pressure of two separate pound weights in a pair of scales, and the pressure of two separate units of gas (be they similar or different) in an exhausted vessel. In both cases, each presses with its own individual pressure; and in every case, the *joint-pressure* upon the sides of a vessel will be exactly as the sum of the individual tensions.

Volatile substances have different maximum points of tension, beyond which they will not volatilise. A cubic inch of water at 100 C. will evaporate into an exhausted vessel of 1,700 cubic inches capacity, and produce a pressure on the sides of 760 millimètres of mercury (or one atmosphere); and if more water be added, it will not be evaporated; while, if the pressure be increased, water in proportion would be condensed.

Such points of maximum tension for water are at 100° = 760 mm.

,,	,,	,,	alcohol	,,	1,697 ,,
,,	,,	,,	ether	,,	1,953 ,,

(b) *One Gas does behave as a Vacuum to another.*—If I understand the books rightly, one cubic inch of water would evaporate into the aforesaid vessel, equally whether it be a vacuum, or filled with air, or any other gas; so that if the vessel were previously full of both alcohol and ether vapours, their joint pressures would be 6,650 millimètres; against which the cubic inch of water would evaporate; but more slowly as the pressure increased.

In the books these two aspects are confusedly mixed up together, and perhaps a novice has not been quite clear in separately and strongly stating the paradox.

It is rather curious that Clerk Maxwell, in his treatise on "Heat," while admitting that one gas may be a vacuum to another, yet says nothing in justification of the second aspect.

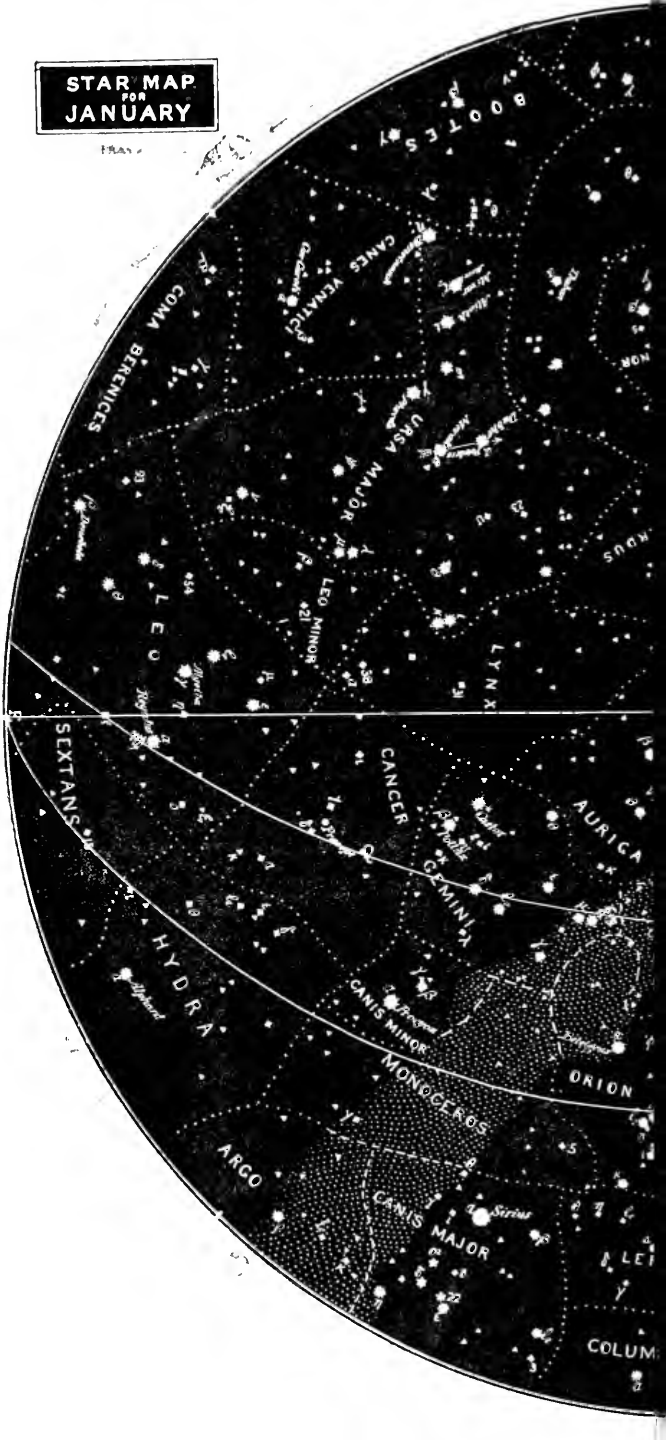
ECLECTICUS.

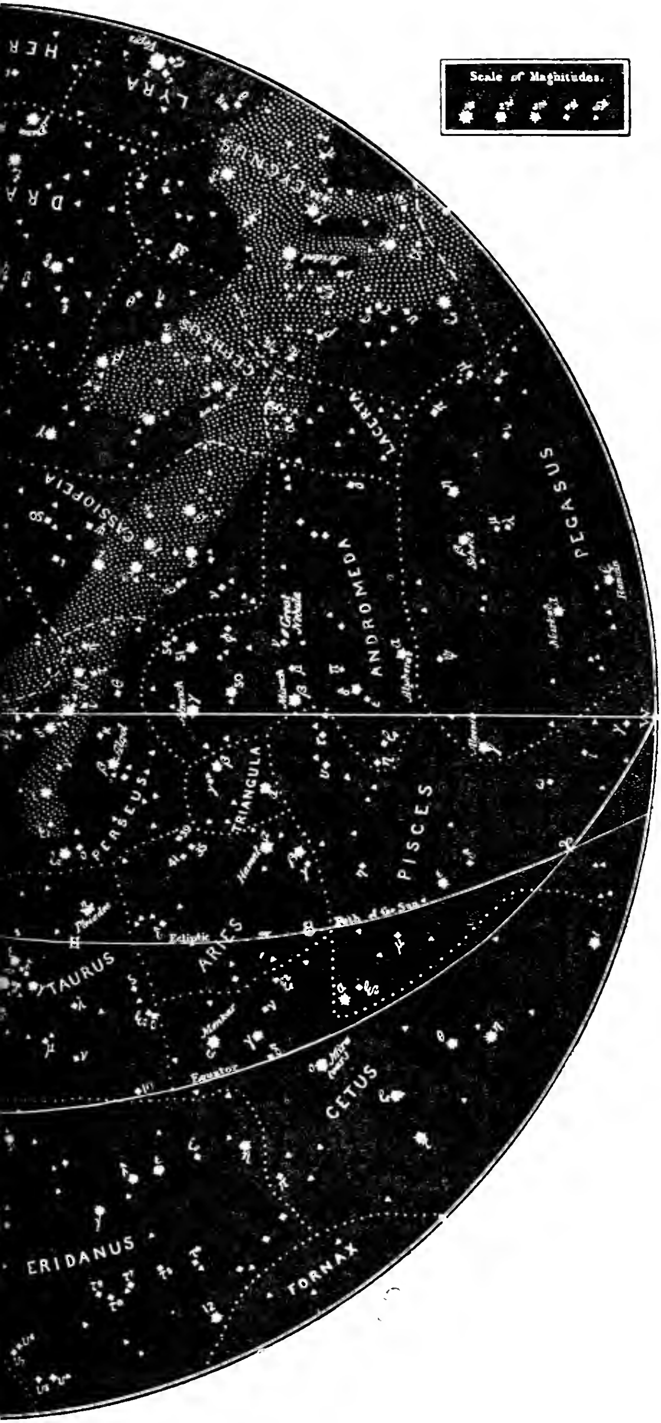
VITALITY OF TOADS.

THE following passage from an old number of the "Cosmos," may interest those who have taken part in the discussion about the vitality of toads. It is an account of various experiments on this subject, by M. Victor Legrips, of Chambon. M. Legrips put some toads in chambers hollowed in the earth to the depth of sixteen inches, placing them on a tile, and covering them with a pot. Others were immured between two discs of glass in plaster cells, without access of air; and some were imprisoned in masses of mixed plaster, which touched every part of them. The first were examined monthly, and exhibited no mark of decay till towards the twelfth month, their excretions being taken as nutriment. They lived thus, on an average, for twenty-three months. The second lot, examined through the glass, presented the following phenomena: Abundant excretions of the debris of insects and larvæ; torpor while in darkness; sparkling of the eye at approach of light; powerful efforts to escape; progressive emaciation, till death, which took place generally after fifty-six days. Among the third class some toads were living after twenty-eight months of absolute sepulture. These facts prove that the toad can live a long time without aliment or aëration; he lived longer in the chambers where his movements were unimpeded than in the cells where he could hardly change his position; but his life was very much longer when he was completely embedded in the plaster. Not being able to move, he lost nothing; and thus it will be easily comprehended that alimentation was much less necessary, and that his life, as if suspended, might continue for an indefinite period. M. Legrips states that toads are not only inoffensive, but exceedingly useful in gardens, and that he is not at all surprised at the increasing commerce in these animals, who live exclusively on worms, caterpillars, and insects, great and small, and are thus protectors of a host of useful and ornamental plants. Market gardeners will find them invaluable.

STAR MAP FOR JANUARY

On December 31, at 10.30 p.m.
On January 3, at 10.15 p.m.
On January 7, at 10 p.m.
On January 10, at 9.45 p.m.
On January 14, at 9.30 p.m.
On January 18, at 9.15 p.m.
On January 22, at 9 p.m.
On January 25, at 8.45 p.m.
On January 29, at 8.30 p.m.
On February 2, at 8.15 p.m.





OUR STAR MAP. — In response to the wishes of many correspondents, we show this week the star maps which would otherwise have been divided into four weekly maps, in a single star map. It will be understood that the circular boundry of this map represents the horizon. The map shows also the position of the equator, and of the ecliptic, with its signs. We propose next week to give the position of the Zodiac, now most favourably situated for observation, with the motions of the planets thereon.

Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

THE WEATHER FORECASTS.—PSYCHO.—TOADS STUNG BY INSECTS.—BOOKS ON HISTOLOGY AND THE UNDULATORY THEORY OF LIGHT.—TABLE OF LOGARITHMS.—DIAGRAMS WITHOUT DESCRIPTION.—PRONUNCIATION OF "BETELGEUX."—THE COAL AGE AND THE EARTH'S INTERNAL HEAT.—ANTIQUITY OF MAN.

[164]—The letter [121] of Mr. Spiller, on p. 140, is a very instructive one, and may well stimulate inquiry into the procedure of that rather remarkable department, the Meteorological Office. I, like Mr. Spiller, took considerable pains some time since to compare the daily vaticinations issued from Victoria-street, with the actual weather obtaining at the periods for which they were made, and with the following noteworthy result. At first I found that the predictions were very much more frequently wrong than right, and this suggested the idea that the officials were on the track of *some* law, but were merely misinterpreting it. Later on, however, I came to the conclusion, in common with your correspondent, "that they are about as often wrong as right." It is absolutely needless to point out to any one with the least smattering of mathematics, what this indicates. Put shortly, it is that equally valuable weather prophecies might be made by the simple process of tossing up a florin and calling "heads" fine and "tails" stormy. Now this suggests to me at once, as a scientific man and as a taxpayer, that the British public has a distinct right to know why it should be called upon to pay £14,500 annually for such results as these? Moreover, it is rumoured that the office is supervised by a certain "Meteorological Committee of the Royal Society," who divide £1,000 a year among themselves. One would be pleased to ascertain definitely what is actually done by these gentry for this modest little sum. The Meteorological Office exists for the benefit of the nation—not the nation for that of the Meteorological Office, and the sooner this is realized the better for all those concerned. It seems ridiculous that we should receive such accurate forecasts of gales gratis from a New York newspaper proprietor, and that we should be reading about the "calm," prophesied by our own paid servants, while those gales are howling around us. As a very humble effort towards the solution of this concluding part of Mr. Spiller's letter, I would venture to suggest *Payment by Results.*

May I say, in connection with the question put by W. H. B. (letter 126, p. 143), that three or four visits to Psycho sufficed to convince me that a small boy is concealed within the figure. Something I once observed through a powerful field-glass satisfied me of this.

Ornithorynchus (query 100, p. 145), is wrong in supposing that toads are not affected by the stings of the Hymenoptera. I have myself seen a toad stung by a wasp which it attempted to swallow, its tongue subsequently protruding from its mouth in the form of an inflated bladder, obviously causing it serious, if not very protracted, inconvenience.

If D'Artagnan (query 103, p. 145), does not mind reading a book thirty years old, he may derive an immense amount of information from Quekett's "Lectures on Histology." It was originally published by Baillière; but one of the second-hand scientific booksellers would be the likeliest place to procure it now. Dr. Lloyd's "Elementary Treatise on the Wave Theory of Light," published by Longman's, is excellent too, for the purpose for which he requires it.

To the list of books of Logarithms, given on p. 102, I should like to add Cape's "Mathematical Tables," published by Longman in 1860 (3rd edition), as the most convenient 6-figure set with which I am acquainted. The arrangement is excellent. In the trigonometrical tables the successive differences are given for 100″ instead of 60″, thus saving a quantity of calculation. I use these in my observatory, and Chambers' in my library.

May I venture to suggest that Mr. Thorp's drawings on p. 100, by themselves, are scarcely sufficiently explanatory of the instruments they represent? Notably Fig. 2, in the absence of verbal explanation, fails wholly to show how an ellipse can be described by the piece of apparatus delineated. It looks as though it must draw a circle—and nothing else.

In answer to query 107 (p. 167), astronomers, in practice, always pronounce the proper name of (a) Orionis "Bételjews."

"Ignoramus" (query 110, p. 167) should obtain and carefully read through that part of Page's "Advanced Text-book of Geology," which treats of the Coal Measures. It is not now supposed that the internal heat of the earth had anything to do with the production of the carboniferous flora; in fact, it is a grave question whether such flora was, in any legitimate sense, tropical at all. A humid and equable, rather than a tropical climate, would seem to favour the type of vegetation of which our coal measures are composed. The earth's superficial temperature is quite unappreciably afforded by her internal heat (Feurier says $\frac{1}{17}$th of a degree), such surface temperature being practically wholly derived from the sun. This influence extends to a depth varying from 60 to 90 feet. Downwards from this stratum temperature rises 1 degree for every 60 to 65 feet; so that at a relatively short distance from the earth's surface, it would seem that the most infusible rocks must be molten. Possibly, the sun may one day cool down, and the earth with it, but it will not be in "Ignoramus's" time, or mine either.

Any one reading the isolated words quoted in inverted commas from Sir Charles Lyell in reply 84 (p. 168), will imagine that he did not believe in the great antiquity of the objects discovered by Mr. Horner in Egypt. Those who have been misled into this belief had better read Chapter III. of Sir Charles's own "Antiquity of Man," as recommended by "Kemp" in the preceding answer.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

A CORRECTION: DATE OF MENES.

[165]—I perceive that "A Member of the Society of Biblical Archæology" quotes Mr. Stuart Poole as an authority for the date B.C. 2717 for the period of Menes. Permit me to say that Mr. Stuart Poole has long since abandoned that position in favour of a much more remote epoch, as may be seen by reference to his articles in *The Contemporary Review* for 1879.

ANOTHER MEMBER OF THE SOCIETY OF BIBLICAL ARCHÆOLOGY.

PERSONAL IDENTITY *versus* TATTOO MARKS.

[166]—Am I right in understanding that, owing to the Physiological waste and decay, our bodies virtually change in every part, so that our bodies to-day are not the same bodies seven years hence? If so, may I ask the following:—When a boy, I tattooed my arm with Indian ink; my body must have changed four times during that time; the design is as distinct and permanent to-day as ever. Will some of your correspondents kindly enlighten me upon this subject?—Yours, &c. WALTER H. MAGUIRE.

Dec. 5, 1881.

P.S.—I wish your valuable journal every success.

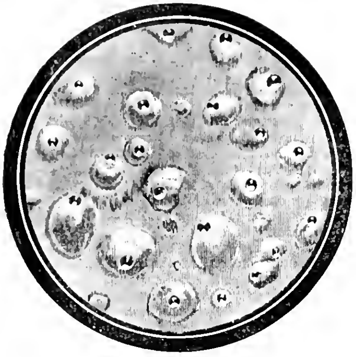
THAWING ICE.

[167]—In a book which I have—a translation from the French of Professor A. Cazin—the following experiment is described:—

"Take a piece of clear ice and place it so that a pencil of sunlight, condensed by a lens, shall enter it parallel to the planes of congelation; then with a microscope, placed at right angles to plane of congelation, examine the illuminated part, in which many luminous specks will appear, gradually increase in size, and send out little branches, generally six in number and of varying forms, &c."

I have tried this interesting experiment with several pieces of ice, but failed to see any traces of these beautiful little branchlets. What I saw was the specks of light rapidly increasing in size, and

of a more or less nearly-circular form. Each of these cavities contained water and a bubble (of attenuated steam, I suppose); some of these bubbles remained in the centre of their cells, but others soon (especially if the sun was hot) began to move round their cells, sometimes in jerks, at others smoothly, occasionally oscillating. I should be glad to know why I was unable to see the branchlets, and should be greatly obliged to any reader who would explain the cause of the little bubble's curious movements.



Enclosed is a drawing which will give a good idea of what I observed. The larger discs represent the cavities containing liquid, while the small circular black and white spots are the bubbles. E. C. R.

DIFFICULTY OF OBTAINING "KNOWLEDGE."

[168]—Having experienced the same difficulty as mentioned by your correspondent in No. 7, I would recommend your would-be readers to order KNOWLEDGE of their newsagent, instead of the bookseller, who, for some reason best known to himself, professes ignorance of the publication.—I am, Sir, yours faithfully,

A. GAUBERT.

[We have received several letters to the above effect.—ED.]

[169]—In reference to Letter No. 134, page 144, the fact that I have generally obtained KNOWLEDGE from my bookseller in North Shields before 9 a.m. on Friday mornings may convince Mr. Armstrong that either his booksellers or their London agents are alone to blame.—Yours, &c., GEORDIE.

"OUR UNBIDDEN GUESTS."

[170]—Surely "the great lesson to be learned" from Dr. Andrew Wilson's frightful disclosures in the last number of KNOWLEDGE, respecting tapeworm and trichinæ, is one quite different from that proposed by him, and not "thorough cooking," but total avoidance of the substances liable to be infested, is the true and sensible remedy. From the "Perfect Way in Diet," recently favourably noticed by you, it would appear that man is, by his constitution and structure, not carnivorous at all, but becomes so only through degeneration of habit. From this it ought to follow that man can attain to the perfection of his nature only by subsisting on the substances indicated by his structure. My own experience favours this conclusion. Having abstained from flesh-food for some seven years, I find the results—physical, intellectual, and other—such as to make me regret that I was not a follower of the "Perfect Way" from the first, and my experience is by no means a singular one within my own circle of acquaintance.—Yours, &c., E. M.

THE POLE STAR AND PRECESSION.

[171]—In your promised paper on the Precession of the Equinoxes, can you give us a star-map, showing the circle described by the North Pole, and therefore all the stars which have been successively Pole-stars? One meets with the statement that about 4,000 years ago *α Draconis* was the Pole-star; but no full information is given in popular books. With such a star-map as I suggest, we could find for ourselves the Pole-star for any period of the past. —Yours, &c., GEORGE ST. CLAIR.

[Will supply such a map the week after next.—ED.]

A NEW COMPARISON OF POISONS.

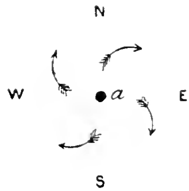
[172]—Notwithstanding your approval of "Technical Chemist" (Letter 102, p. 116), I venture to think he is not quite right. The allegation is that li. ce. is three times as poisonous as ba. ce.; and, while admitting that ba. ce. is poisonous, it is urged that li. ce. is often prescribed in comparatively large quantities for gout. Now, why mystify M. Richet's plain proposition? Li. ce. has 20 per cent. of metal, where the citrate has probably much less than 7 per cent.; besides, iron and mercury may be very poisonous in one form of combination, and very innocuous in another. S. E. P.

SOUND.

[173]—"C. T. B." (query 60, p. 125) may be right in saying "the lighter the weight, the better does a body transmit sound"; but only in conjunction with a mysterious function of elasticity, which figures so largely in scholastic formulæ and ideas. We know that air transmits sound in round numbers, about 1,000 ft. per second; water 4,000 ft.; and some dense woods and metals, 10,000 to 15,000 ft. per second. A great chemist on the Continent is holding up to ridicule a kind of weekly anthology of modern chemical utterances; with some such feeling I would try to fairly paraphrase the sound contentions of "T. J. H." (query 14, p. 123). The condensation augments the elasticity by the heat generated in the condensation of particles. The rarefaction augments the elasticity by the cold generated, and also by the separation of particles. The heat generated remains there to increase the velocity. It is because the heat generated in the condensation augments the rapidity of the condensation, and the cold developed, augments the rapidity of the rarefaction, that the heat and cold both help to augment the velocity of the sound wave. ECLECTICUS.

THE MAGNETIC NEEDLE.

[174]—There is no attraction of the kind "W. H. P." (query 90, p. 123) seems to suppose. The affection is one rather of polarity or deflection. Let "W. H. P." imagine a globe with convolutions of wire conveying electricity round the equator, representing *actual* earth currents, then he will find that particles of air or iron will have a binary polarity induced in them, at right angles to the direction of current. There will be a field of magnetism where the lines of force point N. and S., or to the two poles; but there is no tendency to movement or change of position of the polarized medium.



In order to remove any ambiguity about these poles, it may be well to explain that this same field of force subsists all round any wire conveying a current. Here, then, we have a circular field of force with no poles. Let (*a*) be a section of the wire carrying a current downwards or from the point of view; then small unmagnetized needles (with no directivity) would have polarity induced in them such as to point east, west, north, or south, as per diagram. If the current flow upwards, these polarities would be reversed.

In very many cases, arrows indicate motion or a tendency to motion. In this case, they only convey the idea of polarity in the media, where iron is immensely more sensitive or conductive than air. ECLECTICUS.

BUTTERCUPS—BEES AS FLOWER FERTILISERS.

[175]—In answer to "West Riding," I should like to remark that where grasses, daisies, and docks predominate, I have never observed that the vegetation was "thick and matted;" I was alluding rather to tangled hedgerows and overgrown spaces. "West Riding" can hardly expect me to explain the whole philosophy of leaves, among other things, in a single short article. Oddly enough, my intention, before seeing his letter, was to write a paper for KNOWLEDGE on the foliage of daisies and plantains, and, with the Editor's kind permission—[Gladly accorded.—ED.]—I will now do so shortly. The subject is one which I have long been observing.

Mr. Donbavand is mistaken in supposing that bees never visit

buttercups. Whether the hive-bee in particular does so, I cannot say with certainty; but I am sure that the common bumble-bee is often found among the flowers. Of course, other insects also aid in fertilising them.

GRANT ALLEN.

NUMERICAL COINCIDENCES.

[176]—This numerical disease is not confined to the Pyramids and astronomy.

M. Berger, referring to the failure of Prout's theory, that all the atoms might be multiples of the unit hydrogen, finds out that by dividing the chief elements into five groups, then all are multiples, or submultiples of five specified values, which are notated H, D^1, D^2, D^3, and D^4. He attaches much value to this classification, but admits that "these five divisors have no value or relation among themselves."

A professor of Harvard College, America, professes to see farther into a brick wall than M. Berger, under the attractive title, of "Atomic Phyllotaxy," to wit :—

Berger.				Phyllotactic.		
H	=	·9997	=	1-16th of O	=	·998
D^1	=	·769	=	5-13th of D^2	=	·768
D^2	=	1·995	=	1-8th of O	=	1·996
D^3	=	1·559	=	$(\frac{1}{2} \times \frac{5}{8})^2$ of O	=	1·559
D^4	=	1·215	=	5-8ths of D^2	=	1·247

ECLECTICUS.

THE SUN'S CONSTITUTION, AND ORIGIN OF SUN-SPOTS.

[177]—I have noticed that in many modern text-books of astronomy (especially those published since 1870), doubts are expressed as to the truth of Herschel's theory of the sun's constitution (to which for so many years astronomers had inclined) viz., the theory of a *comparatively* cool nucleus, enclosed in two concentric shells of matter, analagous to our clouds, of which the outer forms the visible surface of the sun. In your "Poetry of Astronomy" you say, "We know the sun to be infinitely more complex in structure . . . . than it was formerly supposed to be. . . . . We have learned that . . . . the glowing veil of air hides by day . . . . the largest (though not the most massive) part of that sun. . . . ." Would you give us a paper in KNOWLEDGE on this most interesting of astronomical subjects, as in your books you do not explain what you intend to convey by the above? I presume you speak of the sun's chrom[at]osphere, corona, and the atmosphere discovered by Professor Young. I should be much obliged if you would insert my letter, as I should much like to see correspondence on this most interesting subject. Discussions on it would be far more interesting than those on Anti-Guèbre's absurd theory. Hoping for the favour of insertion,—Believe me, yours, &c.,

VIGNOLES.

[We shall be only too glad. Our fear is lest readers should think we give too much space to our own subjects.—ED.]

SINGULAR PROPERTY OF NUMBER 4.

[178]—The following is a solution of this interesting property of numbers for the number 19.

$$\underline{|4} - \left(4 + \frac{4}{4}\right) = 19$$

H. SNELL.

[Functional 4, or the products of the numbers 1, 2, 3, 4, can hardly be regarded as a fraction of 4 in the sense required for the solution of this little problem. Neither can ·4, or 4 divided by 10.—ED.]

SMALL TELESCOPES.

[179]—As I am about to purchase a telescope for astronomical purposes, I am at a loss whether to invest in a refracting or a reflecting telescope. The work I want it for is the course specified in Webb's "Celestial Objects," at least as far as an ordinary $3\frac{1}{4}$ in. refractor, with powers of 70 to 200, would suffice; but I do not know whether to purchase a refractor of this aperture, or a reflector with corresponding powers. I am not prepared to invest beyond £15 for the instrument, and should feel extremely obliged if you could advise me as to what to buy. By so doing you would infinitely oblige, yours truly,

W. RIDD.

VERMIN.

[180]—I should be glad if you would insert an article in your valuable paper upon the uses of those apparently useless insects, bugs, fleas, flies, roaches, &c., or if you could name a good book upon the subject.

Hoping that your paper will have the utmost success.—Yours,

AN AMATEUR.

[We hope our readers will not say, with Mr. Pecksniff :—"Oh, vermin! Oh, bloodsuckers! Begone! abscond!" —ED.]

MALE AND FEMALE HEADS.

[181]—It appears to me that in the correspondence on this subject, too little prominence is given to the effect of long-continued training in the development of the male head and its faculties, while, in estimating female powers, few writers or speakers care to remember that, till within the last few years, a liberal education was beyond the reach of average women. Among the uneducated classes, is it not frequently the woman who is the manager, the shrewd head of the household? It would be fairer to measure relative power where both sexes are comparatively untaught, rather than in the classes where the men have for generations had the benefit of schools and colleges, while their sisters were indulging in "vapours" and "sensibility." Of course, there are plenty of fashionable fools still (whose waists are as small as their sense), but it would be rude to suggest that they might easily find their parallels among the loungers in St. James's-street, especially during the Derby week. I heard lately of a singular case of growth of the head of a student who has begun his work somewhat late; and, *pace* the artists, I hope that in a few generations our women's brains may show the result of broad education. If it is true that sons take after their mothers, the future Englishmen should not be the worse for increased intelligence and culture among those who make their homes.

M. McC.

PHRENOLOGY AND THE BRAIN.

[182]—I was very much pleased with your remarks on phrenology in "Answers to Correspondents" the other week, and must certainly concur with them. I think that the whole drift of modern physiological experiments tends to a disproval of the conclusions of phrenology. Dr. Ferrier's experiments, for instance, have shown that the individual convolutions of the brain are separate and distinct centres, and that "in certain definite groups of convolutions, and in corresponding regions of non-convoluted brains, are localised the centres for the various movements of the eyelids, the face, the mouth and tongue, the ear, the neck, the hand, foot, and tail." We have thus certain definite areas of the brain superintending various motions of the body, but we can find no trace of the numerous "esses" with which the phrenological vocabulary abounds. Certain lesions, moreover, prevent the voluntary movement of special groups of muscles.

J. H. H.

DARWINISM.—THE DESCENT OF MAN.

[183]—The Darwinian theory of the origin of man, of all forms of vertebrate life—that is, of all animals having a backbone and internal skeleton—is not, apparently from communications to KNOWLEDGE, so generally accepted as I supposed. There can be, then, no singularity in the apparition of another doubter.

"Vestiges of Creation" initiated the great public in the doctrines of the evolutionists. The work is a reputed hash of matter and ideas from German and French sources. The work had a great run, lived its day, died, and left no permanent impression. Mr. Darwin's unique works have influenced the entire civilised world. His profound investigations and remarkable method of developing his labours to the public gave Mr. Darwin, almost at a bound, a scientific and literary position such as few other men hold. But, with all this, I cannot reconcile myself to his theories, nor to the theories on which they are based.

I am neither biologist, nor ethnologist, nor anthropologist; I am simply one of the common herd of readers, with the difference, perhaps, that occasionally I venture on the more difficult labour of thinking. I may not have, but I presume I have, discernment enough to follow the lines of Darwin, and his co-labourers, so far as the steps of what, to me, is doubtfully the propylæum of the impenetralium that conceals the secrets of the Almighty Intellect we name Nature, and adore as Jehovah, Lord, and God.

"Vestiges" excited theologians, but the "Decent of Man" provoked them to rancour. The forcibly disagreeable, which the "Descent" is to very many, bites into the mind; the feeble slides over it. But the idiocrasy of the caste, the fenced lines of thought they habitually move in, blinded them to the actuality. They beat, and continue to beat themselves against a gross misapprehension of their own. Mr. Darwin presented his thesis as an argument to a probable conclusion; not as demonstrative of the absolutely certain. He has not arrived at a perfect induction, and makes no pretension to it, that I perceive.

Darwinism is based on the labours of the German transcendental anatomists, and on later theories by Étienne Geoffroy. Mr. Darwin elaborated on their principles by an *organon* of his own.

Geoffroy's epigrammatic enunciation, "There is but one animal, not many," involves the whole case of the evolutionists. The plain meaning of this dictum is, that all animals of the vertebrate class are formed on one plan; that all animals are a primogenial animal, repeated through time, in modified plan.

Goethe's theory is apparently identical with Geoffroy's; but the revelation of the German comes to us a great thought, in chaste grandeur of expression." "Comparative anatomy," he writes, "has united all organic nature under one idea; it leads us from form to forms, and while we contemplate near or far-removed natures, we rise above them all, to see their individualities in one ideal type." The entire literature of biology can show no equal to this unfolding of the transcendental idea of evolution.

This is Darwinism, in my conception of it. The "ism," then, rests on the assumption that all animals are descendants from one common ancestor.

Linked with this fundamental, there are four propositions we may expect without endangering any agreement to negative the fundamental. Indeed, save to present the case of the evolutionists in completeness, they need not have been brought in here. They are.—1. That no two animals are completely identical. 2. That offspring tend to inherit peculiarities of parents. 3. That of animals brought into existence, but a small number attain maturity. 4. That those which are best adapted to the circumstances in which they are placed, are most likely to leave descendants.

Wallace, who worked on lines conterminous with Darwin's, without being conscious of the fact, put this matter in a much better manner. He postulates: 1. Peculiarities of every kind are more or less hereditary. 2. The offspring of every animal vary more or less in all parts of their organisation. 3. The universe in which these animals live is not absolutely invariable. 4. The animals in any country (those, at least, which are not dying out) must at each successive period be brought into harmony with the surrounding conditions. "These," he affirms, "are all the elements required for change of form and structure in animals, keeping exact pace with changes of whatever nature in the surrounding universe. Such changes must be slow, for the changes in the universe are very slow."

I have, I believe, now put before you, briefly but accurately, the basis and principles of the evolutionists—of Darwinism, so called.

The first, I might say the only, difficulty of the theory is the foundation. That all animals are the issue of one common parent, and are but varied plans of that parent, brought about by time and change of telluric and climatic conditions, is a postulate that has no support in tangible fact, or appearance of fact, may be as safely affirmed as we may affirm that it is the expression of a phantasy of brains driven to overreach their powers.

What was the first-born animal, the common parent of all animals? How did it come to be, and in what form did it appear?

There is no answer to these two questions: to neither of them.

If we could rid ourselves of Pasteur's disproof of spontaneous generation, we might imagine a segregation of atoms that should acquire life, and develop into a caterpillar-like creature, which would pass through several transformations, embryonic, we may say, after the manner of butterfly development, ending in an animal of some kind, even man—the requisites, heat and food, being present. Very big things are produced from very small germs. Admit a beginning of this kind, we admit probability of innumerable various organs, and so account for every distinct animal in creation; for the endless kinds of insects, and the living myriads of the sea. In reality, the admission would put us in accord with the prodigious fecundity of Nature.

Then, how shall we account for the many kinds of vegetable forms? the ash, the oak, the beech, the elm, the pine, the birch? Are they evolutions from each other, or from imaginary trees of a long past epoch of earth-history?

But my main object is man. How came he? whence? and in what shape? Settle that, and all is settled. Darwinism tells us he is a lower animal, moulded by time and environments into his present form. The popular chant, "The long-tailed ape was the primal shape that led up to Adam and Eve," is not exactly an expression of Mr. Darwin's notion, though it is of Monboddo's. But Mr. Darwin might just as well have assigned us to an ape origin, as to a featureless thing of his own prolific imagination.

The origin of man has not been reasoned to. We cannot go back to it, fact by fact, for the needed facts are not. From first to last, we run through conjectures, and arrive at nothing but a final conjecture, worth no more than the conjectures that preceded it.

Whether the Caucasian man and the negro man have the same origin, is a problem standing from the general question for separate solution. Following the germ theory I have hinted at, would the germ from which the Caucasian would issue be one and the same, chemically, with that from which the negro would issue? But hinging on this is another question, Did the men appear contemporaneously?

Here, however, I must stop without completing my design. I have, I fear, already overrun the space I should have confined myself to.—Yours faithfully, B. Donbavand.

Picton, Chester.

Queries.

[113]—Gravity.—Does the orthodox definition of mass in terms of gravity $gM = W$ mean that it requires $\frac{1}{32}$ part of the weight of a body to overcome its inertia?—Zares. [It is a numerical statement, not a definition.—Ed.]

[114]—Mass.—If a weight, say one ton, be suspended by a perfectly flexible line of infinite length, what force in pounds would overcome the inertia of the mass in a direction at right angles to the direction of gravity?—Zares. [Any force, however small.—Ed.]

[115]—Inertia.—How is it that when I make 10,000 gallons of water pass over a perforated plate per minute, in a level position, there is a loss of 20 gallons per minute, but when the velocity of the water is reduced so that only 5,000 gallons per minute pass over, that then there is a loss of 250 gallons per minute through the perforations?—N.B.—50 per cent. of the plate has been punched.—Zares.

[116]—Chemical.—(1.) Why is the nitrogen contained in admixture with the oxygen in atmospheric air not absorbed by the lungs, as is the oxygen? (2.) If—as stated by Dr. Pavy and others—the value of hydrates of carbon as food is to be estimated *only* by the amount of unoxidised material they contain, what is the part played in the living body by the portion of the food already oxidised? Starch and sugar, *e.g.*, contain about 49 per cent. of carbon and hydrogen, and 51 per cent. of oxygen; so that but a very small amount of carbon remains unoxidised and available for combustion in the organism. What becomes of the bulk of such food?—E. M.

[147]—B. Sc. Examination, Edinburgh University.—I am desirous of obtaining information regarding the degree of B. Sc. at the Edinburgh University Examination. Would any of our correspondents kindly inform me through the medium of Knowledge what the subjects of examination are, and if it would be possible to pass without attending the University? If not, how long would I possibly have to attend, and what would be the probable costs for fees, books, &c.? I have attended evening classes in connection with the "Science and Art Department," and have passed first class in the elementary and advanced stages of chemistry (theoretical and practical), electricity, and acoustics, light and heat. Would the passing of these examinations be of any assistance? I have also an elementary knowledge of geology, botany, zoology, theoretical mechanics, and mathematics. An answer to the above will greatly oblige—A Philosophical Brushmaker.

[148]—Brewing.—(1). Having been in the habit of separating dextrose from cane-sugar by dissolving out the former in common alcohol, and having read in Prof. Graham's "Chemistry of Bread-making," that dextrose is *less* soluble in alcohol than cane-sugar, I am anxious to ascertain which sugar is the more soluble in the said reagent. (2.) Does basic acetate of lead precipitate dextrin? All text-books I have read state so, and yet I cannot obtain a precipitate on adding small or large quantities of the said salt of lead to either dilute or concentrated solutions of dextrin.—E. M. D.

[149]—Diameter of Sun.—As we cannot see the half of a globe whose diameter is greater than the width of our eyes how much larger is the real diameter of the sun than the diameter we see? As I have not seen this taken into account in any book I have read, an answer would oblige, yours truly. A. B. J. [The ratio of real diameter to apparent is that of tangent to sine of apparent angular radius, or, say, of 16 minutes. The logarithm of this ratio is 0·0000047, the number corresponding to which is about 1·000001; so that the sun's real exceeds his apparent diameter by about one-millionth part, or rather less than a mile.—Ed.]

[150]—Alpha Cassiopeia.—Can you tell me what is the magnitude of the companion of Alpha Cassiopeia?—Harris. [Estimated as about eleventh magnitude—bluish in colour.—Ed.]

[151]—Jordan Barometer.—What is the density of the glycerine in this, as used in the *Times* office? I make it 1·262 by calculation. Is this pure glycerine?—C. T. B.

[152]—Nickel-plating.—How is this done on iron without a battery?—C. T. B.

[153]—Cessation of the Sun's Heat.—It was stated by Sir J. Lubbock, at the last British Association meeting, that, after the lapse of seventeen million years, the sun would be cooled down to such an extent as to cease to emit light and heat. Will you kindly inform me on what grounds this is ascertained, and, if true, what must be the ultimate condition of the solar system, especially that of our own globe?—A. von Roulte.

[153]—Doubtful Organisms.—Kindly give me the names of those organisms, the nature of which, whether plant or animal, is doubtful.—H. J. C. W.—[Are any organisms doubtful, according to the modern definitions of plants and animals?—Ed.]

[154]—FROGS. Why are frogs excluded from the class Reptilia? —H. J. C. W.—[We always supposed that the class Reptilia included the Amphilia, and that frogs were classed as Batrachian Amphibia.—ED.]

[155]—TORTOISES.—What is the average duration of life of the tortoise, and how long can they remain under the earth?—H. J. C. W.

[156]—WORMS.—How is it that when a worm is severed in two, its parts still show signs of activity?—H. J. C. W.—[If you consider the nature of the nervous system in worms (and all articulated animals) that a double chain of ganglia, one may almost say of brains, runs along the body, you will see that the phenomenon is natural enough.—ED.]

[157]—ALUMINIUM.—The characteristic ingredient of common clay—what is the present process of obtaining this metal, or is there a treatise published on its extraction? Will any one of the metallurgists of KNOWLEDGE kindly furnish the information to one who believes that (by a new process) the price of aluminum might be reduced to that of copper?—LUNA.

[158]—A 1 lb. weight is carried to the top of a tower. Would this, if allowed to fail, raise another 1 lb. from the ground? They are connected by a thread passing over a pulley. Neglect, of course, the weight of thread, and assume it to be perfectly flexible and to move without friction.—H. ROLFE.—["H. Rolfe" should read a description of Atwood's machine. The weights would not move unless some impulse were communicated to one or other. Such an impulse downwards on the upper weight would cause uniform motion of both weights, until the one which had been uppermost reached the ground.—ED.]

[160]—BOTANY.—Can any one tell me who was the author of "The British Garden," a descriptive catalogue of hardy plants, indigenous or cultivated, in Great Britain, with Latin and English names? Two vols., published by S. Hazard, of Bath. 1799.—EUPTERIS.

[161]—HEAT FROM THE STARS.—Does the earth receive an appreciable, or any amount of heat from the stars?—STUDENT. [From measurements of the heat of a few bright stars and comparison with heat received trom sun, as also of light of star with light from sun, the inference seems sound that the total heat received from stars, bears to solar heat something like the same proportion that the light received from all the stars bears to the sun's light.—ED.]

Replies to Queries.

[79]—MENTAL PHYSIOLOGY.—As "S. S. S. S." seems anxious to test the accuracy of my information concerning Mr. Cyples's book, I can only tell him how it came under my notice, which was by press reviews, particularly one from Prof. Croom Robertson's organ, *Mind*, which carried conviction to my mind that a very unique and able work on the subject was referred to. I at once obtained it, and (as stated before) on the *mental* side, and as being exactly in keeping with its title, have never had any regret in so having purchased it. It would be out of place here to say further. If he went to Strahan's and asked to see the book, he might get a little idea thus of its character, &c.—S.

[125].—It *is* possible to prepare indigo on the large scale, but, unfortunately, *not* profitably. The well-known German chemical factory at Baden succeeded in producing artificial indigo, which made its appearance in the market as a commercial article, but it was announced in the newspapers a week or two ago that operations have been discontinued, as at present it cannot be made to pay.—H. GRIMSHAW.

[136]—SUNLIGHT ON FIRE.—The draught of a fire depends in great measure on difference of temperature between air in chimney and air in room. Sunlight, by heating the air round a fire, tends to create a draught in wrong direction. A smoker's draught, being created by the lungs, does not seem a parallel case.—C. T. B.

[71]—NAMES OF FLOWERS.—Hayward's "Botanist's Pocket-Book," 4s. 6d. (Bell & Sons), gives both scientific and common names, with concise characteristics. Dr. Hooker's "Student's Flora," 10s. 6d. (Macmillan), though giving fuller particulars than any other handbook, contains comparatively few common names. Bentham's "British Flora," 12s. (Reeve & Co.), contains many common names and a complete "English scientific nomenclature," also outlines of botany, &c.; but it includes fewer species and varieties than either Hayward's or Hooker's.—EUPTERIS.

[80]—THE CHIN.—"Ethnologist's" observations are not in accordance with the remarks of Lavater, who says that "flatness of chin bespeaks the cold and dry; smallness, fear; and roundness, with a dimple, benevolence." Elsewhere, he adds.—"A long, broad, thick chin—I speak of the bony chin—is only found in rude, harsh, proud, and violent persons.—EUPTERIS.

[90]—THE MAGNETIC NEEDLE.—I believe it is considered that a current of electricity is constantly passing round the earth from east to west, causing the magnetic needle to point north and south. Similarly, a wire from a battery, passing over or under the needle, will make it stand at right angles to the current.—EUPTERIS.

[105]—"J. S." can obtain all the information he requires from Mr. James English, naturalist, of Epping village, who is to be congratulated as the discoverer of a very ingenious, and, I believe, the only sure process of preserving fungi and lichens, and not only these, for in his hands even flowers of the most delicate structure and hue retain all the grace of form and richness of colour provided by nature. Having myself seen many remarkably perfect and beautiful examples of Mr. English's work on both fungi and flowers, I can recommend (as it gives me much pleasure to do) your correspondent and others interested in this really valuable discovery to communicate with him. In consequence of the great success of the method, and the large demand following upon it, I understand Mr. English is engaged upon publishing it in full—a generous act for the benefit of the world at large—and the subscription-list is open to any wishing to obtain a copy of his book. It only remains for me to add that, personally, I am entirely disinterested in the production, and offer this information as well for the profit of those botanists who are as yet unacquainted with this somewhat obscure but worthy worker, as for his own reward, and knowing that every nature-loving student will be glad to learn that the longed-for end has at last been secured, and that he can, without difficulty or expense, avail himself of its accomplishment. It may also be here recorded that it was the same industrious and deserving naturalist to whom we are indebted for introducing the largely-adopted practice of "sugaring" for moths.—W. W., Highbury.

[105]—FUNGI AND LICHENS.—In answer to "J. S.," in last Friday's KNOWLEDGE, Mr. D. Bogue, publisher, 3, St. Martin's-place, Trafalgar-square, publishes a book on British Fungi, by M. C. Cook, M.A., LL.D., which is, I believe, generally considered to be an excellent work.

[108]—THE EYE AS ONE OF THE SENSES.—In answer to "T. T." (query No. 128), the same publisher advertises a little book by Dr. Dudgeon, entitled, "The Human Eye: its Optical Construction popularly explained." Price 3s. 6d.—R. T.

[110]—THE COAL AGE AND THE EARTH'S INTERNAL HEAT.—The fact that in the lower levels of the silver mines on the "Cornstock" lode in Nevada (say 1,600 feet from the croppings), the men can only work fifteen-minute shifts, owing to the heat, may throw some light on this subject.—E. F. B. HARSTON.

[110]—THE COAL AGE AND THE EARTH'S INTERNAL HEAT.—The theory that the earth was once in a state of fusion, has many sound arguments in its favour, one being that the oblate-spheroidal shape of the earth was produced by the exertion of the centrifugal force on the molten mass of the earth, like a similar shape would be produced if a mop were whirled rapidly round in the hand. We have the evidence of geysers and hot springs, and, to some extent, of volcanos and earthquakes, that some of the original fire in the earth's internal regions still exists. The increase of temperature as we descend into the earth is 1° F., for every 50 or 60 ft. The gigantic flora of the coal period was perhaps as dependent on the internal as on the external heat which was exerted on it; that is, supposing, as most likely was the case, that the regions of fire in the earth were, in those remote ages of time, much greater than now,—each age witnessing a decreased space of internal heat compared with the preceding.—HERBERT R. WELLER.—[The answer is rather crude, but some of the relations indicated are worth studying.—ED.]

[131]—CREATION.—Read also Lyell's "Antiquity of Man" and Lubbock's "Pre-historic Times."—PAUGUL.

[133].—THE *Wesleyan Methodist Magazine* for science article every month, *Good Words*, of coming year, for articles on "Science and Religion"; also "Proceedings of the Royal Society," for a year or so ago, contain—or will contain—articles by the Rev. W. H. Dallinger. None of Mr. Dallinger's lectures have been published, I believe.—PAUGUL.

[134]—CHEAP TELESCOPE.—Complete instructions to make a telescope would, I fear, be too voluminous for this journal, requiring, as it would, a page or two; but if the querist will write to me I will give him the information he wishes for.—PAUGUL.

[136]—SUNLIGHT ON FIRES.—It is useless to quote housemaids about such things. It is absurd to suppose that sunlight prevents a fire or a cigar from burning. The fire will appear to be out when a bright light shines on it, and you *let* it go out when the sun shines, because it is warmer then than at other times. The fire in my study is in sunlight every day (if the sun appears), and sunlight has never yet put it out. I can also testify that in India the sun never puts out either fire or cigar.—PAUGUL.

[141] TIME OF GLACIAL EPOCH. This querist need not trouble himself about any other theories than Croll's. There are others, however, and if he is ambitious of wasting some valuable time he may read Col. Drayson's "Last Glacial Epoch." PATGUL.

NAMES OF STARS. In reference to letter 127, page 143, there is no work in English on the names of the stars. There is one in German, by a writer named Ideler, and is called "Ueber den Ursprung und die Bedeutung der Sternnamen" "On the Origin and Signification of Starnames." It is a pity that there is no translation of this work into English. Of the great interest scientific, archæological, and poetic, attaching to the names of stars, there surely can be no question.—ZETA.

WEATHER GUIDE. (Page 128). Allow me to mention that Messrs. Routledge publish just such a guide, entitled "A Manual of Weathercasts," 1s. EUPTERIS.

Answers to Correspondents.

**** All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of* KNOWLEDGE, *the increasing circulation of which compels us to go to press early in the week.*

HINTS TO CORRESPONDENTS. 1. *No questions asking for scientific information can be answered through the post.* 2. *Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries.* 3. *No queries or replies savouring of the nature of advertisements can be inserted.* 4. *Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge.* 5. *Correspondents should write on one side only of the paper, and put drawings on a separate leaf.* 6. *Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

KAY. Your suggestion, that ladies should meet for discussion of matters scientific, educational, phrenological, and physiological, instead of tea and small talk, is no doubt excellent; but our space is too crowded for the insertion of your remarks in full.—ZARES. We agree with you that all paradoxes should not be omitted from a paper like the present. We propose to act in accordance with that view.—T. PRESTON BATTERSBYE. From some of my published essays, you will see I take great interest in the phenomena of mesmerism: I would like much to see your papers.—W. A. C. What we said about vivisection was very moderate. We, of course, have nothing to say to the change of law, which you suggest as logical. If you had ever known the torture of one dear to you alleviated through knowledge acquired from such experiments as you denounce, you would possibly see that the question has two sides to it. ONE INTERESTED IN SCIENCE. Heat waves and light waves are of the same nature, and both travel through the ether. Many light waves are heat waves, and *vice versâ*. Your second question belongs to a region outside of knowledge. The gratings referred to by Prof. C. A. Young, are what are called refraction gratings, in reality, series of fine parallel lines cut on glass very close together. The formation of a spectrum by means of such a grating requires a fuller explanation than we can give here. A collimator is a portion of the spectroscopic apparatus by which the rays are made parallel before entering the spectroscope proper.—GUN. The dimensions of space may be described as length, breadth, and depth. In a plane we have only two dimensions, length and breadth. Some geometers think they can imagine the possibility of a fourth dimension. When they can show us that a point may be neither in a plane nor out of it, we may begin to think with them.—W. WILSON, M.A. Is it not purely a question of words? You would say, we see the light that comes from an object; others would say (and, I think, rather more correctly) that we see the object by means of the light.—HENRY WENTWORTH MONK. You suppose I "have not forgotten publishing" for you "in the *English Mechanic* about nine years ago;" I remember writing a short notice in the Paradox Column of your theory of Re-Creation, but "publishing" for you would have been a different matter. I have read your letters headed "The God of Israel" and "The Lord of Hosts" in the *Jewish World*. Thanks for sending the paper to me; but the letters are hardly suited for notice in these columns.—F. P. No; at least that was not the name given. Sleep preventatives are not safe. Drowsiness (unless following after too heavy a meal, the use of stimulants, opiates, and the like), means that rest is needed, and that, therefore, rest should be taken. Your other query would hardly be understood. Even Dr. Andrew Wilson could not, off-hand, tell you the name, origin, and habits of creatures about which you only say that they are minute, have developed themselves recently within your aquarium, are white, have numerous legs, and dart through the water with a jerky, spasmodic movement, some of them carrying what you suppose to be their young upon their backs. But if you were to describe briefly the original contents of your aquarium, give the exact number of legs, and state something definite as to the size and shape of the small white creatures, your query should appear.—HARRY WHATES. We should have to insert rejoinders if your article were published. We have definitely stated more than once that our subject is science, and that in these pages the religious doctrines of no sect whatever shall be either attacked or defended.—E. BURKE. Declined with thanks; no space.—R.T. Thanks; but we ought not to insert what amounts in fact to a definite advertisement of the books named. Cause of curved shape of rainbow has been explained in recent numbers. Along lines inclined at a certain angle to the line from sun to observer (they make an acute angle with this line produced) come the rays giving, after internal reflexion in rain drops, each particular colour. Therefore, the rainbow arc of that colour is a circle on the sky, having the point directly opposite the sun (with reference to the observer) as its centre. Loomis's "Treatise on Practical Astronomy" is, we believe, to be obtained of Trubner, if not published by them. Its price is 8s. or 8s. 6d. —W. B. RUSSELL. The promised paper on the subject of moon's former proximity to the earth shall presently appear. (The moon was not projected from the earth, according either to this theory or to any other regarded as admissible by science.) No. 7 can still be obtained from the publishers.—TOPER. Your question is vague. You can get a useful knowledge of the elements of astronomy with the time you mention as at your disposal, if you use it well. But the books you have are not very well suited for your purpose. Herschel is too difficult, and the "Elementary Lessons" (though written by one who has done excellent work in some departments of astronomy) has too many errors in it to be of much use, unless, indeed, you could get from Appleton's, New York, the American edition, in which the errors arising from the author's want of familiarity with mathematical and theoretical astronomy have been corrected. —EXCELSIOR. We thoroughly agree with you, though we have no room for your letter. Whipping means, in ninety-nine cases out of a hundred, laziness and bad temper on the teacher's part; where the teacher is also a parent, you may say a hundred instead of ninety-nine.—AMICUS SCIENTIÆ. We have already reprinted back numbers, but third editions are rather costly affairs.—M. J. H. As a rule, extra outlay for larger size telescope will repay. Few ever buy a telescope who do not before long wish they had bought a larger one. I would advise you to get the largest and best you can afford. Such an instrument as you describe would do a great deal of interesting work for you, if the object-glass is by a good maker. The question about nebulæ and double stars is vague. Every telescope will show some double stars, and give interesting views of some nebulæ. See answer to "Amicus Scientiæ" as to back numbers.—J. C. LLOYD. The constellations revolve around the pole, the pole itself remaining unchanged in position. The pole-star revolves in a small circle around the pole.—M. M., *alias* J. H. Have we not requested that you would put outside your letters an address to which they may be returned? Did you think we were blind, that we should not see through so thin a disguise? —W. SCOTT. Mr. Allen shows that where such and such qualities appear, such and such results follow. If the results you suggest followed from the silveriness of whitebait, natural selection would cause the species to become less silvery, generation after generation. But doubtless the colour is protective. In what you suggest as to creatures animate or inanimate having anything to do with the matter, of their own will, you are, of course, joking.—WILLIAM FREDERICKS. Is there a bump of spelling in your phrenological system? Or are we to suppose that the "prooff" and "infamation" you require are some articles of which we have not yet heard? We have not asserted that "to term a system a science it must have adherents among men of science," because that needs no assertion, and requires no proof. To be scientific, a system must be able to bear scientific tests.—J. BARETZ. You say, amongst other remarkable things, that the celebrated Courvoisier was a great admirer of Gall and Spurzheim: surely you must mean Corvisart. Courvoisier was a murderer.—W.B.G. You are right, but the fact is pretty well known that Archimedes showed the sphere and circumscribing cylinder to have equal curved areas, as a preliminary to establishing the relation between their volumes. It has never yet been shown that the π relation in the great pyramid should replace that given by Herodotus as the one determining the pyramid's height—namely, that surface of each face is equal to square on diameter. The pyramid fulfils this quite as closely as the other.—COSMOS. We sympathise with your views; but we have to combine several qualities in order to appeal to as many as possible.—W. CAVE T. Longmans, Chatto & Windus, and Smith, Elder, & Co.—S. E. O'DELL. No, sir. We are obliged to you, but desire no continued articles in favour of phrenology, or against t

either.—ZARES. When did we promise to insert authentic abnormal mental phenomena? We promised to insert accounts of scientific experiments relating to mental matters. The story you relate, "told you by a reliable person," can hardly be so described. It is, in fact, one of those which we considered likely to reach us too freely if we opened the columns of KNOWLEDGE to accounts of spiritual manifestations.—H. WOOLLEY. We are inclined to agree with you, perhaps because it would save us much trouble to exclude such letters as you refer to. AMOS HINTON. Because fresh cold air continually replaces that which had been in contact with the body, which in a calm would be warmed. A CROSSLEY. The nebular hypothesis of Laplace is seldom correctly explained. An interesting account of it is given in Nichol's "Architecture of the Heavens."—G. H. MAPLETON. Printing the star-maps on a separate loose sheet involves extra expense, and this is a rather important consideration in a journal so cheap as ours.—A. T. C. Absolutely impossible to find room for your solar puzzle. But it is certain that if you had got up while the phenomena were in progress, and looked through the holes, at the sun, you would have seen some object, near or far off, obscuring his disc.—OSWALD DAWSON. You require our correspondents to be somewhat too precise. They know what they mean, pretty well, when they speak of the relative position of the sexes (to take one of your examples); why insist that they should define when, where, and how, in precise detail, they mean the sexes to be compared.—A correspondent, who gives us no name, asks us to explain the electro-magnetic theory of light. We know of no such theory. The writer who says the undulatory theory is fast being swallowed up piecemeal by the electro-magnetic knows very little about the matter. The evidence for the undulatory theory is simply overwhelming.—W. E. BLYTHE. Thanks for abstracts, which shall appear.—FRED. DENIER, Milwaukee. Thanks for encouraging words.—HARRIS, J. J. BRUM, and J. P. GILMOUR. Thanks; one sees the silver side, the other the golden: but it is the same shield.—J. CALVERT. Your advice to the eminent professor, coupled with that which you are good enough to give us, brings to the mind, somehow, the instructive lines:—

Teach not a parent's parent to extract
The embryo juices of an egg by suction;
The good old lady can the feat enact
Quite irrespective of your kind instruction.

A. J. MAAS notes that he receives KNOWLEDGE regularly every Sunday in Switzerland, so that booksellers who supply it in England on Tuesday or Wednesday might presumably do better. —EDWIN WOOTON. Fear we cannot in any way advance your scheme. Personally we are not in love with the society system of science work. Most scientific societies seem, somehow, to act as nurseries of disputes and difficulties.—RAVEN. Whether the account you refer to is reconcilable or not with the theory of evolution is a question not open for discussion in these columns. The account, whether right or wrong, is extra-scientific.—F. S. C. Your original polygon was an octagon. The polygon which your later communication requires could be readily drawn if any angle could be trisected, otherwise not. Consider the trouble taken by Euclid in Book IV. to show how polygons whose sides subtend particular angles may be described, and you will see that we cannot give as part of a solution such a direction as this: "The apex of angle being at centre of circle, inscribe a polygon which shall have three of its sides between sides of angle, commencing the polygon at one of the sides," without showing first how this is to be done. Your other communications thankfully received.—H. C. (i.) The accepted theory of light is that it arises from an undulatory motion in an ethereal medium occupying all space. (ii.) Cold water is heavier than warm. (iii.) We have heard of no new theory respecting the formation of the coal-measures. (iv.) I.H.S. stands for *Jesus hominum salvator*.—PHILADELPHUS. The writer of the article in question in no sense infringed our rule. He puts it as a scientific view that faith in dreams as supernatural visitations is one among many survivals of rude primitive philosophies. He indicates also pretty clearly his own belief that the phenomena of dreams are all readily interpretable without any appeal to the supernatural. This is unquestionably the attitude of science in the matter. I, at any rate, should be very much surprised to hear that any man of science viewed the matter differently. Well, now, you quote certain statements which do not seem reconcilable with these views. But science has nothing whatever to do with those statements. They are entirely extra-scientific. You might as well quote other statements, found in company with those you mention, to show that an account here of scientific views respecting floatation must be regarded as a breach of our rule that dogmatic religion should not be attacked in these columns. Or a Brahmin might as reasonably object to the views about distracted attention under head, "Mind Troubles," that they seem to him inconsistent with correct views about the Nirvana. Can you not see that the supernatural has no place in arguments relating to the natural? As to the inconsistency you indicate, we may or may not, Mr. Clodd might or might not, agree with you. What can it matter one way or another, when we positively decline to have such questions discussed here? In reply to your other question, Whitaker's Almanack decidedly overrates the prolificness of Bradford folk. It should be not 83·1 but 38·1 per thousand.—F. STANLEY. Newton's estimate of terrestrial compression was based on an incorrect hypothesis as to density at different levels below the surface. Joyce is not an authority, any way. The true compression is about 1-300th, or polar radius about 13¼ miles less than equatorial. A. J. MARTIN. Rightly understood, what we said was an answer to your question. The focal image of a planet is examined by the eye-piece (which is really a microscope), and cannot be examined with an eye-piece of more than a certain power, because its imperfections are such—no matter how excellent the object-glass—as to preclude more than a certain degree of magnifying. By receiving the image on a screen, even were the screen perfect, we do not diminish its imperfections, and we lose light. Therefore, we cannot use a microscope in the ordinary way with any advantage. In fact, if an eye-piece is used to throw the rays on the screen, the image so formed can be best magnified by simply increasing the screen's distance from the eye-piece. We are then magnifying without any of the optical disadvantages which would result from using a microscope. But we find no increase of distinctness in this way after a certain convenient distance has been reached—only loss of light and such increase of all imperfections that the image becomes confused and indistinct.—PAUGUL. Thanks; but at present no space.—EXCELSIOR. If you only knew how much labour we should save by doing what you ask! But then many would say it was pure selfishness.

Notes on Art and Science.

A NEW VARIETY OF GLASS.—A Vienna chemist has recently discovered a new variety of glass. It does not contain any silica, boric acid, potash, soda, lime, or lead, and is likely to attract the attention of all professional persons on account of its peculiar composition. Externally it is exactly similar to glass, but its lustre is higher and it has a greater refraction, of equal hardness, perfectly white, clear, transparent, can be ground and polished, completely insoluble in water, neutral, and it is only attacked by hydrochloric or nitric acid, and is not affected by hydrofluoric acid. It is easily fusible in the flame of a candle, and can be made of any colour. Its most important property is that it can be readily fused on to zinc, brass, and iron. Is can also be used for the glazing of articles of glass and porcelain. As hydrofluoric acid has no effect on the new glass, it is likely to find employment for many technical purposes.—*Wiener Gewerbe Zeitung.*

AN ELECTRIC BUOY.—A daily contemporary states that experiments are being made in the Lower Bay, New York, with a new electric buoy, the invention of Mr. Bigler, of Newburg. Mr. Bigier, it appears, owns the patent of the old Courtney Whistle Buoy, the principle of which he combines with an intermittent light, the same power which blows the whistle being used to generate the electricity that furnishes the light. The rise and fall of the waves compresses the air inside the buoy. When this pressure has reached a certain point, it works a dynamo machine and burner furnished by the Edison Electric Light Company. This machine is supposed to generate enough electricity to show an intermittent light. When the pressure is exhausted by the action of the machine, which makes about 300 revolutions per minute, the light goes out until the pressure is renewed by the motion of the waves. The more violent the waves the more powerful the light, up to a certain point. Thus the light is at its brightest during a hurricane.—*Scientific American.*

THE WINTER FLIGHT OF THE SWALLOWS.—The swallow is one of the best known, and, therefore, most interesting, of migratory birds. Excepting when kept in confinement, this bird knows neither the extreme of hot nor cold weather. As soon as the cold weather approaches, he migrates with his family to a warmer climate, and again to the northward when the temperature of its second home becomes inconvenient to its sensitive existence. In England, as a general fact, the swallow does not arrive until the second week in April, and takes his departure about the middle of September. Before the time of their flight, they assemble in vast numbers in a comfortable locality, and are seen chattering very eagerly, as if holding a huge convention for the settlement of affairs before starting on their long journey. Although starting off

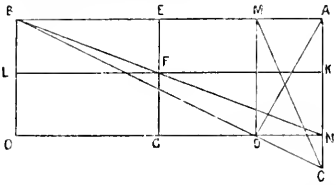
together, they do not remain so, preferring to separate into innumerable groups, like families or tribes, and sometimes making the long transit in companies of two, three, or five. While remarkable for the power and speed of their flight, they become fatigued in passing the sea, and will flock in great numbers upon the rigging of a ship passing their course for a rest. Sometimes the birds are so utterly worn out with fatigue, that when they have perched upon the side of a boat they are unable to take again to the wing, and, if disturbed, can scarcely fly from one end of the boat to the other. They have even been seen to settle upon the surface of the waves, and to lie with outspread wings until they were able to resume their journey. Guided by some wonderful instinct, the swallow always finds its way back to the nest which it had made, or in which it had been reared, as has frequently been proved by affixing certain marks to individual birds and watching for their return. Sometimes it happens that the house on which they had built has been taken down during their "season abroad," and in that case they exhibit a most pitiable distress, flying to and fro over the spot in vain search after their familiar domiciles, and filling the air with a mournful cry, announce to their friends that they have been dispossessed or evicted in the interest of local improvements. The swallow is widely spread over various parts of the world, being familiarly known throughout the whole of Europe, not excepting Norway and Sweden, and the northern portions of the continent.—*Frank Leslie's Magazine*.

Our Mathematical Column.

MATHEMATICAL QUERIES.

[11]—Can you inform me—(1.) Whether the axis of any cone passes through one of the *foci* of every ellipse formed by a section of that cone? (2.) Whether the two ellipses formed by the section of the two cones having a common apex and a common axis, by the same plane passing through both, at any angle to the common axis, are of similar eccentricity? (3.) Whether or not the angle of inclination of the ecliptic to the axis of rotation of the sun bears the same relation to the eccentricity of the earth's orbit, as the angle which the plane of any ellipse forms with the axis of its cone bears to the eccentricity of such ellipse?—NO MATHEMATICIAN.—[None of these relations hold. The simplest way to determine the foci is this:—Take a plane through axis of cone and at right angles to the cutting plane. A circle inscribed in the triangle in which the plane cuts cone and cutting plane will touch the axis of ellipse in one focus. The escribed circle touches it in the other.—ED.]

"T. R." sends an ingenious solution of No. 7, p. 148 (KNOWLEDGE, No. 7), in which he claims (erroneously) that no proposition beyond those in Euclid Book II. is employed. We have slightly modified the construction in what follows, in order that the figure may be more conveniently shaped, but the solution is in effect the same that "T. R." has kindly sent us.



We have in right angled triangle BAC, AD perpendicular to hypothenuse, DM, DN perpendicular to BA, AC; and we have to show that angle BMC = angle BNC.

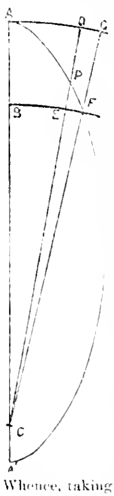
Rect. $BM.MA = MD^2$ (whereabouts in Books I. and II. is this proved? It might be given as a corollary from II., 14, but not without some proof bringing it within the range of Book III.). Hence, adding MA^2 to each, we have—

$$BA.AM = AD^2 = \text{(similarly) } AC.AN.$$

Complete rectangle $ANOB$, take $AK = AM$; draw KL parallel to AB, cutting BN in F; and draw EFG parallel to AN. Then rect. EO = rect. AL (FA and FO being complementary) = $BA.AK = CA.AN$. Hence BE must be equal to AC; and $EF = MA$. Hence triangle BEF is equal in all respects to triangle CAM. Thus angle ACM (= alt. angle CMD) = angle EBF = alt. angle BNO. Adding a right angle to the equal angles CMD and BNO, we have angle BMC = angle BNC.—QED. The proof is not so easy as either of those we gave, but it illustrates a useful method.—ED.

W. Ridd obtains a result, in examining the problem dealt with in query 92, p. 145, slightly different from ours. We gave for the eastwardly deflection of a projectile let fall from a height h, $\frac{2\pi ht}{P}\cos\lambda$ where t is the time of the fall, λ the latitude, and P the earth's rotation-period. He gets instead $\frac{2\pi(r+h)t}{P}\cos\lambda$. Mr. Ridd overlooks the circumstance that the point below moves eastward at such a rate as to be carried a distance $\frac{2\pi rt\cos\lambda}{P}$ eastward in time t, so that the actual eastwardly deflection is only the difference of these, or $\frac{2\pi ht\cos\lambda}{P}$. The result is not slightly, but very, different from that we gave, being more than $\frac{r}{h}$ times as great, so that if h be 88 yards, W. Ridd's result would be greater than mine in the same degree that the earth's radius, or about 3,960 miles, exceeds 88 yards, or $3{,}960 \times 20$ times, or 79,200 times! In fact, Mr. Ridd's error is the converse of Tycho Brahe's, who, in a letter to Rothmann, asked, "how it was possible that a ball dropped from the summit of a tower should always fall close to the foot of it, since the tower must have moved a considerable distance towards the east while the ball was falling; if the height of the tower were 100 feet, the falling body should strike the ground $1\frac{1}{2}$ miles westward from the foot of the tower, which is contrary to all observation."

But, as a matter of fact, the result we gave is only correct when we neglect the circumstance that during the fall the direction of gravity on the falling body varies, so that—first, the direction of the body's excess of eastwardly motion over the eastwardly motion of the point vertically below the point of suspension, is not always at right angles to the moving vertical, and, secondly, gravity acts during the fall to partly diminish this part of the motion. These may seem very unimportant matters, but, as a matter of fact, when they are taken into account, the calculated eastwardly deflection is found to be diminished from $\frac{2\pi ht\cos\lambda}{P}$ to $\frac{4\pi ht\cos\lambda}{3P}$.



We leave it as an exercise to the student to obtain this result by analytical methods. (If any difficulty should be found, we shall be glad to give the solution.) The following geometrical method will be readily understood by a larger number:—

Let A be the point of suspension, B the point vertically below it, C the earth's centre, BEF the earth's surface along a great circle through BA, and touching the latitude-parallel (or small circle) through B, so that BF may be regarded as part of this latitude-parallel. The body falling from A, with such eastwardly motion as belongs to the point of suspension A, travels in an elongated ellipse, AFA', having C, the earth's centre, as a focus, and reaches the ground at F, the arc APF being appreciably parabolic. Suppose that while this descent is taking place the point of suspension, A, is carried by the earth's rotation to D, and join DC and FC, DC cutting BF in E, and APF in P. Also let arc AD produced meet CF produced in G.

Then, since the point of suspension A, and the falling body when just leaving A, are sweeping out equal areas around C, and continue to sweep out areas uniformly during their motion (the former because of the uniform rotation of the earth, the latter by Kepler's second law), it follows that

Area ACD = area $APFC$.

Whence, taking away from each the area APC

Area APD = area CPF.

Whence approximately (since PE and EF are each very small, compared with AB, BF, &c.)

Area AD = area CEF,

or, approximately, $\frac{1}{3}AB.BE = \frac{1}{2}EF.BC$.

Whence $$EF = \frac{2}{3}\frac{AB.BE}{BC};$$

or, since $AB = h$, and $BE = 2\pi r\cos\lambda\left(\frac{t}{T}\right)$

$$\text{the easterly deflection } EF = \frac{2}{3}\cdot\frac{h}{r}\cdot 2\pi r\cos\lambda\left(\frac{t}{P}\right)$$
$$= \frac{4\pi ht}{3P}\cos\lambda$$

Our Whist Column.

BY "FIVE OF CLUBS."

THE LEAD.

THE customary way of treating leads at Whist is found perplexing by beginners. A number of suits are considered, and the proper lead from each is indicated, with perhaps the play second round; until the learner wonders how much he is expected to remember of what appears to him a perfectly heterogeneous collection of rules. Thus, take Captain Campbell Walker's very useful book, "The Correct Card." In this there are 36 cases of suits headed by an Ace, with the play for each; 18 cases of suits headed by King; 7 of suits headed by Queen; 9 of suits headed by Knave; 4 of suits headed by 10; and two of suits headed by a small card. In all, 76 cases are considered. The natural idea of the learner is that he ought to commit to memory all these 76 cases, with the exceptions noted in 19 notes, before he can lead properly; while, after that, he will have to learn an equally voluminous series of rules for play second hand, third hand, and fourth hand. He naturally despairs of accomplishing this without giving much more time to the matter than the game, good though it is, seems worth.

But even when the learner has committed all these rules to memory, he still finds that there is something—embodied, indeed, in them, but not obviously expressed by them—which it is absolutely essential that he should grasp. He requires to know not only what he should lead from a given suit, but what each lead means.

Now it does not seem to have been noticed by writers on Whist, that by beginning at this end they get rules much more easily remembered, because at once made practically available, and also much fewer in number. In point of fact, the rules which seem without system have a system at the back of them, and this system is at once displayed when we reverse the usual method of presenting the rules for leading, and begin by asking what particular leads may mean. Afterwards we may collect together a hundred or so of such rules and exceptions, as appear in Captain Walker's book, for then each rule will be easily remembered as a necessary inference from the principle on which the lead and the interpretation of the lead alike depend.

We begin then by considering, *not* the multitudinous leads from suits headed by an Ace, but from what suits containing an Ace, the Ace should be led. It will be seen that there are only a few cases in which Ace is led, and these easily remembered; and also that once we know when an Ace should be led, we know what the Ace lead means—

When, then, should an Ace be led?

From long suits, and from suits of not less than three, Ace is only led:—

(1) from Ace and four or more others (not including King).

(2) from Ace, Queen, Knave, with or without others.

From suits of two cards (which it can hardly ever be right to open—and never as an original lead), containing an Ace, Ace is always led.

From long suits, then, or suits of three, which only are in question in ninety-nine cases out of a hundred, there are only two cases to be considered. The play second round, supposing the Ace not trumped, will show from what sort of suit the Ace was led. For,

(1) If Ace is led from Ace, four or more, a small card is led second round.

(2) If Ace is led from Ace, Queen, Knave, and others, either the Queen or the Knave is played second round—the Queen, if the suit did not originally contain more than four cards, the Knave if it did.

Thus when your partner leads an Ace, you know at once that he has not the King. If you have the Queen or the Knave, you know he has not led from Ace, Queen, Knave, and therefore that he has four more cards in the suit.

If the lead is not an original lead, and the play has given reason to believe that your partner has been driven to a forced lead, the Ace may have been led from Ace and another. This can scarcely ever happen, but when it does happen the previous circumstances of the play and what follows the forced lead (together with the study of your own hand) will almost always show you that the lead has not been from strength.

In our next we shall consider *why* Ace is only led from long suits, under one or other of the circumstances stated above. We may note, indeed, in passing that on the Continent, Ace is led from Ace and three others (not including King), though the laws of probability point to the play as not the best. It is well to remember, however, when playing with Continental players, that this is the rule with them.

Our Chess Column.

TWO KNIGHTS' DEFENCE (*Continued.*)

IF White on his 8th move should play B. to Q.R.4., Black will soon obtain the better game, *e.g.*,

1. P. to K.4 / P. to K.4	2. Kt. to K.B.3. / Kt. to Q.B.3.	3. B. to B.4. / Kt. to K.B.3.
4. Kt. to K.Kt.5. / P. to Q.4.	5. P. takes P. / Kt. to Q.R.4.	6. B. to Q.Kt.5.ch. / P. to Q.B.3.
7. P. takes P. / P. takes P.	8. B. to Q.R.4. / P. to K.R.3.	9. Kt. to K.B.3. / P. to K.5.

In reply White has no satisfactory move, *e.g.*,

10. Kt. to Kt. sq. / B. to Q.B.4., or	10. Kt. to K.5. / Q. to Q.5., or	10. Q. to K.2. / B. to K.3.
11. P. to Q.B.3. / Q. to Q.Kt.3., or (*a*)	11. B. takes P.ch. / Kt. takes B.	11. Kt. to K.5. / Q. to Q.5., or (*A*)
12. Q. to K.2. / B. to Q.R.3.	12. Kt. takes Kt. / Q. to Q.B.4., winning the Knight.	12. B. takes Q.B.P.ch. / Kt. takes B.
(*a*) 11. Kt. to K.2. / Kt. to K.Kt.5.		13. Kt. takes Kt. / Q. to Q.B.4.
12. Castles. / Q. to K.R.5. with a winning game.		14. Q. to Q.R.6. / B. to Q.sq.
		15. P. to Q.Kt.4. / Q. takes Q.B.P.
		16. Q. to Q.Kt.5. / Q. takes B.ch.
		17. K. to K.2. / Q. takes R. with a winning superiority.

(*A*) 11. Kt. to Kt.sq. / B. to Q.B.4.	12. P. to Q.B.3. / B. to Q.B.5.	13. Q. to Q.sq. / Q. to Q.Kt.3.

And Black has a fine game.

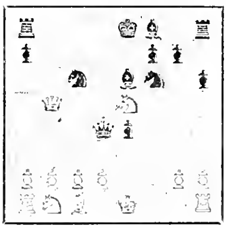
In this variation an interesting novelty has recently been discovered on White's 13th move, viz.,

1. P. K.4. / P. K.4.	2. Kt. K.B.3. / Kt. Q.B.3.	3. B. to Q.B.4. / Kt. to K.B.3.
4. Kt. to K.Kt.5. / P. to Q.4.	5. P. takes P. / Kt. to Q.R.4.	6. B. to Kt.5.ch. / P. to B.3.
7. P. takes P. / P. takes P.	8. B. to Q.R.4. / P. to K.R.3.	9. Kt. to K.B.3. / P. to K.5.
10. Q. to K.2. / B. to K.3.	11. Kt. to K.5. / Q. to Q.5.	12. B. takes P.ch. / Kt. takes B.,

instead of the usual move 13. Kt. takes Kt., which, as we have shown, results to the advantage of Black. White can also play 13. Q. to Kt.5.,* out of which reply some interesting variations arise.

POSITION of 13. Q. to Kt.5.

BLACK.



WHITE.

Should Black now play the likely looking move of 13. B. to Q.2., White would win by 14. Kt. takes Kt. / Q. to Q.3. 15. Q. to K.5.ch. remaining with two Pawns ahead. The proper reply to 13. Q. to Kt.5. is B. to Q.B.4.,† which we will examine. 14. Q. takes Kt.ch. / K. to K.2. White has now three moves at his disposal.

* Played at St. Petersburg, in a game between Prince Dadian, of Mingrelia, and M. Liselle.

† This defence was discovered by Signor Constantini, one of the strongest amateurs in Italy.

1.	2.	3.
15. Q. to Kt 7 ch. / K. to Q 3	15. Q. to B 7 ch / K. to B.sq.	15. Castles. / Q. takes Kt.
16. P. to K B 4 / P. takes P. e. p. or (1)	16. P. to Q B 3. / Q. takes P.ch. or (1)	16. P. to Q.3. / K. R. to Q B.sq.
17. Kt. takes P. / Q. to B 7 ch.	17. K. to Q sq / B. to Q B.sq.	17. Q. to Q R 4. / Kt. to K Kt 5.
18. K. to Q sq. / Q. takes Kt. P.	18. Q. to Kt 7 / Q. to K B.4. and wins.	18. P. to K Kt 3 / P. to K 6. and wins.
19. Q. to R 6 ch / K. to B.2		
20. Q. to K B sq. / B. to K R.6.		
21. P. to Q 4 / Q. takes Q.		
22. R. takes Q. / R. takes R.		
23. P. takes B. / Q. R. to Q sq.ch.		
24. B. to Q 2. / K. R. to K.sq.		
25. Kt. to Q.B.3. / Kt. to K.5.		
26. Kt. takes Kt. / R. takes Kt. Black wins.		

(1)
16. Castles. / R. to Q.B.sq.
17. P. to Q B 3. / Q. to Q 4.
18. P. to Q B 4. / Q. to Q 5.
winning the Knight.

(a)
16. Kt. takes B.P.ch. / B. takes Kt.
17. Q. takes B. / Q. takes P.ch.
18. K. to Q.sq. / Q. takes Kt.P.
19. R. to K.sq. / Q. to Kt.5.ch.
20. R. to K.2. / K. R. to K.B.sq.
21. Q. to Q.Kt.7. / Kt. to Q.4.
and wins.

If White on his 8th move should play Q. to K.B.3., Black ought, likewise to obtain the better game, *e.g.*,

1. P. to K 4. / P. to K 4
2. Kt. to K.B.3. / Kt. to Q.B.3.
3. B. to Q.B.4. / Kt. to K.B.3.
4. Kt. to K Kt.5. / P. to Q 4.
5. P takes P. / Kt. to Q.R.4.
6. B. to Q.Kt.5.ch. / P. to Q.B.3.
7. P. takes P. / P. takes P.
8. Q. to K.B.3.

In reply, Black has three moves, viz.,

8. —— / Q. to Q B.2. or	8. —— / Q. to Q.Kt.3., or	8. —— / P. takes B.
9. B. to Q R 4. / B. to Q 3.	9. B. to Q.R.4. / B. to K.Kt.5.	9. Q. takes R. / B. to Q.B.4.
10. P. to Q 3. / Castles.	10. Q. to K.Kt.3. / P. to K.R.3.	10. Q. to K.B.3. / B. to Q.Kt.2.
11. Castles. / P. to K R 3.	11. Kt. to K.B.3. or (4) / B. to Q.3.	11. Q. to K.Kt.3. / Castles.
12. Kt. to K 4. / Kt. takes Kt. to be followed by P. to K B 4., with a good game.	12. P. to K.R 3. / Kt. to K.5.	12. P. to Q 3. / P. to K.5.
	13. Q. takes B. / Kt. takes K B.P.	13. Castles. / P to Q Kt.5.
	14. Q. takes P. / Kt. takes R.	14. B. to K.3. / B. takes B.
	15. Q. takes R ch. / K. to Q.2., winning the Queen as he threatens Mate by Q. to B.7 ch., Q. to B 8.ch., and Kt. to B.7.ch.	15. Q. takes B. / Kt. to Q 4.
		16. Q. to K.Kt 3. / P. takes P.
		17. P. to Q B 3. / Q. to K.B.3., or to Q.Kt 3., and Black has a good game.

(4) If White should play Kt. to K.R.3., the following would ensue—

11. Kt. to K B. / B to Q 3
12. Castles. / Castles, Q R.
13. Kt. to Q.B.3. / P. to K.5.
14. Q. to K 3. / Q. to B 2
15. Kt. takes P. / B. takes P.ch.
16. K to R sq. / K. R. to K.sq.,

and Black has the better game. Of course he could not play 11 Q takes P.ch., for Black would reply with K. to Q 2., which would win, as he threatens R. to K sq., and the white Knight is *en prise*.

A. J. MAAS.—Thanks for end game, which shall be analysed.—H. A. N., R. KELLY, S. K. L. L., and others. Problem No. 5 cannot be solved, as you suggest, by 1. R. to Q.Kt. 7. If Black take Kt. with B., there is no mate, or Black may play Kt. to R.'s 5th ch., taking B. next move.—J. B. M. and S. K. L. L. In our note on problem 6, we should have said, "by adding a Black Knight at Q.'s sq., not Queen's 8th." Better consider, however, that a second solution is required, the position remaining unchanged.—D. SEE. If eight first moves are given as odds, none to be across the board, the receiver of the odds can make the game absolutely certain in a number of ways. We do not know that there is any way by which mate in a given small number of moves may be announced before Black plays a move. There may be, however.—H. A. L. S. Thanks. Your solutions of Nos. 7 and 8 correct, of course. The question was not as to the justice of rejecting No. 7, but of ignoring its author's statement, that, so far as he was concerned, it was original. As a part of the idea had been anticipated, there was a valid—though, we think, insufficient reason for declining to insert. You admit that the editor's is superior in finish, &c., to D'Orville's. The idea is one which would be apt to suggest itself to a problem composer, but in D'Orville's problem the solution can hardly be escaped; in the editor's there are several promising lines of attack.—JAS. D. MEEK. You are right. White could not draw; though, of course, he would not throw away his Rook by checking, as when Queen was made.

CURIOUS FREAK OF A DOG.—Dr. Onderdonk sends the following story of a freak of a dog to the *Scientific American*:—"Simmons" (that is the dog's name) is very remarkable for her sagacity, and often excites remark by the "reasonableness" of her actions. She is a constant companion of the boys, and seems to consider herself one of them. She has been a mother three times; the third time some ten days or so ago. At her two former *accouchements* she did herself credit by the respectable size of the family she brought to light; but this last time she gave birth to but one pup. Two or three days before the birth of this pup there was a litter of kittens born on the place. Simmons, disgusted at the smallness of her family, and evidently thinking that the cat had more than her share, captured one of the kittens in the absence of the old cat, and carried it in her mouth to where she kept her pup, and deposited it in her basket. In a short time she was suckling both the pup and kitten, who were hard at work side by side. The next day the kitten was taken away in the absence of Simmons, but on her return she hunted up her adopted child, and brought it back to her basket, where it has remained until now. Simmons has now been nursing the kitten for more than a week, the kitten seeming to be perfectly satisfied with her foster-mother.

Contents of KNOWLEDGE *No.* 9.

NOTICES.

The Publishers beg to announce that in future Monthly Parts of KNOWLEDGE will be issued. The following are now published:—

PART I. (November, 1881.) Containing the first four numbers. Price 10d. Post-free, 1s.

PART II.—(December, 1881.) Containing five numbers. Price 1s. Post-free, 1s. 2d.

The Back Numbers of KNOWLEDGE are now in print, and can be obtained from all booksellers and newsagents, or direct from the Publishers. Should any difficulty arise in obtaining the paper, an application to the Publishers is respectfully requested.

TERMS OF SUBSCRIPTION.

The terms of Annual Subscription to KNOWLEDGE are as follows:—

	s.	d.
To any address in the United Kingdom	10	10
To the Continent, Australia, New Zealand, South Africa, Canada, and the United States of America	13	0
To the East Indies, China, &c. (*via* Brindisi)	15	2

All subscriptions are payable in advance.

P. O. Orders and cheques should be made payable to the Publishers, MESSRS. WYMAN & SONS, London, at the High Holborn District Post-office.

OFFICE: 74 & 75, GREAT QUEEN STREET, LONDON, W.C.

MAGAZINE OF SCIENCE
PLAINLY WORDED-EXACTLY DESCRIBED

LONDON: FRIDAY, JANUARY 13, 1882.

Contents of No. 11.

A WINTER WEED.

By Grant Allen.

A DAY or two of warm weather, wafted to us by the westerly breezes, has brought out the daisies on the lawn as vigorously as if it were May, instead of January. The sward is dappled all over with their little timid white blossoms in a way that quite defies the decencies of the season. The fact is, modest and shrinking as they seem to be, daisies are very hardy and hard-working small plants, which never miss an opportunity of pushing their way in the world; and no doubt they have their reward, for probably no other flowering kind, except, perhaps, one or two grasses, have been half so successful in colonising the fields and hill-sides as these unobtrusive, wee things have been. In the spring, they are the very earliest plants to bloom; and since the early flower catches the bee, they begin setting their seed before the other blossoms are well awake; all through the summer and autumn they go on blooming uninterruptedly; and even when winter comes, they are ready at a moment's notice to take advantage of any brief gleam of sunlight which may happen to occur, putting forth their pretty buds fearlessly, and alluring the last stray insects of the season to visit their tiny golden bells.

Here in my hand I have grubbed up one entire daisy-plant, root and all, with my cane; and when one comes to look closely at its structure, the secret of its success in life is not difficult to decipher. In the first place, there are the leaves. These we seldom notice when we are examining a daisy, because they are so very retiring and unobtrusive. They lie flat upon the ground, in a small, round, spreading rosette, pressed as tightly as possible against the soil beneath. That is one of the tricks by means of which the daisy secures itself a place in the world. It grows generally in open pastures and commons covered with grass; and as the grass tends always to raise its tall blades as high as possible, the daisy might easily be overshadowed by that powerful competitor. Now, there are two ways in which different plants living in such circumstances can avoid being elbowed out of existence. One way is by sending up taller and bigger leaves than the grasses, so as to intercept the air and sunlight; and this is the plan adopted by such weeds as dock, burdock, coltsfoot, and some plantains. As a rule, however, such tactics can only be followed by plants which possess a reserve fund of food-stuffs laid by in their roots or stocks, for otherwise the young leaves would be choked and starved before they could grow high enough to overtop the competing grasses. Or, to put it more definitely, those kinds alone have succeeded in this way which happened to develope both large leaves and rich reserves of starch at one and the same time. The second plan is that followed by the daisy, the hoary plantain, and many other field-weeds. These plants have learnt to press their foliage closely down in a little circle upon the ground, so as to prevent any grasses from growing up around them and intercepting the sun and air. In other words, such individuals among them as happened to display this tendency, in a slight degree, survived the best; and among their descendants, such as carried it out further and further, spread most afield, while such as fell short of the desired quality, got killed off young by neighbouring weeds. Thus, at last, the daisy acquired its present successful habit of growing close to the ground, and so checking competition in the bud, or rather in the very seedling.

But why, it may be objected, do not all other plants do the same? The answer is, because all are not adapted for the same sort of life as the daisy. One kind survives in virtue of one point of vantage, another kind survives in virtue of another. The English meadow plantains are three closely-allied types of weed, hardly differing from one another in any essential point; yet each of them has solved this problem of foliage in a separate way. The great plantain sends up big, broad leaves on longish stalks, something like those of garden lettuce, which overtop most of its neighbours; the hoary plantain spreads a little tuft close to the earth, like the daisy; and the ribwort plantain meets the grasses on their own ground, by reducing its leaves to mere long, thin, lance-like blades. In each case, the explanation must be accepted on its own merits, without prejudice to different explanations elsewhere. The forms of leaves, indeed, are among the most difficult problems of botany, and it must not be supposed that we can account for them all at once by a single simple and easy formula. One might as well ask why the rabbit is not as big as the red deer, or why the fox is smaller than the lion. Each fills its own niche in nature; so each has been developed into exact correspondence with that particular niche and no other. And different means often subserve exactly the same end. The fleetness of the hare is produced by quite other adaptations than the fleetness of the stag; the foliage of the daisy succeeds by being compact and rounded, the foliage of the buttercup by being cut up into numerous small divergent segments. In short, whatever accidental habit happens to give a plant or animal any advantage in the struggle for existence is perpetuated in its descendants, and gradually perfected by natural selection, and thus the most diverse means often lead up in the long run to the same end.

The reason why the daisy is able to send up buds and blossoms at a moment's notice seems equally clear. The buds are always lying by in readiness close to the little perennial tufted stock. I cut it down the middle with my pocket-knife, and see, in the centre of the tuft, there are two or three unopened flower-buds even now lurking unseen and waiting for their turn to appear. Practically speaking, the daisy is an evergreen, for it always has green leaves upon it all the year round; and these green leaves are perpetually engaged, summer and winter, in manufacturing starch from the carbonic acid of the air, which starch is at once laid by in the root stock to feed

the young flowers when they are ready to sprout. So the moment a little warm weather arrives, the bud begins to start into life, and is supplied with food from the starch laid by in the root, as well as from the constant gains of the ever-busy leaves. All annual plants have to grow from the seed in a single season, and they have to produce a large number of leaves before they have digested food enough in these their expanded stomachs to feed the future flowers and seed; so that they cannot begin blossoming till comparatively late in the season. But the daisy, being a perennial, with slightly starchy root and practically persistent foliage, gets the start of them from the beginning, so as to put forth its flowers at the earliest possible moment.

And now let me look briefly at this flower itself. It is made up, as everybody knows, of two parts. The centre or disk is yellow, while the outer rays are white. But if one pulls it to pieces, one sees that the disk is really composed of many separate little golden bells, each one something like a harebell on a very small scale. The daisy head, in fact, is not one flower, but a whole lot of distinct flowers crowded together into a single truss. Taking one of the little central yellow bells in detail, I find that its petals are not separate, as in the buttercup, but are all united together into a long tube. The ancestors of the daisy had doubtless ages ago five distinct petals, like those of the buttercup; but at some time or other these petals showed a tendency to coalesce, and as this tendency proved useful to the plant, by more certainly securing its fertilisation by insects, it rapidly grew through survival of the fittest into a fixed habit, not only of the daisy, but of all the great group of flowers to which it belongs. The reason why the tubular shape is more useful than the arrangement with five spreading petals becomes clear enough if we recollect that the insect has to thrust his proboscis down to the bottom of the tube, past the pollen-bearing stamens and the sensitive pistil, in order to reach the tiny drop of honey concealed within. In doing so, a little of the pollen naturally adheres to his proboscis, and is then brushed off against the sensitive surface of the next blossom which he visits, so as thus to impregnate and fertilise its seed. To this day, however, the daisy still retains a reminiscence of the distant period when it possessed five separate petals; for each of the central florets has a vandyked edge of five points, these points being the last representatives of the original distinct flower leaves in its remote progenitors.

The tubular arrangement is common to many flowers besides the daisy family; but the daisies and their allies have carried their development one step further than the rest, for they have learnt to collect several tiny blossoms together into a single compact head, and thus to bid for the attention of insects far more powerfully than they could do in single display. More than that, in the daisy itself, and one or two others of its near relations, the outer florets of each head have become flattened into long ornamental rays, so as to play the part of petals to the compound group. In this way they make the little bunch very noticeable to all passing insects. The ray florets, when closely examined, look like tubes split down one side and opened out, so as to produce as much show as possible. They are the attractive part of the flower-head, and they do little active work themselves, having no stamens and no pollen, but laying themselves out mainly to look pretty alone. For this purpose they are coloured white, with pinky tips, instead of being yellow, like the central florets. Yet, of course, the whole plant is ultimately benefited by this arrangement, because the insects are thus induced to visit the entire little colony at once, and by carrying pollen from one floret to another, to fertilise the whole row of yellow bells then open. For if you look intently into a daisy, you will see that it does not open all over at the same time, but begins opening from the edge, and gradually proceeds towards the centre; so that in most daisies you will find a row or two of over-blown florets outside, a row just open or opening half-way through, and a lot of unopened little buds in the very middle. Doubtless, this arrangement also conduces to the good of the plant, by ensuring the highest and best sort of cross-fertilisation—that which is obtained by impregnating the blossoms of one individual with pollen brought from those of another.

PRECESSION OF THE EQUINOXES.

By the Editor.

THE precession of the equinoxes is, properly speaking, the observed motion of the points on the earth's orbit, where she is when the sun passes from north to south, or from south to north of the celestial equator, these points moving always in a direction contrary to that in which the earth circles round her orbit, so that they travel backwards. As precession really means going forwards, it may seem a little strange that this travelling backwards of the equinoctial points should have received such a name. But, as a matter of fact, the motion of these points (which are those where spring and autumn begin) in a direction opposite to that of the earth's motion, causes them as it were to meet the earth, shortening the time she takes in reaching them, so that the beginnings of spring and autumn *precede* the epochs at which otherwise they would have occurred.

But usually the term "precession" is understood to include all the circumstances on which the observed change depends, and writers will often speak of the precessional reeling of the earth. The reeling itself is, of course, not precessional, it is but the cause of precession.

The change in the position of the points where spring and autumn begin was first discovered by Hipparchus, though Ptolemy usually gets the credit of it. It was found that the point of the ecliptic where the sun is when spring begins—we may say when the year of seasons begins—is slowly moving backwards among the zodiacal constellations. It was once in Taurus, which was spoken of even by Virgil (long after the relation had ceased to exist) as opening the year with its golden horns. Then it passed to Aries, thence to Pisces, in which constellation it is now.

The effects thus produced in the position of the celestial equator, poles, &c., will occupy us hereafter. For the present we wish to consider their cause, or, rather, first we wish to describe what is the actual motion of the earth to which they are due, the real cause of precession being the forces which cause the earth to move in the particular manner in question.

Let us for the moment leave out of account the motion of the earth round her axis, and regarding her centre as at rest, let us consider what is the real nature of that motion of hers which causes precession.

Observation shows that the plane of the ecliptic, in which the earth travels, is almost unchanging in position. The course among the stars along which the sun (if we could see the stars when he is shining) would appear to travel, is almost exactly the same now as it was in the time of Hipparchus. Again, the inclination of the earth's polar axis to the plane in which she travels varies very slightly (the variation shall presently be described, and its physical cause indicated).

But the line in which the plane of the earth's equator

cuts the plane of her motion (the ecliptic) is constantly shifting in position. Suppose ABDF a view of the earth from a point on the northern side of the plane of her motion, the North Pole being at P. Then, again, let

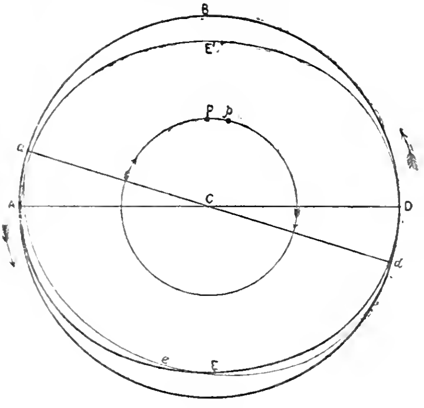

Fig. 1.

ABDF be a section taken through the earth's centre, C, and let AD be the line in which the plane of the equator, AEDE' (E' being on the farther or southern hemisphere),

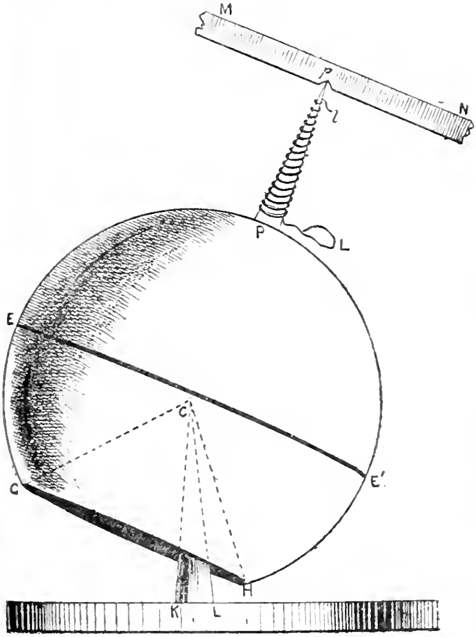

Fig. 2.

cuts ABDF. Then, if the arrow outside ABDF shows the direction in which the earth moves round her orbit, the small arrows inside show the direction in which this line of intersection is constantly travelling. In some thousand years, for instance, it would pass from the position ACD, to the position *a*C*d*; the equator would have passed to the position *aed* (one half only is shown), the northern pole from the position P to the position *p*.

Now, if we consider this motion carefully, paying especial attention to the movement of the pole, we see that it precisely resembles the reeling of a top. P might be the middle of the top's upper surface, C the peg, CP and C*p* two positions of the axis of the top as it reeled around C.

Or, instead of a top, the middle of the body of which is not the centre round which the reeling occurs, imagine a globe as GEPEH having a section such as is shown by the dotted lines in Fig. 2, GCH indicating where a conical hole has been cut into the globe, right to the centre. Such a globe set rapidly spinning in an inclined position (as in the fig.) on the top of a vertical spike like KCL, would be found to reel in a direction contrary to that of its rotation (just as in the case of the earth's precessional reeling), and if a circle EE' were drawn to represent the equator, and a point P marked exactly opposite the small circle GH, this point (or preferably a point *p* at the end of a polar spike P*p*), watched from above, would be seen to move round just as the pole of the earth supposed to be watched from the direction indicated in Fig. 1.

The motion of the earth, then, by which precession is caused, resembles that of a reeling body, like a great spherical top. The period of this reeling motion is, however, so much longer than that of the revolution, that its effects seem, by comparison, very slight. The whole lifetime of a man may pass, and only the astronomer would notice the effects which it had in reality produced.

Let us see what these effects must be.

The poles of the heavens are those points on the celestial sphere towards which the axis of the earth is directed, while the celestial equator is the great circle of the celestial sphere lying midway between the poles. The celestial equator, in fact, corresponds with the earth's equator, insomuch that, if we imagine a straight line drawn from the earth's centre to any point of the terrestrial equator, and prolonged indefinitely outwards, then this line as it was carried round by the earth's rotation, would sweep out the circle which we call the celestial equator.

Now, since the earth is reeling like a gigantic top, its axis moves—just as the axis of such a top moves—over the surface of a gigantic cone. Neglecting—as relatively insignificant—the range of the earth round her orbit, we may regard the earth's centre as the apex of this gigantic cone. The points in which a line perpendicular to the plane of the earth's motion meet the imaginary celestial sphere, or the poles of the equator, are those towards which the axis of the great precessional cone is directed. Around these points the poles of the heavens revolve in two small circles, the distance of each pole from the pole of the ecliptic round which it rotates corresponding to the inclination of the earth's axis, or in arc to about 23½°. The equator moves correspondingly, and a complete circuit is accomplished by each pole in rather less than 25,900 years.

Next week I propose to consider more particularly the effects of this reeling motion, so far as it affects the apparent position of the heavenly bodies—showing in particular how it has affected the positions of certain constellations. Then we have to consider how the seasons are affected by the change. Lastly, it will be well to consider how the reeling motion is produced, and how certain peculiarities in its progress are brought about.

In the meantime, I would invite the student to notice that very interesting illustrations of the earth's precessional

reeling can be quite easily made. A convenient way is to have a globe of iron hollowed out, as in Fig. 2, and set in rapid rotation which may most conveniently be done by having a projecting rod at the top, pierced to receive a string, as R, and pointed, so that a metal plate, as MN, with a hollow to receive the end of axis p, may be held against it while the wound-up string is sharply drawn off. The heavier the globe the steadier will its motion be found to be, the slower and the more constant its reeling.

There is, however, a more perfect method of illustrating the precession of the equinoxes or the earth's *reeling*, and also the nutation (or *nodding*, still to be described), in the instrument invented by my esteemed friend, the late Mr. Burr, of the Astronomical Society. This instrument I will sketch later.

NIGHTS WITH A 3-INCH TELESCOPE.

PRESUMING the reader to be now in possession of such a telescope as that described in our first article, and that he has placed it on a firm stand of convenient height, with the bar, BM, as nearly as practicable in the meridian, we will begin our examination of the heavens by turning towards the western and south-western sky, inasmuch as the stars there situated will set sooner and sooner every night until they disappear for the season. Arming the instrument, then, with a power of 160 (a lower eye-piece may be employed to find the object), we will begin by directing it towards the star marked γ in Cetus (*vide* Map on p. 119).

Fig. 4.—γ Ceti.

At the first glance, probably, the student will see nothing but a yellowish star of considerable brightness; but, by careful attention, he will not be long ere he catches its small companion, seemingly to the left of and just below a horizontal line, passing through the larger star. Its blue or dusky tint will at once strike the observer, as well as its small size as compared with that of its primary. This elegant pair form what is known to astronomers as a "binary system"; in other words, the stars are physically connected, and the smaller star revolves round the larger one—or both round their common centre of gravity—in a very long period, the exact duration of which is as yet undetermined. There are other objects of interest in this constellation, but the difficulty of recognising them without the aid of an equatorially mounted telescope, furnished with graduated circles, compels us to omit reference to them in these very elementary papers. Among them, 66 Ceti may be mentioned as a charming pair. It may be found with numerous other doubles—on Map 3 of Proctor's "Star Atlas."

Above, and to the right of that part of Cetus in which γ is situated, will be seen a curved line of three stars (Map on p. 201); the chief ones in Aries, the bottom, and least of which is remarkable as being the one of which Hooke wrote in 1664, "I took notice that it consisted of two small stars very near together; a like instance to which I have not else met with in all the heaven." It is almost needless to tell the student that double stars are now numbered by thousands. Viewed with a power of 160, γ Arietis presents the appearance shown in Fig. 5.

Fig. 5.—γ Arietis.

The components of this asterism will be observed to be pretty nearly equal in size. The apparently lower and slightly smaller star of the two will be seen to be of a greyish hue. If now the observer will follow an imaginary line from γ through β in the map, it will strike upon a star, not lettered there, but fairly well seen by the naked eye to the right of α. This is λ, a wide but pretty double. Here, again, the smaller star is more distinctly coloured than the larger one. Forming the apex of a right-angled triangle, with α and λ Arietis (whereof α is at the right angle), is a wide triple star, 14 Arietis. Sweeping where Aries and Triangula are conterminous, several pairs of small stars will pass across the field of view. Some 2° (four times the diameter of the Sun or Moon) above, and to the right of β, Arietis (as seen by the naked eye) will be found a beautiful close double star, which will tax the powers of the incipient observer to see fairly separated. It is 179 of Hour I. in Piazzi's Great Catalogue. The yellowish tinge of the larger component contrasting with the blue of the smaller one renders this a very pretty object.

And while his telescope is directed to this region of the sky, the student will not fail to turn it upon the planet Saturn, still employing the same power. The aspect of the planet as seen in an instrument of the size of that which we are supposed to be using is shown in Fig. 6.

Fig. 6.—Saturn.

It was drawn with a 3-in. telescope of the highest class expressly for these papers, and exhibits what the possessor of such an one may fairly expect to see under similar circumstances. A little careful attention will show how the ring is divided into two by a dark line which will be most easily traceable in what are called the "ansæ" (or handles—*i.e.*, in the easternmost and westernmost parts of it. The inky-black shadow of the ball of the planet, to the right of it, on the rings, and the slight curvature of this shadow will also be made out without much difficulty. The darker shading on the southern half of Saturn's globe, and the bright belt on the planet's equator between this polar capping and the ring, will be recognisable without diff

culty. His largest moon, Titan, will be seen at once, and Japetus (which was visible, as shown, when the drawing was made) may, perhaps, be picked up. Tethys, Dione, and Rhœa, are too severe tests for a 3-in. object-glass, and the other three satellites are hopelessly beyond much larger instruments. The incipient astronomer must not expect to perceive all the wonderful Saturnian detail shown in astronomical books. Should his 3-in. telescope show him exactly what is exhibited in the engraving, he may rest assured that he is the possessor of a first-rate instrument. Neptune, who may be found from the map, will be undistinguishable from a fixed star with the optical means at our command. Jupiter, however, represented in our next figure,

Fig. 7.—Jupiter.

is a brilliant and most conspicuous object, and the eye of the novice will have to become accustomed to the brilliance of his light before much detail can be made out upon his surface. At the period in his rotation, corresponding to that at which our sketch was taken, the great red spot which has been such a conspicuous object on his disc for the last two or three years will be at once recognised; a dark belt to the east, and somewhat above (or south of) it, bending down seemingly towards it. Then, north of the great spot, we note a well-defined band, the darkest portion of the planet's surface. The northern edge of this, and the southern edge of a belt nearly on the planet's equator, enclose an irregularly-formed lighter area between them. They are succeeded by a third dark belt, after which the whole of the planet's limb up to his north pole is covered with a continuous shading. Jupiter has four moons, but their positions are so continually shifting as to render it impossible to insert them in any drawing, unless its exact epoch be given. They may all four be outside of the planet's disc, or on the same side, or some on one side and some on another. Or they, or one or more of them, may be hidden in the shadow of Jupiter, or be passing across his face. In this latter case, the shadow of the crossing satellite may be detected like a little circular dot of ink upon his face. Our sketch of Jupiter, we must warn the young observer, is made on a smaller scale than that of Saturn, the latter having been enlarged to exhibit detail. When the observer has gazed his fill upon this superb planet, he may raise his telescope to that lovely object γ Andromedæ (above Triangula in the map). The contrast between the yellow of the large star and the exquisite green of the small companion is very striking. π Andromedæ to the right of β is a very pretty object, the contrasting colours being in this case very pale yellow and blue. 59, Σ 3, P. XXIII., 240, and other beautiful pairs will be found marked in Proctor's "Atlas."

Exchanging now his high power for the lowest one supplied with his telescope, the beginner should fish a little above to the right of ν Andromedæ (see map, p. 204) for that most remarkable object, 31 of "Messier's Catalogue," the well-known great nebula in Andromeda. Sir John Herschel quotes Simon Marius as describing the appearance of this nebula as resembling that of a candle shining through horn; and this really does not give a bad idea of it, as viewed in such an instrument as that which we are using. We purposely abstain from giving any figure of this nebula, inasmuch as no woodcut is competent to reproduce the peculiar effect of a nebula, and our object is to show as exactly as possible what the reader, furnished with a first-class 3-inch achromatic, may expect it to show him.

None of the larger stars in Taurus present any features of interest in small telescopes. χ Tauri is a somewhat wide, but pretty pair. It is the one above the letter S in the word "Taurus" in the map on page 119. Identification of the smaller ones without graduated circles is almost hopeless. Using a low eye-piece through, the Pleiades present a fine spectacle; and about two diameters of the moon, above and to the right of ξ Tauri, will be found a pale, elongated nebula. A low eye-piece, too, must be used for this. Nearly over head, just now, Perseus will be observed; a constellation rich in objects of interest, of which, however, we can only give an account of a very few suitable for the instrument we are employing. Reference, as before, must be made to the maps on pages 97, 119, and 204 for their identification. ϵ is a very fine pair, but the smaller star requires some little looking for. It is as shown in Fig. 8 below, and *just* to the right of its primary. ζ Persei is really a quadruple star, although the student will scarcely discern more than three out of its four components with the aperture we are considering. η is another pretty pair, too, but somewhat difficult, from the faintness of the companion. Perseus contains several interesting clusters—notably one of the most glorious fields of stars in the whole heavens, in what is called the "Sword-handle." This may be seen by a sharp-sighted person with the

Fig. 8.—ϵ Persei.

naked eye between Perseus and Cassiopeia (map on p. 75) as a bright spot in the Milky Way. This superb object requires the lowest eye-piece in the observer's possession to do it anything like justice. No view of it, however, with so small an aperture will give any idea of the gorgeous effect it presents in a large instrument.

South of Aries and the Pleiades lies the straggling constellation Eridanus. It contains numerous interesting pairs of stars; but for them the student must sweep, if confined to the maps in Knowledge, as they are not numbered there; and hence, any attempted description of their localities could only be confusing. 32, 39, 55, and P III., 98 will all be found to be beautiful and attractive objects, and are marked in Proctor. A curious planetary nebula H IV. 26, seen best with a low power, will be found there too. Having then furnished the incipient star-gazer with a good hard night's work, we take leave of him for the present. In our next lesson we propose to deal with that splendid and all-repaying constellation, Orion.

FOUND LINKS.

By Dr. Andrew Wilson, F.L.S., &c.

PART II.

TURNING now to the last-named fishes (*Lepidosiren* and *Ceratodus*), we discover that their fish-characters exist on the very surface of things. Their blood is cold; their bodies are scaly; they have fins and fin-rays; and above all, they possess gills existing in the sides of the neck, and in which, so long as they swim in the water, their blood is purified. But here the fish-characters end. Another aspect of the mud-fishes and the barramunda reveals characters which startle us as being not those of fishes, but those of frogs; and frogs, toads, and newts form, as every one knows, the second higher class of vertebrate, that of the *Amphibia*.

Firstly, then, the *Lepidosiren* possesses a heart, which is not that of a fish, but modelled on the type of the frog or reptile heart. Instead of being two-chambered, it is three-chambered; and no other fish save itself possesses such an advance on the ordinary type of fish-heart. But, secondly, their "paired fins," which represent in all fishes the "limbs" of higher animals, resemble—in the mud-fishes at least—rudimentary limbs. Then the nostrils, thirdly, open into the mouth—a character agreeing with frogs and all higher vertebrates, but possessed by one other fish-group only—the low hag-fishes, which are poor relations of the lampreys. These characters, then, are the characters of frogs, and not of fishes. But a far more interesting likeness to the frogs and higher vertebrates yet remains for notice. The "air bladder" of the mud-fish and of the "Jeevine" alters wonderfully, both in form and function, from its nature in other fishes. It becomes divided in two, and it opens into their throat by a windpipe, at the top of which is a "glottis," corresponding to part of our own organ of voice. Furthermore, it is divided internally into cells—in a word, the air-bladder of the mud-fish and its neighbour *has become a lung*. But this wonderful transformation is not quite ended with the recital of the altered structure of the air-bladder in these fishes. A lung is an organ which not merely receives blood in an *impure state*, but which, as in ourselves, returns that blood *pure* to the heart for re-circulation through the body. If, therefore, the "lung" of the fish is to be accounted a true "lung," we should be able to show that it performs the functions and discharges the duties of an organ of breathing.

Now the life of these fishes exhibits exactly the peculiarities which demand the exercise of an air-breathing organ like a lung. The mud-fishes inhabit their native rivers during the wet season; but when the dry season approaches, they bury themselves in the mud, and lie there, baked as in a kind of mud-pie, until the return of the persistent rains. During this land-existence their "lungs" come into play. So long as they live in their native waters, they breathe by their gills like ordinary fishes; but, ensconced in the mud, they breathe air directly from the atmosphere, like ourselves. The air-bladder purifies the blood, which the heart pumps into its vessels, and from the "lungs" the purified blood is returned to the heart. The fish is thus truly a "double-breather;" it exhibits in itself the combination of the characters of the frog and the fish. Dr. Günther tells us that whilst the mud fishes remain in the "torpid state of existence, the clay balls containing them are frequently dug out, and, if the capsules are not broken, the fishes imbedded in them can be transported to Europe, and released by being immersed in slightly tepid water." The "Jeevine," with its similar "lung," is said to leave the Australian rivers at night, and to waddle its way to the marshes and swamps, there to feed upon the vegetable matter that forms its staple food. In the nocturnal journeyings of the fish we can readily perceive the utility of the "lung."

It may lastly be remarked that other fishes are known to leave the water and to exist for a time on land. The climbing perch of India, and the *Ophiocephali*, also of India, illustrate such fishes: but in these forms the breathing in air is contrived in a different fashion from that process in the mud-fishes, and has no connection with any "lung."

Let us now reflect that a frog itself begins life as a fish. The "tadpole" has gills and a fish-heart, whilst it has no lungs. Ultimately it acquires lungs and loses gills and tail as its mature shape is attained. Summing up these plain facts of zoology, I think it is not difficult to see that in the mud-fishes and "Jeevine" we find a "link" between the lower water-living fishes and the air-breathing frogs. If we suppose that a form like the mud-fish could rid itself of its gills when it became adult, and that it could throw off the scales of the fish, and develope the limbs of the frog, we might figure to ourselves the ascent of the frog-type from the fish-type. There is nothing more wonderful or impossible in this idea than in the veritable fact that every frog is at first a fish, then a tailed newt, and only ultimately becomes the amphibian. Anyhow, one fact seems clear enough, that fishes and frogs—two utterly distinct classes—are "linked" by the mud-fishes and "Jeevine;" and this single fact in itself supports powerfully, in a rational view of matters, the theory that the air-breathing tribes of animals sprang originally from water-living forms. We shall see in future papers that "links" even of stranger kind unite classes of animals as dissimilar as the fishes and the frogs.

FALLACIES ABOUT LUCK.

By the Editor.

WALKING down to the boat-houses, one day, when I was at Cambridge, a friend (now a clergyman) who was taking part, like myself, in the four-oared scratch races, remarked that his boat was sure not to draw the unlucky first place that day. "How's that?" I asked. "Why, because we have had to row first every day until now, and the luck is sure to change to-day." (It may be necessary to explain that boat-races on the Cam are bumping races—unless where time races are rowed between the last two or three left in—and that the first place is, of course, the worst in a bumping race, for the simple reason that the first boat shares with the others, all but the last, the risk of being bumped, but cannot make a bump. In the eight-oared races, indeed, the first place is the place of honour, attained by bumping boats below; but where, before a race, lots are drawn for position, the first place is the worst, the last place the best.) I tried to explain to my friend what seemed so obvious as to need no explanation, that his fate in the day's drawing could not possibly be affected by the resuits of previous drawings. The simple circumstance that to draw a given place day after day, for six days (five were past), was a thing unheard of, so far as he knew, sufficed to assure him that his coxswain would not that day draw a particular ticket. It so chanced that what he was sure would not happen did actually happen, though it would in no way have affected my argument if his hopes had been fulfilled.

The mistake made by my friend on this occasion is one of the commonest fallacies respecting the laws of chance. Of course, it requires no mathematical knowledge or reasoning to show the opinion to be quite erroneous that past events can in any way influence events which are of their very nature entirely independent of them. If there is an urn in which we know that there are a number of white and a number of black balls, and we draw one after another several white balls, *not returning them*, we have some reason for thinking that we are more likely to draw a black ball at the next trial, for every white ball drawn diminishes the chance that the next one drawn will be white. But if each ball after being drawn is replaced, it is evident that the chance of drawing a white ball at any given trial must be the same as that of drawing it at the first or at any other trial. Or take the tossing of a coin. Antecedently it seems so unlikely that head (say) will be tossed ten times running, that we can easily imagine how anyone who had tossed head nine times running might entertain for a moment the idea that he was less likely to toss head the tenth time. But if he had any reasoning power at all, and used it, he would see that no number of past trials could in any degree affect the next tossing.

There is a fallacy equally common, and held commonly by the same persons who make the mistake just considered, which yet is opposite to it in character—in fact, directly contradictory to it. The mistake we have dealt with above may be called belief in the change of luck, and in a somewhat disguised form it is this foolish fallacy which leads the weak-minded pigeon to fall an easy prey to the rooks, from the fond delusion, in which, of course, they encourage him, that though he has lost—or rather because he has lost for a long time—he must presently begin to win. The fallacy we have next to mention is faith in luck. You will hear people say that they never have luck in games of chance, or that they always have luck; and you will find hundreds ready to believe in the good luck or bad luck of others. We say that this belief is contradictory to the other. If it be considered for a moment, this is seen to be the case. What does belief in a man's good or bad luck mean but that, because he has been fortunate or unfortunate for a long time he will continue to be so? and what does the other belief mean but that, because the luck has been one way for a long time, it will no longer continue to be so? One would suppose that two ideas so incompatible with each other could not exist in company; that everyone must see one or other to be fallacious, or (which, of course, is the actual case) that both are so. Both views are in fact ridiculous, though both, with many other equally preposterous superstitions, are entertained by persons who are not supposed to be wanting in keenness of perception, and in other matters are intelligent enough. Here, for instance, is an account given by one keen card-player of another who was as keen, or keener. "He was very particular about cutting the cards; he always insisted on the pack being perfectly square before he would cut, and that they should be placed in a convenient position. There is an old adage that a slovenly cut is good for the dealer, but whether there is truth in the statement we know not. He was superstitious to a degree that was astonishing." (It must be a rather startling superstition that would seem astonishing to a man who could gravely ask whether there is any truth in the preposterous adage just quoted.) "We are not aware that any one has ever attempted to solve the problem why so many great minds" (among card-players, fighting men, and men who have to work much at odds with fortune) "are superstitious. This is not the time or place to attempt that solution. We record the fact. He believed in dress having something to do with luck, and if the luck followed him, he would wear the same dress, whether it was adapted to the weather or not. He believed in cards and seats. He objected to any one making a remark about his luck. He had the strongest objection to our backing him, because of our bad luck, and we have often had to refrain from taking odds, because of this fad. He was distressed beyond measure if any one touched his counters. His constant system of shuffling the cards was at times an annoyance." This was a great card-player.

It will be asked, perhaps, how cases of notoriously lucky men are to be accounted for, if there is no such thing as luck. If the laws of probabilities say that no man can be regarded as a lucky or unlucky man in matters of pure chance, how is it that so many men have been lucky or unlucky? But science by no means denies that men have been or will be lucky or unlucky; on the contrary, the laws of probability can *prove* that among the millions who try their fortunes in matters of pure chance, thousands must be exceptionally lucky or unlucky, and a few must have luck perfectly marvellous to all who witness it. Given the nature of any chance game and the number who play at it, science can tell, within very narrow limits of error, how many will have ordinary luck, how many will have moderately good, or moderately bad luck, how many will be very lucky or very unlucky, and how many will have absolutely astounding luck of one sort or the other. When Science is asked how, with her absolute rejection of all faith in luck, she can account for men who have had amazing runs of good or bad luck, Science can reply not only that she has no difficulty in accounting for them, but that she can prove this to be to all intents and purposes inevitable.

What, then, is it that science rejects as untenable, or how, with such views, can science be truly said to have no faith in luck? The answer is, that the laws of probability—and (rightly understood) the laws of common sense—forbid our believing that a man *is* either lucky or unlucky. He may have been so; but, so far as matters of pure chance are concerned, the man who has been most unlucky is as likely as not to be lucky at any given trial as one who has been exceedingly lucky. He is not more likely to be so, as the fallacy respecting change of luck implies, nor is he less likely, as the fallacy of faith in luck implies; he has simply just the same chance as another, neither better nor worse.

If twenty million persons in England were to begin tossing a coin, each stopping so soon as he tossed "tail," and each to receive a pound for one head, two for two heads, four for three, eight for four, sixteen for five, and so forth, it is practically certain that several would win a prize of £131,072 after tossing head eighteen times running, and all but certain that some would get the prize of £262,144 for tossing head nineteen times running, and one or two perhaps the prize of £524,288 for tossing head twenty times running. These would all have been very lucky persons (and as long as they kept their winnings, we may say that they were in luck afterwards as well as before). The laws of probability show that among so many trials there must be some such lucky persons. But, supposing the experiment repeated, science assures us that those persons who had been so lucky would have neither a better nor a worse chance of success than those who had had but moderate luck, or the unfortunates (some ten million in number) who had tossed tail at the first trial. What would believers in the two fallacies we have considered, think? If they had watched one of the luckiest tossers, would they say that, as he had tossed head so many times running, he was unlikely to toss a single other head in the second trial

or that, as he had shown himself a lucky man, he was sure to continue tossing heads in the second trial also? One idea is as consistent with the common fallacies about luck as the other. Both cannot be true; but, in point of fact, they are alike erroneous. Carefully studied, each is seen to involve an absurd mistake.

THE PRINCIPLE OF THE VERNIER.

By J. R. Campbell.

The vernier is a short scale, which, applied to the edge of another, on which we measure a length, enables us to read to within a certain fraction of the smallest division of the latter scale. Thus, suppose the scale we measure on to be divided into tenths of an inch, by means of a suitable vernier we can read to within the hundredth of an inch.

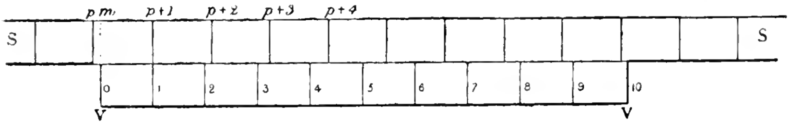

Fig. 1.

In Figs. 1 and 2, SS represents a portion of an ordinary scale of equal parts, reading from left to right, p being p^{th} graduation from the zero on the left, and $p+1$, $p+2$, $p+3$, &c., the graduations which follow; the distance between each being = 1 unit. Suppose m to be some point lying between p and $p+1$, at a distance x from p, then the vernier VV is a contrivance for giving us the numerical value of x, to within a constant fraction of the unit, supposing its zero to be on m.

Let us suppose the fraction to be $\frac{1}{10}$. In this case VV has a length = 9 divisions of SS, but is itself divided into ten equal parts, figured 1, 2, 3, to 10. Each division of the vernier will, therefore, be $\frac{9}{10}$th of a unit. If now we find that (as in Fig. 1) the graduation 1 on the vernier coincides with the graduation $p+1$ on SS,

$x = 1 - \frac{9}{10} = \frac{1}{10}$, and for the measurement we read $p + \frac{1}{10}$.

If 2 on VV coincides with $p+2$ on SS,

$x = 2 - 2 \times \frac{9}{10} = \frac{2}{10}$, and we read $p + \frac{2}{10}$.

If 3 on VV coincides with $p+3$ on SS,

$x = 3 - 3 \times \frac{9}{10} = \frac{3}{10}$, and we read $p + \frac{3}{10}$,

and so on.

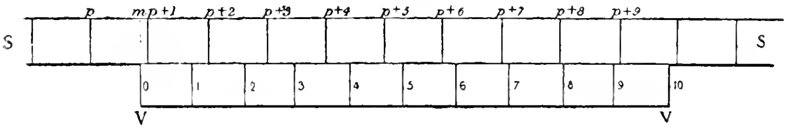

Fig. 2.

In Fig. 2, 8 on VV *more nearly* coincides with $p+8$ on SS than either 7 with $p+7$, or 9 with $p+9$. In this case, therefore,

$x = \frac{7}{10} +$ a fraction less than $\frac{1}{10}$, and we take $p + \frac{8}{10}$ as the measurement required.

Were the length of the vernier = 29 divisions of SS, and that length portioned into 30 equal parts, each would be the $\frac{29}{30}$ th of the unit; and it is easy to see that such an arrangement would read to within the $\frac{1}{30}$ th of a unit on SS. Generally, if the vernier be of a length $= n - 1$ units on SS, and consist of n equal divisions each $\frac{n-1}{n}$, it will measure to within the $\frac{1}{n}$ th of a unit.

The advantage gained from the employment of a vernier arises from the fact that the eye can determine the coincidence of two lines, when it cannot accurately judge the distance of other lines which do not coincide, thereby rendering a minute subdivision of each division on SS unnecessary.

Verniers are mostly applied to the measurement of arcs of circles, and form an important element in the theodolite, sextant, and other instruments of that class. In these, the scale SS forms a portion or the whole of a circle, and the vernier is an arc having the same centre. In measuring an angle by means of these instruments, we move the vernier, the scale of degrees, SS, being fixed.

COLOURS OF ANIMALS.

The colour and flesh of trout are affected by the water and bottoms they haunt. I know a river, the upper water of which passes over gravel and sand. Below that length, it streams through bog and alder scrub. In the first length, the fish are golden, well-formed, and good food. In the bog length they are black, bull-headed, and flabby—utterly good-for-nothing. He must be a starving otter who would make a meal of them. When these trout passed into good water, they recovered shape and condition. Again, I once lived in a wild part of Ireland. Opposite, and close to my house, there was a lake connected to another lake by an outflow. The water of the one, or upper lake, was clear, resting on brilliant white sand—a thoroughly raw bottom. The trout in it were bright and light in colour, not plump, white fleshed, and tasteless as dace. The lower lake was on bog and blown sea-sand. The water was darkish. In this, the trout were something to look at. Dark backs, merging into bright olive on the sides, and shading into white on the belly. They were beautifully spotted. Cooked, these fish excelled in delicacy of flavour any salmon I ever tasted. Now, these lower lake trout were the same as the white lake trout, but changed in appearance by different conditions of water and food. That the upper lake trout came down to the lower lake was notorious; but none was ever caught in its original condition. Was this change for concealment?

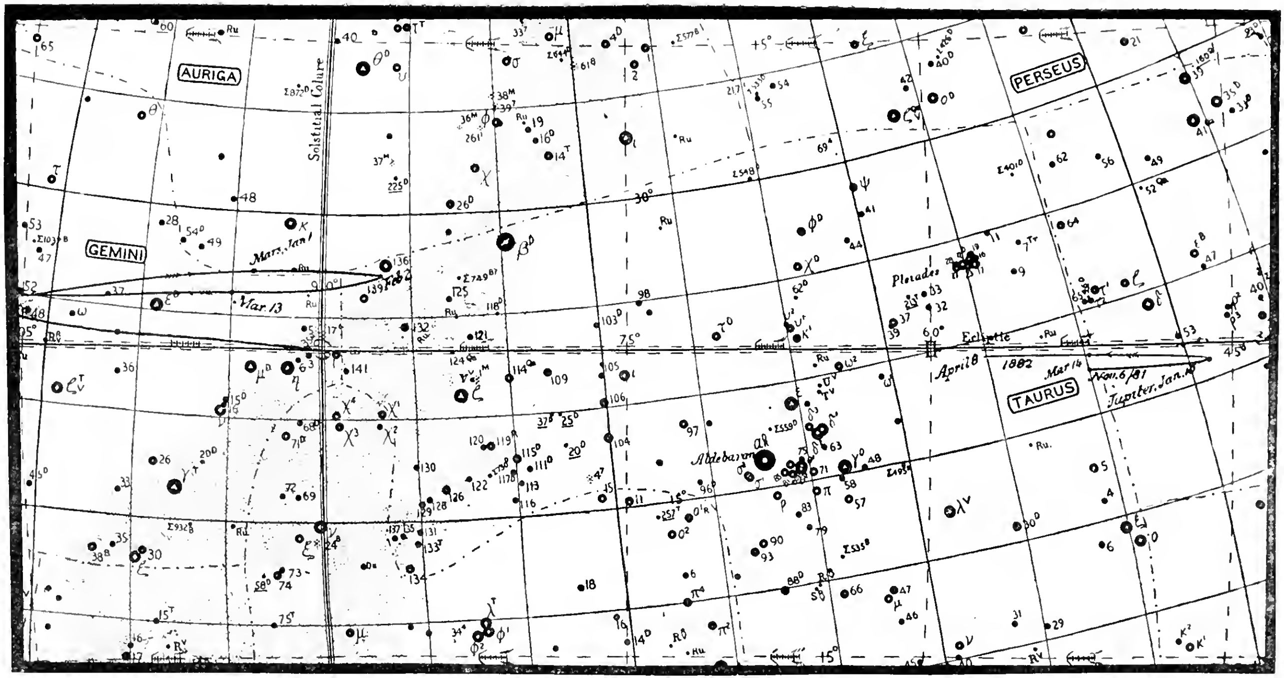
The flying-fish in the Gulf-stream have markedly the blue tint of the stream, and are of darker hue in the darker sea-water. Was this for concealment? [We should say yes.—Ed.]

A lady, accurate in observation, has told me that the eggs of the cloth-moth vary in colour with the colour of the cloth they are deposited on. Is that for concealment, or from an explainable cause?

I cannot accept Mr. Darwin's worm theory in its totality, and I repeat that which Dr. Wilson affirms is "a trifle too near silliness," namely, that the theory of worm action on the soil is an elaboration of exceptional minutiæ into huge paradox. [Might it not be well if our correspondent would mention some statement or conclusion in the work, to which he objects?—Ed.]

Dr. Wilson's answer to 'Ornithorhynchus," on the toad's immunity from the common effect of bee poison, misses the fact. The toad that munches a bee is not stung. He darts his long rapier tongue like a flash of lightning at the bee, and as rapidly withdraws it, with the bee fast to his mouth. The bee is killed before it recovers sense to sting. Neither bee nor wasp will sting when in a state of sudden terror. B. Donbavand.

Erratum on Page 179, No. 9.—In the sixth line of the fourth paragraph of the article on "Primary Colours," insert a colon after "not," and delete the full stop after "theorists."—E. H.



ZODIACAL MAP.

WE give a map this week showing on an enlarged scale (as compared with the monthly map) the part of the Zodiacal map best suited for observation during this month and the next. (The map is reduced from the editor's larger Star Atlas, Map IV.) The path of Mars during its present approach to our earth is shown, as also the path of Jupiter. Many of the stars, of which "A Fellow of the Royal Astronomical Society" will have occasion to speak during the next few weeks, will, we doubt not, be within the limits of the region pictured in our map

THE PYRAMID OF MEYDOOM.

By Amelia B. Edwards.

To open the Pyramid of Meydoom was one of the unfulfilled projects of the late Mariette Pasha. Prof. Maspero takes Egyptologists by surprise in achieving this great work during the first weeks of his second year's campaign. For more than a month it had been known to a few of his private friends that he had a gang of fellaheen at work upon this pyramid; but the secret has been carefully kept; and not till success was actually achieved was it even suspected in the public offices and hotels of Cairo.

The Pyramid of Meydoom, situate about a mile and a-half to the north-west of the village of Meydoom, is built in three stages, each inclined at an angle of 74° 10′. It rises to a height of 122 ft. from the midst of a high hill of fallen masonry and rubble. The first stage shows a height of 69 ft.; the second measures 20½ ft.; the third, which is much ruined, measures 32 ft. in height. The outer masonry is of admirable workmanship, and consists of polished blocks of Mokattam limestone. The general effect of the structure is very imposing. It has been aptly compared to the keep of a Norman castle, if we can imagine a keep built in three superimposed stages. Archæologists have till now believed that this pyramid was inviolate. Dominating a vast burial-field containing the *mastabas*, or built sepulchres, of many nobles and "royal relatives" of Seneferoo, the last king of the Third Dynasty, it is supposed to be the pyramid of that monarch. It would in such case be of earlier date than the pyramids of Gheezeh.

Professor Maspero began his work by opening a vertical trench down the northern face of the mound out of which the pyramid rises; the first result being to show that the masonry goes down to the level of the desert, and that the mound is entirely formed of accumulated sand and *débris*. Professor Maspero believes this *débris* to be very ancient, and thinks it may even date as far back as the end of the New Empire. The entrance was found precisely in the centre of the north face of the first stage, about 20 mètres above the level of the plain; which would give about 134 feet for the actual height of the first stage as now laid bare. This entrance was opened on the 13th of last month. It gave access to a descending passage about 1 mètre 60 centimètres square. The incline of this passage is very steep, and for the first 10 mètres it is lined with masonry finer, if possible, than that of the external facing. At a depth of 10 mètres the passage strikes the living rock, and becomes in its continuation an excavated sloping shaft of the same dimensions as before. The pyramid, for at least half its height, is therefore formed upon a core of rock, around which the pyramidal structure is elevated. About 5 mètres from the entrance there was once a "stopper" stone, which closed the mouth of the passage. This "stopper" has disappeared; but the construction of the passage shows that it was contrived quite differently from the portcullis-stones of the Gheezeh pyramids. There is no void in the roofing above where it is placed. It must, therefore, have been inserted after the mummy was laid in the sepulchre; then filled up to the level of the outer wall, and covered with the same *revêtement*, so leaving no external trace. The removal of this stone must have been effected at a very distant time, there being three hieratic inscriptions of the period of the XXth Dynasty scrawled upon the ceiling at the very point which the stone formerly occupied. These inscriptions, written in accordance with a brief formula common to the epoch, merely record the visit of two Egyptian tourists—the scribe Sokari and the scribe Amenmes. Hence it would seem that the pyramid of Meydoom was open, and visited by the curious, as early as the XXth Dynasty. The descending passage has been cleared to the depth of 40 mètres, without any landing, branch-passage, or chamber having yet been reached. Thus far, the structural arrangement seems to reproduce the internal plan of the Great Pyramid. The work is of extreme difficulty, owing to the want of air and light, and the overwhelming heat. The workmen faint from time to time, and have to be carried out. Prof. Maspero finds it impossible to stay inside for more than half-an-hour together.—From the *Academy*.

VEGETABLE POISONS.

The evidence in reference to the death of Percy Malcolm John was of a character which seems to leave no doubt that the deceased was poisoned by aconitine, however or by whom it may have been administered. The medicinal qualities proper to various of the most active members of the vegetable kingdom, such as opium, hemlock, aconite, hellebore, cinchona, and others, have long been known to be due to the presence in their juices of substances called their active principles, and known chemically as alkaloids. Of these, quinine, the active principle of cinchona bark, and morphia, the active principle of opium, are of such comparatively slender potency that they are constantly administered in medicine, and their names have become household words—even to the extent, in the case of morphia, that it has lost its original French designation of morphine, and has become Latinised or Anglicised in common use. When the active principles were first discovered, they were almost entirely manufactured or separated in France, for the reason that the process required the employment of a large quantity of rectified spirit or pure alcohol, and that the excise duties on alcohol had not then been relaxed in favour of chemical manufactures, and were practically prohibitory in this country. The analysis of vegetable poisons, in quest of the active principles which they might contain, fell almost exclusively into the hands of French chemists; and hence these active principles, when separated and identified, were naturally called by French names. With those which are so powerful as to be dangerous in any but the most skilful hands, and which have never been popularly known or talked about, the French terminology has been commonly retained; and hence the active principle of hellebore is still called veratrine, and that of aconite aconitine. The aconite itself is the plant known to botanists as *Aconitum Napellus*, and familiar in many old-fashioned country gardens as monkshood, and its graceful form, dark and deeply indented foliage, and tall spikes of large dark blue flowers, are attendant upon one of the most deadly poisons which are contained in the vegetable kingdom. The root bears a superficial resemblance to horseradish, and there have been numerous instances in which this resemblance has led to fatal consequences. It cannot strictly be said to resemble horseradish in taste, but it produces upon the tongue a peculiar sensation of tingling, followed by prolonged numbness; and it has been eaten as horseradish over and over again, in sufficient quantities to cause the deaths of many persons, and serious illness to many others. When such is the virulence of the root itself, it cannot be matter for surprise that its alkaloid, or active principle, separated from every inert constituent, should be dangerous to man in a dose of the fiftieth of a grain, and fatal in the dose of a tenth of a grain; or that it should produce, in an intensified degree, the peculiar tongue sensation which is produced by chewing the plant itself. It is by these characteristics that the analysts, Dr. Stevenson and Dr. Dupré, have been able to identify aconitine as the poison which proved fatal to the deceased.

The vegetable alkaloids, when administered for criminal purposes, were long thought to present peculiar difficulties to chemists. The fatal dose might be so small in absolute amount as to be easily lost among the other ingredients of a meal, or the other constituents of the animal body; and the substances themselves do not offer the facilities for analysis with which we are familiar in the case of the mineral poisons. A preparation having a metallic base, such as arsenic or antimony, is practically indestructible; for, if it is swallowed in sufficient quantities to cause death, this base must always be present in the remains in a condition in which it can be separated and identified by processes of the simplest kind, with which it is the business of every medical student to be familiar. The alkaloids, on the other hand, instead of having permanent bases peculiar to themselves, are composed of the same elements which build up the fabric of the body, and of the food from which its sustenance is derived, and there are very few of them which, in the presence of any tests, yield reactions that can be described as positively characteristic. In these circumstances physiology has come to the help of chemistry, and the practice which is pursued is, in the first instance, to treat the contents of the stomach, or the substance of the viscera, in such a way as to extract from them any alkaloid which they may contain, and then to test this extract by its effects when administered to small animals, instead of by its behaviour in contact with re-agents. The evidence of Dr. Stevenson is to the effect that he made an extract from the matters submitted to him for analysis, and that he administered minute quantities of this extract by injecting it under the skin of mice, which thereupon died with symptoms of aconite poisoning. It further produced upon his own tongue and upon that of Dr. Dupré the characteristic tingling and numbness which would be produced by aconite, and which lasted from four to six hours; and, finally, some mice were poisoned with genuine aconitine, and their symptoms were compared with those exhibited by the mice poisoned by the extract. In this way the chemists were able to arrive at a conclusion which they appear to have placed beyond dispute. The body of the deceased contained aconitine enough to have killed a dozen people; and no one who had swallowed the alkaloid in the amount in which it was shown to have been present could have had, from the first moment, even the smallest chance of escape. In its legitimate uses, indeed, aconitine is scarcely ever employed by physicians except as an external application. A minute quantity of it is sometimes pre-

scribed as the basis of an ointment, which is rubbed into the skin in some forms of obstinate neuralgia, but its internal administration would be attended by perils, from accidents in dispensing or in the measurement of the dose, which no prudent practitioner would be likely to incur.—*Times.*

THE NEW STAR IN CASSIOPEIA.

THE following particulars respecting this wonderful star may be of interest to your querist and other readers (see query 65). The star known as the "Pilgrim," which suddenly blazed out in Cassiopeia in 1572, was, according to Smyth, first seen by Schaler, at Wittenberg, in August, 1572. Tycho Brahé, whose name is usually associated with the star, first saw it November 11. It increased in brilliancy until it surpassed Jupiter, and equalled Venus in brightness when it was visible at noonday. This state of things was not, however, of long duration, as it gradually diminished, and in March, 1574, had completely disappeared. Its curious changes are thus described:—"As it decreased in size, so it varied in colour; at first its light was white and extremely bright; it then became yellowish, afterwards of a ruddy colour, and finished with a pale livid colour." Smyth incorrectly gives its position as north of 55 Cassiopeiæ. This mistake has not been corrected by Chambers in his new edition of the Cycle. A reference to the original sketch, by Tycho Brahé, accompanying his description of the star, shows that it was situated close to κ Cassiopeiæ—a star of about fourth magnitude. The place deduced by Argelander, from Tycho Brahé's observations, is, for the year 1878, R.A. 0h. 18m. 2s. 1; N.P.D. 26° 31′ 43″. The position thus indicated is very void of stars to the naked eye, and even in an opera-glass.

Within one minute of arc of the place assigned by Argelander, d'Arrest, in 1865, observed a small star of the eleventh magnitude, of a reddish hue. By frequent comparisons made by Hind and Plummer in 1873, they found that this small star, which is No. 129 of d'Arrest's catalogue, is sensibly variable to the extent of nearly a magnitude. "It frequently presented a more blurred appearance than the neighbouring stars, and on several nights was remarked to flash up very sensibly for moments, assuming at these instants a redder tinge than at other times. The star assumed to be Tycho's will be readily identified by means of a bright ninth magnitude—8·9 according to Argelander, which is No. 22 of his Zone 60. It follows this ninth magnitude 29°·6, and is south of it 10′ 1·1.″" D'Arrest's star was also observed by Espin in 1878. Sir J. Herschel thought it probable that the object was identical with temporary stars which are said to have been seen in the same region of the heavens in the years 945 and 1264. Should this be the case, the next few years may possibly witness a repetition of this extraordinary phenomenon. J. E. Gore.

ACTINIUM; A METAL FOUND IN WHITE ZINC PIGMENT.

DR. T. L. PHIPSON'S experiments have at last proved successful, and he describes the process by which he has isolated the oxide and sulphide of the new metal, "actinium" (to which white zinc pigment owes its remarkable property of darkening in the sunlight, returning to its white state in the dark, and not being affected in this manner under a sheet of glass), in a state of tolerable purity. He says:

Perhaps this process may be improved hereafter, but it is not very complicated, though it has required an enormous number of experiments to arrive at it. First, one word as to the manner in which the pigment found in commerce is prepared. Ordinary zinc scrap is dissolved in sulphuric acid, and a considerable excess of zinc is left in the solution in order to keep out iron, lead, arsenic, and other metals. The liquid is drawn off, and then precipitated by a solution of sulphide of barium; the precipitate is dried, calcined, raked while hot into cold water, dried again, ground, &c. It then consists of sulphide of zinc, oxide of zinc, and sulphate of baryta, with minute quantities of iron, lead, arsenic, manganese, &c.

The manner in which I have obtained the oxide and sulphide of actinium from this pigment, is as follows, and the process will doubtless serve for the treatment of other substances in which the presence of the new metal may be detected:—

About 15 grms. of finely-pulverised pigment are left for twenty-four hours in dilute acetic acid (strongest acetic acid and water, equal parts), and the mixture well stirred or shaken occasionally. This takes out most of the iron, manganese, magnesia, lime, and oxide of zinc. The residue, after being washed, is treated exactly in the same manner with dilute hydrochloric acid (acid 8 parts, water 92 parts), with the object of completing the action of the acetic acid. The residue, well washed, is then treated with strong hydrochloric acid, to which a little nitric acid is added from time to time. The solution of the chlorides thus obtained is filtered to separate free sulphur and the insoluble sulphate of baryta, and remaining sulphur in suspension after filtration being oxidised by a few crystals of chlorate of potash. To this solution of chlorides, somewhat diluted, a considerable excess of caustic soda is added, and the solution heated. The zinc oxide goes into solution, and the white oxide of actinium remains; the latter is received upon a filter, washed, dissolved in hydrochloric acid, and the solution again treated with excess of caustic soda (these operations may be repeated two or three times, in order to eliminate the zinc oxide as much as possible). Finally, the oxide of actinium, still impure, is washed on a filter, and dissolved in a considerable excess of hydrochloric acid. The solution is neutralised by ammonia, and then the latter is added in excess. All but a little iron oxide remains dissolved (if not, dissolve again in HCl, and add ammonia in excess, which this time will only precipitate the iron). The iron oxide is separated by the filter, and to the filtrate sulphide of ammonia is added, which throws down the sulphide of actinium as a bulky, pale, canary-yellow precipitate, the colour of which is best seen when it is received on a filter.

Oxide of Actinium.—The hydrate, as precipitated by soda or ammonia, forms a bulky white precipitate, more gelatinous than oxide of zinc; unlike the latter, it is only very slightly soluble in caustic soda, even when the liquid is heated; it is not precipitated by ammonia from solutions containing ammoniacal salts. It is a permanent white, with a slight tinge of salmon colour when seen in bulk, and it does not change colour when exposed to the air, as oxide of manganese does, neither does it appear to be affected by the direct rays of the sun. It is readily soluble in acid. The anhydrous oxide is not volatile nor decomposed by heat. It has a pale, fawn-coloured tint.

Sulphide of Actinium.—The hydrate, as precipitated from its neutral or alkaline solutions by sulphide of ammonium, is a bulky pale canary-yellow precipitate, insoluble in excess of sulphide of ammonia, scarcely at all soluble in acetic acid, readily soluble in mineral acids, even when they are diluted. When exposed to the direct rays of the sun, it darkens and becomes quite black in twenty minutes, except in those places where it is protected by a piece of ordinary window glass.

The amount of actinium sulphide obtained from the white pigment amounts to no less than about 1 per cent. This yield is enormous. The presence of this new element in zinc will probably account for the discrepancies noticed in the equivalent of this metal, as determined by various observers. The new element differs very essentially from manganese, zinc, and cadmium, but has, perhaps, some points of similarity with lanthanum. It exists, evidently, in considerable quantities, in at least some kinds of commercial zinc.

FOSSILS IN METEORIC STONES.

THE question whether life exists, or ever has existed, in any the celestial bodies, under conditions similar to those which prevail upon the earth, has been one of deep interest ever since astronomy in modern times dissipated the old theories and set up correct ideas in regard to the solar system. It has been, however, a mere matter of affirmative belief, without any sort of proof to give it a foundation. It has been quite rationally argued that the All-Wise Father of the Universe would not allow such vast worlds, as we are now certain the heavenly bodies are, to remain waste places, without making them the abodes of life. Such was one of the sublime ideas of Thomas Dick, the famous "Christian Philosopher." And some of the materialistic evolutionists of more recent times, who exclude every idea of special creation from their doctrines, have suggested that possibly "in the beginning" life originated upon this earth in one or more germs which fell from some of the circling orbs above us, coming down with or upon those meteoric stones. But aside from the fact that science has shown a strong analogy between the physical conditions of our earth and some of the planets, there has not been until now any other proof of the existence of life as it is manifested to us outside of our own earth. But in the *Popular Science Monthly* for November, Mr. Francis Bingham has a very remarkable and interesting article on the discovery of organic remains in meteoric stones, in which he avers that "we are able to see with our own eyes the veritable remains of animate beings from another celestial body." These stones, which have been falling upon our earth during all historic time, and doubtless from periods far more remote, have been believed by astronomers to be the remains of a planet which had been destroyed in some manner—shattered into fragments by forces which to us may be set down as unknown or mysterious. Two German scientists—Dr. Hahn, a geologist, and Dr. Weinland, a zoologist—have recently investigated

this subject to some extent, and the result of their labours is that they find in these stones fossil sponges, corals, and crinoids. They are also of the opinion that they have discovered a trace of vegetable remains. The best defined fossils are those of corals and sponges, and in regard to these there would seem to be no doubt. The corals belong to classes which on the earth are found only in some of the oldest geological formations, and they differ from ours in being extremely small. Of the sponges, the remains were in such excellent preservation, that "Dr. Weinland succeeded in actually determining three genera."

"Of one characteristic bluish sponge which occurred in several favourable shavings (into which the stone was cut), both as young and old specimens, he was able to make a drawing of its interior construction as easily as from a living specimen."

These startling discoveries point to the fact that in the world where these rocks and animal forms originated, the course of organic evolution was very similar to that which has taken place upon our earth. But these eminent savants are of the opinion that discoveries will yet be made of organisms for which no place can be found in our systems of zoology. The petrifactions all belong to the subaqueous classes of animals of the lower and more primitive forms, and up to this time no trace has been found of any higher animals, as mollusks, &c.

Dr. Hahn has published a book giving an account of this wonderful discovery, which is illustrated with engravings of more than one hundred specimens of these organic remains, no two of which are alike. These have been reproduced by photography, which does not lie. Further investigations in this new and untrodden field of research will be awaited with the most profound interest.—*Chicago Herald.*

DURATION OF LIFE.

An article lately appeared in the *British Medical Journal* on "Has the duration of Human Life in England increased during the last thirty years?" by Dr. Rabagliati. I have condensed most of it for your readers. From 1838-40, the average death-rate was 22·3 per 1,000; in 1876-9, it was 21 per 1,000; or an average of 44·8 years against 47·6 years; this gives an addition of 2·8 years to each one's life. If our population is 25,798,922 people in Great Britain, then 72,236,981 years of life are added to a generation.

The improvement, he says, is due to better ventilation and drainage, less overcrowding, the destruction of fever dens, &c. This addition, when analysed, shows that infant life is more certain, whilst males above 35, and females above 45 are dying faster than thirty years ago.

Between 1851 and 1878, 360·5 male children under five years died per 1,000; in 1879 only 319·5 per 1,000; this is an addition of 11·1 per cent. to life. If we still compare these dates we find that between 5 and 10 years, 19 per cent. was added; 10 and 15 years it was 24·1 per cent.; 15 and 20 years it was 22·6 per cent.; from 20 to 25 it was 22·6 per cent.; from 25 to 35 years it was 11·3 per cent. In females, comparing same data, it was 11·1, 22·1, 24·4, 25·1, 23·7, 16·7; and from 35 to 45 years there was a saving of 5·8 per cent. in 1879. Males in 1879 from 35 to 45 years died 1·5 per cent. faster than before; 45 to 55 years, 2·6 per cent. faster; 55 to 65 years, 11·9 per cent.; 65 to 75 years, 7·8 per cent., and above 85 years, 7 per cent. faster than from 1851 to 1878. Females between 45 to 55 years 6 or $\frac{6}{10}$ per cent. died faster; from 55 to 65 years, 12·2 per cent.; 65 to 75 years, 11·6 per cent.; 75 to 85 years, 9·5 per cent.; above 85 years, 4·8 per cent. died faster. Examine, then, every 10 years and we find in 1841 to 1850 the death-rate was 22·4 per 1,000; 1851 to 1860 it was 22·2 per 1,000; 1861 to 1870, it was 22·5 per 1,000; and from 1871-9 (nine years) it was 21·5 per 1,000. The improved rate of health has taken place since 1870. Deaths from zymotic (infections) diseases have lessened; thus from 1850 to 1854 they were at the rate of 5,234 per million living people; 1855 to 1859, they were 5,039 per million; 1860 to 1864, they were 4,899 per million; 1865 to 1869, they were 5,172 per million; 1870 to 1874, they were 4,849 per million; 1875 to 1879, they were 3,911 per million of living beings. From 1850 to 1854 the death-rate was high from these causes; in 1877 to 1879 it was lower from them; but from other causes it was higher than from 1850 to 1854, minus these. Thus it seems that in those days the people were healthier than our present race—it was a case of survival of the fittest, the weakly ones then died and so increased infant mortality; now the weaker ones live, and die soon after manhood, and swell its mortality, instead. The diseases that attack young lives are also becoming less fatal, such as scrofula and consumption, whilst diseases of more advanced life are, on the other hand, increasing in fatality, such as cancer. This reads us a terrible lesson, and one to which everyone's attention should be drawn, for we undoubtedly hold our lives in our own hands; so it depends with ourselves, in a great measure, whether we die at 35 or 75 years.

T. R. Allinson, L.R.C.P.

KNOWLEDGE FOR THE YOUNG.*

An idea seems to prevail that the best way to make knowledge palatable to the young, or to beginners generally, is to dilute it: if a reader finds one fact in a page he can digest it, and better still if he finds one fact in half-a-dozen pages. Then, again, many imagine that knowledge must be sweetened to suit the taste of young folks: we must be poetical and use flowery language, or they will turn from knowledge in disgust. We believe all this (we may say we know it) to be entirely erroneous. If it were true, the book before us would be utterly unsuited for young people; but, as a matter of fact, it is just the sort of book they want. There is no poetry, no flowery language, no attempt to interest by fine talking; and yet the book is full of interest from cover to cover, and full of poetry, too, for those who can read between the lines. Take the opening words. "Coal.—When wood or woody matter such as roots, bark, leaves, moss, peat, and so on, lies buried in the earth for a very long time, it changes into coal. Wherever coal is now found, there were once forests, or woods, or peat, or else mouths of rivers or other places where plants grew, or their dead parts, or leaves, or branches, and roots got heaped together. Then such places get covered with water, often because they sank below the level of the sea, and the sea covered them, and they were at the bottom of the sea. Then the mud which rivers bring down to the sea sank down and covered them, and the shells and skeletons of dead sea animals fell also upon them, so that they got covered deeper and deeper." Then the later stages of coal formation are described, without a wasted sentence. And at the foot of the second page the coal has been followed to ashes, cinders, coke, and breeze (broken up coke), and so the first chapter ends.

How much more sensible this than a page or two of pretty talk about the cheerful blaze of our home fires, the comforting warmth of stoves, and so forth, followed by vague mention of the work coal does in manufacture, &c., with then, perhaps, a reference to the forest primeval, and poetical picturings of the work done by river and sea. We have before us a work, on another subject, in which just such a course is followed. Six pages are employed in saying what might very well be said in half a page, and then the author has the face to say, "let us recapitulate",—the reader being all the while treated as a child might be to whom a bitter medicine was to be given in a spoonful of sweetstuff.

Now, children as a rule (though elementary books are best written when not specially meant for children) care very little for poetical descriptions, and a great deal for facts. They often find a good deal of poetry *in* the facts; indeed, we can imagine few better lessons for those who want to put poetry into their science books than to tell their facts to a bright child, and to listen to its comments. If you want thoroughly to interest a child you must not dilute, but condense. An intelligent child's digestive capacity for information is greater (not less, as many fondly imagine) than that of most grown persons. The usual way of treating readers of "first books" is as unwise as would be the use of baby food for growing boys.

Let parents try the experiment. Give a boy a so-called scientific book full of poetry and platitudes, with the science disguised out of all knowledge, and note how he will weary of it. Then give him such a book as Professor Guthrie's "First Book of Knowledge," and see how much the lad will prefer good meat to pap. Some reviewers criticise such books as this on the score of what they call a common-place style, not knowing that the true eloquence of the scientific writer resides in clearness and plainness of speech. So judged, Professor Guthrie's style is excellent.

The subjects dealt with in this capital book are classed under the following heads:—"Things and Stuffs used for House-building, The Elements, Wood, Heating and Lighting, Finishing and Furnishing (of houses), Clothing, Food, Cleaning, Writing, and Printing." There are questions at the end of each chapter, but we believe that what is learned for question-answering is not properly learned at all. A clever boy should take such a book as this for the mere pleasure of satisfying the mental craving (natural in all healthy minds) for information,—which is the mind's plain food.

* "The First Book of Knowledge." By Frederick Guthrie, F.R.S. (Marcus Ward & Co., London.)

Letters to the Editor.

[The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

**** All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.*

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

A PRETTY GEOMETRICAL PROBLEM.—FOX AND GUNS.—INTELLIGENT DOG.—FOUR FOURS.—MISSING LINKS.—THE MAGIC WHEEL.—FUNGI AND LICHENS.—FLESH FOOD.—URSA MAJOR, VENUS, AND THE NORTH POLE.

[184].—"Student" gives the following puzzle, to which he says there are twenty-five solutions; but there are really many more. We withhold his solution:—

Take a square piece of paper, and remove from it a corner square (equal to one-fourth of it), leaving three small squares in one piece. It is required to divide this three-square piece so that the parts can be put together to form a single square.

At the same time we submit the following puzzle, sent us by "Mogul," who promised, but did not send, a solution:—

Given any rectangle, to divide it by the fewest possible straight cuts, so that the parts can be put together to form a square.

J. Rae points out that from the way in which the string is fastened, which Mr. Henslow considered a fox might pull "out of the line of fire," our interpretation of these words (letter 158, p. 187), cannot be correct. The fox would inevitably be in the line of fire in touching the string; and in the condition in which the string usually is, would run great risk. Such a fox would "do a most foolish thing, as foolish as a sportsman who should drag his gun on full cock by the muzzle through a hedge."

The Rev. J. P. Sandlands describes how a strange dog stopped him in Westbourne-park, until he responded to the appeal in the dog's eyes that a gate leading to the dog's master's house should be opened.

E. Clarkson, Geo. D. Brown, J. A. Miles, Nemo, F. J. J., and others, give solutions of the four fours, for numbers from 1 to 20 inclusive, except 19. Other problem, Yarletoman gives for 19 the formulæ.

$$(+)\ \frac{4}{\cdot 4} + \frac{4}{\cdot 4} \text{ and } \times\ \underline{|4} - 4 - \frac{4}{4}$$

F. J. J. gives $\sqrt{\frac{4}{\cdot 4}} - \frac{4}{4}$

which is manifestly erroneous. E. Clarkson and F. G. Hooton give for 19, $\frac{4 + 4 - \cdot 4}{\cdot 4}$ J. Bosworth points out that four 3's will give the same numbers as three 5's (except for number 17); and that 19 may be given for any number whatever by the formula $\frac{x + x - \cdot x}{\cdot x} = 19$. It seems to me that as "Amicus Scientiæ" gives, like the others, for 11, the formula

$$\frac{44}{\sqrt{4} + \sqrt{4}}$$

in which the first 4 in numerator really stands for ten times 4. ·4, which stands for 4 divided by 10, is admissible for 19. Otherwise 11, as well as 19, must be regarded as insoluble. The solutions given by "Amicus Scientiæ" are as follows:—

No. 1. $\frac{44}{44}$

2\. $\frac{4}{4} + \frac{4}{4}$

3\. $\frac{4 + 4 + 4}{4}$

4\. $4 + 4 - (\sqrt{4} + \sqrt{4})$

5\. $\frac{4 \times 4 + 4}{4}$

6\. $\frac{4 + 4 + 4}{\sqrt{4}}$

7\. $\frac{4 \times 4 - \sqrt{4}}{\sqrt{4}}$

8\. $\frac{(4 + 4) \times 4}{4}$

9\. $\frac{(4 \times 4) + \sqrt{4}}{\sqrt{4}}$

10\. $4 + 4 + 4 - \sqrt{4}$

No. 11. $\frac{44}{\sqrt{4} + \sqrt{4}}$

12\. $4 \times 4 - (\sqrt{4} + \sqrt{4})$

13\. $\frac{44}{4} + \sqrt{4}$

14\. $4 \times 4 - (4 \div \sqrt{4})$

15\. $\frac{44}{4} + 4$

16\. $4 + 4 + 4 + 4$

17\. $4 \times 4 + \frac{4}{4}$

18\. $(4 \times 4 + 4) - \sqrt{4}$

19\.

20\. $4 \times 4 + (\sqrt{4} + \sqrt{4})$

"Another Ignoramus" writes that the argument of the evolutionists is not strengthened by showing that there are many missing links. He supposes Prof. Wilson "would have us believe that man is connected with some anomalous creature which exists only in his own imagination." Dr. Wilson holds in reality, as every evolutionist holds, that man is related to the Simians; and it is not a mere fancy, but an obvious common sense deduction from what is known about evolution, that the Simians must have changed from the common ancestor as much as man as changed; so that since man differs widely from all Simians, however obviously related to them, both man and Simian must differ widely from the common ancestor of both. "Another Ignoramus" seems to overlook the circumstance that no one has called him an ignoramus but himself. At the close of his letter he says he can see no reason why we should cease to admire the wisdom of God in creation. Neither does any one else. What the evolutionists really say is that we do not quite so thoroughly understand that wisdom as men formerly thought they did. Instead of a finite, and therefore possibly intelligible plan, we find a plan which is infinite alike in time and space, and therefore for us absolutely unintelligible. We can follow its workings over an ever widening domain, but, with the widening of this domain, the domain around, which may be regarded as that of the unexplained, is ever enlarging. Man in the past may be compared to a child, who, having been in ignorance up to a certain age of all the laws of nature, all which constitutes what we call knowledge, should have been told that everything had been fashioned just as he sees it, in a moment of time, out of nothing. If such a child, observing what takes place around him, should gradually learn something of the operation of the simpler laws of nature, he might imagine in his ignorance that they implied, not the operation of a Being living in and through all things, but the blind action of mere matter. Or if, instead of observing these things himself, he was simply told about them by others, he might wish to close his ears and his eyes, lest he should "cease to admire the wisdom of God in creation." The fear would be very idle and foolish, we know. Even the opponents of evolution must see that. But they act in this way themselves, and expect to be regarded as exceptionally devout admirers of the wisdom of God, because they would limit His domain in time, and narrow it in space.

C. H. Wingfield points out that by having eleven slits (at equal distances) instead of ten, the horses round the magic wheel seem not only to move their limbs but to advance. Certainly with the same number of slits as horses, the horse presents a somewhat singular appearance, flourishing his legs about, but not getting over the ground. In *La Nature* the picture in the *Scientific American* is given without change, viz., twelve figures of the trotting-horse, the uppermost of our view and the one next to it on the left being given twice over. We have tried the magic wheel with this arrangement, and find that the horse seems to trot with a singular extra kick once in each double stride. We have not yet tried Mr. Wingfield's plan, but have no doubt it would act as he says.

E. C. Cowley desires to learn Mr. English's address from Mr. W. W. Highbury, and to know in what sense the "subscription list is open" to any one desiring a copy of the book.

"A Fellow of the Chemical Society" points out that if it can be shown, as he believes Mrs. Kingsford has shown, that man in physical formation is nearest to the apes and in striking contrast to the flesh-eaters, the natural food of man must be that which we find apes eating. Might one not argue, almost as effectively, that men should limit their pursuits to those which satisfy their Simian cousins? I do not say men might not live, and thrive, and work, and think, on a diet of nuts, fruits, and vegetables, or that they do not, as a rule, eat much more flesh than is good for them; but we must not adopt a false system of reasoning even to establish the truth. "F. C. S." states what is more to the point, that many who

have suffered from dyspepsia when living on mixed food, have been freed from the malady after (and presumably on account of) a change to a vegetable diet. I wish there were space for his letter in full, but there is not.

"A. G. P." has seen parts of Ursa Major in lat. 20° south, and a shadow thrown by objects in light of Venus. He asks what phenomena beyond total absence of centrifugal force might reasonably be expected at the pole? Extreme cold, we should say, the pole of the heavens over head, sun visible for more than half a year and invisible for the rest of the time. RICHARD A. PROCTOR.

CHEAPENING OF APPARATUS, AS AN AID TO THE DIFFUSION OF SCIENTIFIC KNOWLEDGE.

[185]—At the beginning of a New Year, I venture to suggest that the most worthy and laudable end to which KNOWLEDGE so especially addresses itself—that of the diffusion of sound popular scientific information—might be very considerably advanced by that invaluable class of men, the optical and philosophical instrument makers, if they would only address themselves to the production of apparatus at a cost to bring it within the means of those whose pecuniary means are (like the joint-stock companies) "limited." Conducting some experiments in chromatics recently, I required a double-image prism, for the purpose of superposing coloured discs; but on a friend inquiring on my behalf at two separate shops, he was asked 12s. 6d. for one at one of them, and 15s. at the other! Now, we know pretty well what Iceland spar costs in the rough, and I feel tolerably confident that a prism mounted in a simple bit of brass tubing might be sold at a good profit for half-a-crown. Such, though, is the trade conservatism among those concerned in the manufacture of such things, that they would much rather sell one prism at 15s. than eight for a sovereign. *Mutatis mutandis*, these remarks would equally apply to the transit instrument. There can be no doubt that a real want exists for a simple meridian instrument, which shall be at once trustworthy to use and cheap to buy; but £15 represents the present price of the smallest transit made which is really serviceable. Here, then, is an opening for some enterprising scientific artificer, at once to benefit himself and the community at large. An economical transit instrument once produced, it may be worth the while of clock and chronometer makers to try whether a cheap compensated sidereal clock is quite an impossible thing to construct? The achromatic telescope has been cheapened, and a really efficient photographic camera can now be bought for a small sum. In other types and classes of instruments, however, the opticians are content *stare super vias antiquas*. It is in hopes of rousing a few of the more energetic among them to a course of action which must ultimately benefit them as much as it undoubtedly must the great army of scientific students in this country, that these lines are written.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

INSTRUMENT FOR DESCRIBING THE CONIC SECTIONS.

[186]—In answer to "F. R. H. S.," I may say that in Fig. 2 (p. 160) the central leg of the instrument is held at an angle corresponding with the amount of eccentricity of the intended ellipse, while the moving leg slides up and down the same, thus describing a section of a cylinder.

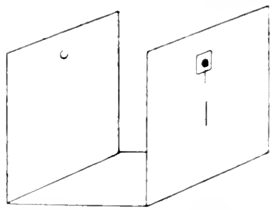
As to Fig. 1, the idea was suggested by the shadow of the upper part of the globe on the gas bracket, cast by the glimmer of light usually left in, on the walls of my bedroom, the style shown moving round a circle simply performing the part played by the rays of light. THOMAS THORP.

A LUNAR ILLUSION.

[187]—"S. H. W." will perceive, on reconsideration, that he has made a mistake in his letter, No. 64, with the above title. The illusion mentioned is only an illusion, and it is solely connected with the projections of the moon and sun on the sphere of vision, which may have any radius we choose to give it, and not with their unequal distances from the eye. In the case supposed by him, viz., when the moon is in the zenith, there will be no illusion; the observer would naturally stand facing the sun, and he would look "square" at both moon and sun, and be able to produce the sagitta correctly, by the eye, to hit the sun. "S. H. W." seems to be thinking of the plane containing his eye and both luminaries; he is thinking, too, of the sun itself, and not of its above projection. The sagitta never points to the sun itself, except at half-moon. If we knew the angle between the sagitta and the line joining the moon and the sun itself, and observed the angular distance of those two luminaries, we could get their proportional linear distances from the earth. But we can never see that angle, since we are in the plane of it; we know, however, its value at half-moon, viz., zero; but we cannot tell, by the eye, any better than Aristarchus, when it is half-moon precisely, and therefore should fail, as he did, to get the relative distances of moon and sun. M.

OPTICAL ILLUSION.

[188]—Take a strip of thin card about three inches long and one wide, bend up the ends at right angles, perforate one end with a pin-hole and the other directly and concentrically opposite with a square hole about one-eighth of an inch square; place a small pin in



From *Nature*, vol. xxiv., p. 53, 54.

this end, so that the head may be in the middle of the square hole; apply your eye to this end, and look through both holes towards the sky, and the pin will be seen apparently beyond the pin-hole and reversed in position. A. T. C.

THE FIFTEEN PUZZLE.

[189]—If we are allowed to turn the board we can pass from the lost to the won position in thirty-nine moves.

For instance, we may move the pieces numbered 12, 8, 4, 3, 2, 1, 5, 9, 13, 15, 14, 12, 8, 4, 3, 2, 1, 5, 9, 13, 10, 11, 12, 8, 4, 3, 2, 1, 5, 9, 13, 10, 14, 11, 7, 6, 10, 14, 15.

There is no solution in less than thirty-nine moves, for thirty-seven moves are needed to move the blocks by the shortest paths from their first to last places; and the other two moves are needed because the four blocks in the middle cannot move round until one of them steps out into the outer row, from which it must again return.

I gave the above solution and proof in the *Brighton Herald* in May, 1880.—Yours, &c. ARTHUR BLACK.

J. Watson gives a similar solution, thus:—4.8.12.R.—12.3.U.—5.9.13.L.—12.14.15.D.—3.4.8.R.—1.2.U.—6.10.11.L.—8.12.D.—2.3.4.R.—5.6.1.U.—9.13.L.—11.14.D.—6.7.R.—9.5.U.—13.14.15.L.

PNEUMATIC BELL.

[190]—The pneumatic bells referred to by me (letter 79, p. 100) were supplied and fixed in my house for me by a firm at King's-cross, where "E. R. C." can obtain every information. I could not instruct in the manufacture of the article. Although the fixing of the three requisites, viz. (1) pipe, (2) press-button, and (3) bell, is very easy, yet space in KNOWLEDGE is, I apprehend, too valuable for such detail as gas-fitter's work. All I can say and assure "E. R. C." of is this—a more simple, reliable, cheap, and instant signal, produced only by compression of the air we breathe, cannot possibly be obtained.—Yours truly, M. TESTER.

P.S. I am sorry to say I could not procure KNOWLEDGE at the bookstalls of Birmingham or Lichfield, where I have been staying the last fortnight, so I have not seen the recent issues until my return to London.

INFLUENCE OF SEX ON MIND.

III. HISTORICAL EVIDENCE.

[191]—History is conclusive as to man's mental supremacy. The inventing, creating, cogitating mind is masculine. Men carry on the world's business in thought and action. The ideas on which depend all the marvellous acts of human intelligence, scientific discoveries, jurisprudence, political, civil, military institutions, maintaining the social structure, are elaborated by men. In the domain of pure intellect it is doubtful if women have contributed one profound original idea of any permanent value. Men legislate, govern, invent, colonise, fight, build, and dig. So little demand is there for woman's *direct* help in the mental departments which are men's special province, that, could all the male intellect in the world be suddenly paralysed or annihilated, there is not in woman

sufficient development of the abstract principles of justice, morality, truth, causality, inventive, and executive power to hold society together for one week.

"In matters intellectual and moral the long strain beats them dead. Do not look for a Bacona, a Newtona, a Handella, a Victoria Hugo. American ladies tell us education has stopped the growth of these. No; these are not in nature. They can bubble letters in ten minutes which you could no more deliver than a river can play like a fountain. They can sparkle gems of stories, flash little diamonds of poems. The entire sex has never produced one opera or one epic that mankind could tolerate for a minute—and why? These come from long, high-strung labour." (Mr. Charles Reade, in "White Lies.")

Women lack the highest quality of the human mind—*justice!* They never see two sides of a question. A woman makes a firm friend—a dangerous enemy.

The eternal subordination of woman is conclusively exemplified in her exaggerated admiration for the male prerogatives—strength and intellect. Were intellectual sexual equality not an idle dream, it would long ago have produced practical results. The strong-minded woman would have proved her pretensions. Woman's individuality and independent action in important matters are more apparent than real. Savage life shows the nearest approach to sexual equality, physical, mental, and moral. Yet among savages woman is a slave! In civilised countries, where she is free, almost every woman is steered through life by the reflecting brain, strong will, and protecting arm of a husband, father, brother, or son. A woman with no male relative has her spiritual director, her confessor, or favourite preacher, her conscience-keeper, whom she regards as a superior being. Even revolutionary women are guided by men. Platform ladies worshipped Mr. J. S. Mill. They could not understand his works on Political Economy and Metaphysics, but he advocated Woman-Suffrage! If there is one woman without such a director, she is guided by male public opinion, supplemented by oracles uttered by men in the past.

Mentally, morally, and physically woman is subordinate to man; although the meek idolator sometimes adores a brazen god!

J. McGRIGOR ALLAN.

POSSIBLE VARIATION OF PENDULUM.

[192]—A letter from "Cogito" in KNOWLEDGE (No. 8, p. 143) refers to mine (in No. 6, p. 88). He speaks of "want of precision of ideas;" true, I am alluding to a stationary pendulum; he is speaking of a vibrating pendulum.

The point is this: suppose a pendulum suspended in a railway carriage. On the train starting, motion must be communicated to the bob through the rod, and the pendulum will be thrown out of the perpendicular backwards; on slackening, the bob will be thrown forwards, momentum having been given and then withdrawn. The motion of the earth round the sun in the short space of twelve hours may be considered as in a straight line, a b, the centre of the earth, travelling uniformly a to b, but the sides nearest to and furthest from the sun will travel, the one 1 000 miles faster, the other 1,000 miles slower (as the upper and lower points of a carriage wheel). The velocity of the bob in the direction a b will, therefore, vary 2,000 miles per hour between midday and midnight, the acceleration and retardation being communicated from the point of suspension through the rod to the bob. If this action were rapid, the effect would be evident enough, the difference of velocity being great, but the time is long, and in consequence the movement of the bob would no doubt be extremely small. The question is, would it, with a rod say of 100 ft. in length, be perceptible under suitable delicate measurement?

HENRY CARR.

RATTLESNAKES.

[193].—You enjoy one great advantage over me. You are like a priest in a pulpit, who from his elevated post can, with impunity, hurl his censures on the devoted heads of obscure sinners like me, who occupy the low free seats, and are debarred from saying a word in our own defence publicly.

Mr. Darwin's discourse on the rattlesnake is to be found at pages 107—110, in his book on "Expression," &c. (first edition). I maintain that the passage is susceptible of the meaning I attached to it; for if your explanation is correct, viz., that Darwin attributes "the habit of the snake to its development."—[We did not say this. "Rather," we said, "he would," &c.—ED.]—then we are landed in the poor, paltry platitude, that when an animal possesses an organ, the creature makes use of it. Most wonderful, truly! But surely it was hardly worth while to write three pages of "information" to establish such an obvious, vapid circumstance—such a feeble inanity.

The cause and mode of developing the rattle are, however, a secondary consideration in comparison with the use to which the snake is said to devote its organ, when it is found, viz., "to frighten its enemies." I contend that the means of accomplishing the assigned purpose are simply suicidal, and that the noise of the rattle attracts the snake's enemies who seek its destruction.

I have read somewhere that in America, when the workmen in the woods hear the rattle they are sure there is no danger, but directly the sound ceases they infer that the snake is bent on mischief. So here it is not the noise of the rattle, but its silence, which is a source of alarm.

You are quite right in thinking that Mr. Darwin has never done me any injury. On the contrary, I believe him to be an estimable man, and incapable of injuring any one intentionally; but his writings appear to me to be a great offence to the Creator, to Nature, and to common sense, and therefore that his productions ought to be denounced. They have also set an example of a lax scientific method. In your own columns, at page 153, a disciple of Darwin's writes in this style on the origin of the grape:—"*Suppose*, however, that any plant *happens* to have its seeds covered with a moderately hard and indigestible coat," &c. And again: "If such a tendency were ever to be *set up* even to the slightest degree by a *mere sport* or *chance* variation," &c.

I venture to think that we shall never properly comprehend God's works in all their might and majesty of original design while we deal with them in such a puerile fashion; and with this sentiment I now respectfully take my leave of you.

NEWTON CROSLAND.

[We insert this letter, though doing so is, we fear, rather hard on Mr. Crosland.—ED.]

LONGEVITY IN ANIMALS.

[194]—In your article on "Food and its Relation to Muscular Work," you only appear to treat with what I would call active beings. I should like to know what you have to say about inactive animals, such as turtles and tortoises. I presume to call them inactive on account of their sluggishness and their dormancy. It is a well-known fact that they will live a long time without having partaken of any visible means of sustenance. I have known turtles to live without food for weeks out of their own element. A wrong idea exists with a good many people as regards the heart of a turtle. Many do believe that they have three hearts. I have examined the heart of a turtle, and I have come to the conclusion that what is taken to be three hearts is but one externally divided into three parts, not like the human heart, which is divided into four, and then encased in a membrane, called a pericardium. Can you tell me if I am right? The late Frank Buckland, when looking at the turtles in the tank at the Adelphi Hotel, Liverpool, supposed they live on the water they take in, then on their fat and blood. How is it they live a long time without water and pass urine? If any of your readers can explain, it would be cordially received by those readers physiologically inclined.—Yours most respectfully,

PHYSIO.

TOADS, &c.

[195]—In reference to query 87, and the doubts expressed as to the existence of toads in rocks of an earlier than the tertiary formation, it is an acknowledged fact amongst miners that toads have been extracted living from the solid coal, at various depths. I heard of one found two months ago in a pit 400 yards deep, near Oldham, where the coal, with the hole where the toad had been imprisoned for countless ages, was preserved, and the toad, although alive when reached, died on being exposed to the atmosphere. If "A Fellow of the Royal Astronomical Society" will make inquiries of scientific men in that district, he will learn the whole truth.

I have heard miners relate the extraction of one from the Lanarkshire coalfield, which was heard croaking before it could be liberated, and so frightened the working colliers that they fled, and would not return without the manager was present, and under these conditions the toad was hewn out, in the presence of several witnesses. Although it was rolled carefully in a wet cloth, it died before it could be taken out of the mine. It was deposited in a local museum, and no one dared to contradict the fact at that time.

ZARES.

[196]—I am only an inquirer without time or means for systematic observance, but I am interested in the query of "Arachnida" (87), and submit that I was disappointed in "A Fellow of the Royal Astronomical Society's" treatment of it (138), page 165, which must be my apology for troubling you with the copy of "cutting" from my scrap-book herewith enclosed.

A tradesman at Bromley, Kent, observed me examining flint pebbles which abound in that district and volunteered the statement, that on breaking a similar one to that I held in my hand, a

have toad hopped out, not very long ago. No allusion had been made to anything of the kind previously, and he could have had no motive for saying what was untrue.

I presume these fossiliferous flints in "the crag" are well known, although I find no particular notice of them in geological works in my possession; but considering the cells in them and the channels by which they are approached from outside, is it possible for a new tenant to be inducted and developed such as the toad?

If Sir W. Thomson could speak seriously of a Colorado beetle surviving a voyage through space in a meteoric stone (see report of British Association Meeting at Plymouth, 1877—Mathematical and Physical Section), I hope you will pardon me if I have strained a point on the capabilities of a toad.—Yours, &c., W. B.

"A CURIOUS FACT.—Many years ago a friend of my father's built a country house, which he fitted up and furnished according to his own taste; to accomplish this he caused to be brought from Italy a piece of pure white marble, out of which a mantelpiece was constructed for his own particular sitting-room. The mantelpiece was of singularly pure marble, in one block, and free from flaw, save in one part. Shortly after its erection, the owner of the house noticed a small damp-looking stain, no bigger than the nail of his little finger in the very centre of the mantelpiece. This, however, was so slight a blemish that it did not trouble him, till, as months and years went by, it became evident that the mark slowly but surely increased in size. For twenty years the good man of the house sat in his arm-chair facing the curious stain and marvelling what caused its certain spread. At the lapse of that period it had increased to the size of the palm of his hand, and he could no longer rest in patient contemplation of it. Masons were sent for and desired to take down the marble and break it in two, so as to disclose the mystery. This was done, and to the amazement of all, out hopped an enormous toad!"—"H. A. F.," in *Chatterbox*.

INTEREST ON A FARTHING.—AN APPLICATION OF LOGARITHMS.

[197]—As the nature of compound interest is little understood by many, we will assume that a farthing was placed out, at compound interest at 5 per cent., payable yearly, commencing at the Birth of Christ, and extending over time till the end of the year 1880. Now, the mean diameter of the planet Jupiter is 88,645 miles; the weight of a cubic foot of pure gold equals 17,486 oz.; and the value of the gold being at the rate of £3. 18s. per ounce; how many globes of pure gold, each as large as Jupiter, would that interest purchase?

The principal and interest of £1 for one year	1·05 log.	0·021189
Multiply by the years		1880
		1695120
		169512
		21189
Raised to the 1880th power		39·835320
Subtract the log. of the farthings in a £.	960	2·982271
Log. of the amount of interest for the given time, equals	7129 +	36·853049
7129 + (thirty-three more figures).		
Diameter of Jupiter in miles	88645 log.	4·947654
Feet in a mile equals (1760 × 3)	5280 „	3·722634
Feet in Jupiter's diameter		8·670288
Raise this quantity to the 3rd power		3
The diameter raised to the 3rd power		26·010864
Add the log. of $\frac{1}{6}$ (3·1416)	·5236 „	·1·719000
Solid contents of Jupiter		25·729864
Weight of a cubic foot of gold in oz.	17486 „	·1·242680
Value of one ounce of this gold, £3. 18/.	3·9	·0·591065
Value of a solid globe similar to Jupiter equals	3661 +	30.563609
3661 + (twenty-six figures)		
Amount of Interest (Log.)	36·853049	
Value of Jupiter	30·563609	
Log. 1947331	6·289440	

It therefore appears that the interest upon a farthing for 1,880 years, at 5 per cent., would purchase 1,947,331 solid globes of pure gold, each as large as the planet Jupiter. Yours, &c., PASCAL.

[The calculation is a pretty illustration of the value of logarithms. The mean diameter of Jupiter is much less than 88,000 miles so that the legal representatives of the original owner of the farthing can claim from the bankers with whom that farthing was placed at interest, a much greater number of gold Jupiters. But that is a detail.—ED.]

THE HOG PUZZLE.

[198]—The following problem may serve to amuse some of the many young readers of KNOWLEDGE who are conversant with the elements of Algebra. It was given me by a young lady, but the analysis is my own.

Question.—Three Dutchmen, Hendrick, Elas, and Cornelius, and their wives, Gurtrün, Katrün, and Anna, purchase hogs. Each buys as many as he (or she) gives shillings for one. Each husband pays altogether three guineas more than his wife. Hendrick buys 23 more hogs than Katrün, and Elas 11 more than Gurtrün. Require the name of each man's wife?

I call this a "puzzle," because I venture to think that nineteen out of twenty would attempt its solution by the common process of simultaneous equations, and would certainly fail, because there are more unknown quantities than the number of independent equations it is possible to construct. The solution is, however, obtained in a very simple manner, thus*:—

For brevity, denote the men and women by their initials H, E, C, G, K, A, and let the corresponding small letters h, e, c, g, k, a, represent the number of hogs (equal to the payment for one) purchased by each respectively.

Then h^2, e^2, c^2, g^2, k^2, a^2 are the sums expended by each. Thus H purchases h hogs for h^2 shillings; E, e hogs for e^2 shillings, &c. Also 3 guineas = 63 shillings.

Observe (1) that h, e, c, g, k, a must be positive integers; and (2) that if m and n are any positive integers, such that

$$m^2 - n^2 = 63$$

or $(m+n)\ (m-n) = 9 \times 7 = 21 \times 3 = 63 \times 1$,

there are three, and only three, possible values of $m+n$ corresponding to three of $m-n$.

If $m+n=9$, $m-n=7$, which gives $m=8$, $n=1$

„ $m+n=21$, $m-n=3$, „ $m=12$, $n=9$

„ $m+n=63$, $m-n=1$, „ $m=32$, $n=31$

Suppose now m to be the price (in shillings) paid for a hog by a man, and n that paid by his wife. It follows that m may have three values, *viz.*, 8, 12, 32, corresponding respectively to three values, 1, 9, 31 of n. Also, since each man is the husband of some woman, and each woman the wife of some man, whatever arrangements may exist between the quantities h, e, c, and g, k, a, each is susceptible of three values. Any one of the quantities, h, e, c, may have a value of m, provided its corresponding quantity in the groups, g, k, a, has the corresponding value of n.

But there are two equations of condition.

$$h - k = 23 \quad . \ . \ . \ . \ . \quad (1)$$

$$e - g = 11 \quad . \ . \ . \ . \ . \quad (2)$$

Referring now to the values of m and n, we find that to satisfy

(1) we must have $h=32$, $k=9$;

. . . . (2) . . . . $e=12$, $g=1$.

We may infer from this that $c=8$, $a=31$.

But to verify our inference, substitute for h, e, k, g in the general equation

$$h^2 + e^2 + c^2 - (g^2 + k^2 + a^2) = 3 \times 63$$

the values just found, and we have

$$a^2 - c^2 = 897,$$

which can be satisfied with no other possible values of a and c than $a=31$, $c=8$.

Having obtained the number of hogs each man and woman has purchased, we at once observe that

$h^2 - a^2 = 63$, and therefore that A is the wife of H,

$e^2 - k^2 = 63$, „ K „ E,

$c^2 - g^2 = 63$, „ G „ C.

Yours, &c., I. R. CAMPBELL.

MOCK SUNS.

[199]—On Monday, Dec. 19, 1881, between two and half-past in the afternoon, on Wandsworth Common, I saw two spectra, irregular in shape, with apparent diameters about twice that of the sun, one on each side of and apparently equidistant from the sun. They were at the same apparent height from the horizon as the sun, and, by guess, appeared to be 25° from the sun. The colour-bands were

* The young reader should try to make out the solution for himself, before reading what follows.

vertical and distinct, the red band being nearest the sun. A band of white light descended from each spectrum half way to the horizon. These bands appeared slightly curved towards one another. The sun was shining through light, ill-defined, massy clouds. FRED. W. FOSTER.

[Distance, theoretically, about 22½° from the sun.—ED.]

SHAPE OF SATURN'S SHADOW.

[200]—Is not the distorted shadow caused by the irregularity in the density of Saturn's rings? I offer this as a suggestion, because I have frequently observed most eccentric forms thrown by a strong light upon mist, totally out of drawing with the object causing the shadow,—Yours, &c., F. YBLES.

[The irregularity of the shadow may be partly due to this cause, but cannot be wholly thus explained, as Mr. Ybles will see if he considers that we see the shadow in nearly the same direction that it is thrown.—ED.]

RING OF LIGHT ROUND MOON.

[201]—Last night (Jan. 1), at 10.5 p.m., I and several others saw a complete ring of light round the moon at a distance from her of about twenty-six moons' diameters. The sky was somewhat hazy at the time, and half-an-hour later was covered with heavy clouds. If you can afford space for an explanation of this fact I shall be much obliged.—Yours, &c., E. W. P.

[What you saw was a lunar halo, caused by the refraction of the lunar rays through ice crystals. You must have considerably under-estimated its apparent distance from the moon, which would be nearer forty-two than twenty-six diameters of the moon.—ED.]

WINDMILL ILLUSION.

Referring to the letter 161, p. 187, I dare say you will remember, at Cambridge, another "illusion," whose discovery was ascribed to Dr. Whewell—viz., look from a point about a quarter of a mile distant, edgeways, at the sails of a windmill in rotation, and you can make them go whichever way you please. THOS. S. BAZLEY.

[So also, if any one at some like distance whirls round a ball attached to a string, the plane of the ball's motion being aslant, so that the ball seems to describe an ellipse, it is difficult to tell which way the ball is travelling, when the distance prevents us from seeing whether it passes on the nearer or farther side of the swinger, when lowest.—ED.]

RICHTER'S DREAM.

[202]—When lecturing at Sheffield in connection with the Gilchrist Fund, you, on two occasions, concluded your lectures with a splendid recitation about an angel taking a man through the realms of space. Will you kindly inform me who is the author of the poem, where I can obtain it, and—if it be not asking too much—the price? I have been told it is one of Jean Paul Richter's "Rhapsodies," and have ordered it at my booksellers, but he could not obtain it for me, though he tried for several weeks. I suppose you would consider it too long to find a place in KNOWLEDGE.—J. W. STANIFORTH.—[It is given in my book, "The Stars and the Universe" (Longmans), also in Mitchell's "Stellar and Planetary Worlds."—ED.]

POPULAR FALLACIES.

[203]—The letter of your correspondent "X." (No. 136, page 188) affords the opportunity of suggesting that KNOWLEDGE might advantageously publish an article or two on "Popular Fallacies," with a view to the destruction of some of the many time-honoured but baseless notions which, handed down from generation to generation, even amongst the fairly educated classes, are accepted without investigation, and believed in with the firmest faith. As examples, I might point to the common practice of placing the poker cunningly over a dull or dying fire, with the idea that "it will draw it up," to the frequently expressed belief in the maleficent influence exercised by the moon when "lying on its back" (whatever that may mean) on the weather, &c.

In the meantime, however, let me advise "X.'s" housemaid to bestow as much care on her fire when the sun shines as when the day is dark and cold, and she need not then fear its going out. I am a pretty regular smoker myself, but I have never yet observed my cigar manifest a greater tendency to go out in sunshine than in cloud.

I suppose that the notion of the sun putting the fire out has arisen from the fact that the brilliancy of the sun's rays overpowers the feeble light of the fire. Let "X." light an ordinary spirit lamp in the sunshine. He will hardly see the flame at all. But if he will put his finger where the flame should be, he will, I think, be less inclined to believe that "bright sunlight interferes with ordinary combustion" than he now professes to be.—Yours, &c. WM. H. A.

GHOSTS.

[204]—Referring to your article on this subject (p. 183, Dec. 30, 1881) with an extract from Dr. Wilson's work, may I ask if all the ghosts, of whose appearance we have well authenticated accounts, are to be accounted for on the principle of the "physical derangement" of the person who saw them? How many such accounts we have of persons seeing an individual exactly at the time of his death, though the said individual was miles away at the time, and had not been thought about for years. Lord Brougham, for instance, made an agreement when a young man at college with a friend, that whichever died first should appear to the other, and very many years aftewards was startled by an apparition of his friend, just at the time of his death.—Yours, &c., EBENEZER KELBY.

[205]—Will Professor Andrew Wilson kindly explain how he reconciles the case of the War Office ghost with his disbelief in ghosts? In that case I think three friends in different parts of England saw the deceased officer at the corrected date of his death abroad. T. D.

COMMUNICATION WITH THE MOON.

[206]—I have seen it stated that a French philosopher suggested the possibility of communicating with the inhabitants of the moon, if such there were, by means of mathematical figures, constructed on a very large scale, in some such region as the Desert of Sahara, Siberia, or the like. Can any readers of KNOWLEDGE give me information as to this idea, and the reasoning by which it was supported? X. DAVINE.

[Probably some reader may be able to answer "X. Davine's" question. I have not myself seen the passage he refers to, but believe it was a German, not a French writer, who suggested the idea. [I find a passage in an old number of the *Magasin Pittoresque*, running as follows:—"If the Selenites are beings endowed with reason, men may establish a system of intellectual correspondence with them. In fact, if the arts and sciences are as much advanced among them as they are amongst us, they must often have gazed on the immense globe which shines in their firmament, having an apparent surface sixteen times as great as that of the full moon as we see it. That globe is the earth on which we live. . . . . They can see our rivers, our great lakes, our chief cities. . . . . Thus, some gigantic telegraphic signal might be seen from the moon . . . What signal should be employed? to what language can we have recourse? All the signs by which we translate our thoughts are arbitrary and conventional. . . . . How are we to correspond with beings who, perhaps, have nothing in common with us but intelligence? Yet there is a method—the mathematical sciences furnish it." The writer goes on to show that if the Selenites have succeeded in constructing telescopes to see such signals as we might make, they must have also mastered the first principles of mathematics. Among the fundamental propositions is one due to Pythagoras, called the theorem of the square of the hypothenuse (*théorème du carré de l'hypothénuse*)" (viz., that the square on the longest side of a right-angled triangle is equal to the sum of the squares on the two shorter sides). He shows that if the Selenites are mathematical at all, they must have discovered this truth. "If, then," he proceeds, "we were to construct, as a German geometrician has suggested, a figure illustrating this theorem on a scale large enough to be seen by lunar telescopists, they would understand its meaning, and would probably reply with another figure, or some other signal. Then we should know that inhabitants existed in the moon, and that they were endowed with reason. Once this correspondence was started, who can say where it would end?" Our author says he sees the smile of incredulity on the lips of his readers. The idea must seem to them ridiculous, and none wonder that it had its origin in a German brain. "But do not judge too hastily:" the word impossible is hurtful to human pride; and if communication with beings in other worlds is not impossible, it must be conducted in this way, for there is no other.—ED.]

Queries.

[162]—INSTRUMENT FOR DESCRIBING ELLIPSE.—On page 160, No. 8, vol. 1, of KNOWLEDGE, Mr. Thomas Thorp gives a design in Fig. 2 of an instrument for describing ellipses. I shall esteem it a favour if he will describe the mechanism of it.—W. G. [It seemed to me clear that the stem of the instrument is intended to be held in a fixed slanting position, while the moveable branch is carried around, sliding at the same time backwards and forwards on the fixed stem. See Mr. Thorp's reply.—ED.]

[163]—SUN AT HIS NEAREST.—At what season of the year are the British Isles nearest the sun?—GEO. D. PATTERSON. [About Jan. 1, when the sun is nearest to the earth.—ED.]

[164]—NON-ACHROMATIC TELESCOPES.—Would a 3-in. OG non-achromatic telescope be of any use for a beginner, or do the tints very much affect the clearness of the object? Also is there any simple way of overcoming the difficulty?—G. W. L. [Such a telescope would be of very little use; a very small achromatic—one, perhaps, an inch in diameter—would show much more, and a great deal more conveniently. There is no way of correcting the difficulty.—ED.]

[165]—HORSERADISH.—What are the properties of horseradish, and how does it act on the gastric juice when partaken of?—T. HENEBMAN.

[166]—SHORTHAND WRITING.—Can you, or any of the readers of KNOWLEDGE, inform me which is the best system of shorthand? Has there been any system of late years which is thought an improvement on, or is more easily learnt, than Pitman's?—ENQUIRER. [There is no doubt whatever that Pitman's is the best, most easily learnt, and scientific; it is used by all the most skilful stenographers.—ED.]

[167]—STAR CATALOGUES.—Will you kindly favour me with the titles and dates of one or two star catalogues, both of ancient (comparatively) and modern dates. Is there one to be depended on of an earlier date than "Flamsteed's Catalogue of 1676?" I cannot meet with one.—ALFRED CHAMPNESS.—[Flamsteed's is the earliest reliable catalogue.—ED.]

[168]—THE MOON.—How is the absence of atmosphere and water in the moon accounted for? Lockyer, in his elementary astronomy, says that the dark portions of the moon are old ocean beds, but does not attempt to account for the disappearance of water.—G. P.—[The general belief is that, as the moon's mass has cooled, the water originally forming lunar seas has been withdrawn (soaked up as it were) into the moon's interior, the atmosphere partly following, partly entering into chemical combination with the substances forming the moon's surface. The moon probably shows the condition the earth will have attained in two or three hundred millions of years.—ED.]

[169]—LIGHT AND LANTERN.—Required names of good book or books for the study of "Light" with the use of the lantern.—J. W. STOW.

[170]—SCENTS.—What is a scent? That it is a substance, I suppose, will be generally admitted, for it is blown along by the wind. It has occurred to me that objects which emit scents do, for the most part, lose some of their weight or bulk—that is, the substance shrinks or becomes lighter, and if so it must throw off something in infinitesimally small particles or otherwise, which affect the sense of smell in animals and human kind. Please explain what is known about it. PRESTER W.

[171]—CHOANITES.—Are the flints, commonly called choanites, "silicified *sponges* from the chalk," or are they petrifactions of a higher kind of animal, an anemone (if, for instance, indeed a sponge can be called an animal at all, which seems to be doubtful with Professor Ansted)? Are sponges, similar in form and arrangement to the flints above named, found in a living state? I have never seen any; on the contrary, living specimens are similar to the sponge of commerce, and to a few only of the petrifactions; exhibiting perpendicular tubes only, not lateral or horizontal, as in choanites. Is the spiral worm round the body or cup of the choanites, a parasite or a part of the intestinal arrangement of the animal itself? I am aware that, if the worm is a parasite, such a conclusion is fatal to the idea of an anemone, for how could a parasite obtain admission into the bodily substance of an animal so organised? And some choanites are found without the worm. Nevertheless I incline to the belief that the choanite is the sea-anemone silicified. PRESTER W.

[172]—SHORTEST DAY.—Please tell me why the sun rises latest (8h. 9m.) on Dec. 29, and sets earliest (3h. 49m.) on Dec. 12, though the shortest day is Dec. 21; and also rises earliest (3h. 44m.) on June 16, and sets latest (8h. 19m.) on June 26, though the longest day is June 21.—J. E. H. P.—[These and similar anomalies arise from our using the mean sun, not the real sun, to measure civil time. At civil noon the sun's centre is not due south, except on certain days in each year, when the imaginary mean sun and the real sun are together.—ED.]

[173]—Will you tell me, does the electric circuit begin in a battery at the zinc or at the copper plate in the acidulated bath?—[Not known: any more than whether action of sun on a planet begins at the sun or at the planet.—ED.]

[174]—STUDENTS' PHILOSOPHICAL AND SCIENTIFIC SOCIETIES.—I should be much obliged if you could tell me whether there are in London any Students' Philosophical and Scientific Societies, as I should much like to belong to one.—HORACE DAVIES.

[175]—HELIX.—In a recent lecture, Mr. Spottiswoode said, "The curve fulfilling these conditions will be a helix, whose *pitch* is half a right-angle." What measurement is this? In the most ordinary form of helix, viz., a screw, the *pitch* is merely a distance, or, say, a straight line, the space between two threads, measured from apex to apex, parallel to the axis. What is this angle?—COGITO.—[Mr. Spottiswoode was, of course, quite right. The pitch of a helix is an angle, not a distance. It is the complement of the angle at which the curve is inclined to the axis.—ED.]

[176]—BRICK CLAY.—Are the blue streaks in brick clay caused by dissolved sea-weed?—M. WEBB.

[177]—THE NAUTILUS.—Is it known for what use is the gut running through the chambers of the nautilus?—M. WEBB.

[178]—SATELLITES OF JUPITER.—I have seen two of the satellites of Jupiter with my naked eyes; is that an unusual thing?—M. WEBB.—[Exceedingly.—ED.]

[179]—FAURE ACCUMULATOR.—Will you kindly tell me if the *quantity* of electricity that a Faure Accumulator can contain depends upon the size or upon the number of the lead plates? Would one or two large plates contain as much as half-a-dozen small ones?—R. P. H.

[180]—THE POLE.—Kindly state how Arctic explorers will be able to tell exactly when they reach the North Pole. How will they know that they are not some miles wide of the mark?—PILULA. [Astronomical observations showing any given star at same height all round the heavens would give their place near enough.—ED.]

[181]—BEES.—I want to keep bees, and want a list of the best honey-producing flowers to cultivate in my garden. Will you be good enough to tell me where to get this knowledge?—PILULA.

[182]—EVOLUTION.—Will Dr. Andrew Wilson or Mr. Grant Allen kindly let me know what is the probable origin of Evergreens? I have tried hard to think it out for myself, but am unable to see what advantage it is to the plant, unless it be that it gives it an opportunity of spreading while the other plants are at rest, or that the exposure to the cold makes it more hardy, and, therefore, better adapted to carry on the struggle for existence.—PLESIOSAURUS.

[183]—EFFECTS OF EFFLUVIA ON HEALTH.—In our dye works here we use a great quantity of bullock's blood, which comes to us in a highly putrid state; in fact, the smell of it at a distance of several yards from the tanks is overpowering to strangers, and causes one to cough. Is it healthy to work amongst it? This is a question which has often occurred to me, and, naturally, I look to the health of those who work during a whole day with this effluvium continually; but, instead of finding them weakly, and exhibiting symptoms of pulmonary disease, I am astonished to see them grow fat and ruddy, and in many cases persons of known weakly constitutions have improved much in health by being put to work in the dye-house.—J. MACCINSLANE.

[184]—ALMANACS AND CELESTIAL MAPS.—Could you kindly inform me through your "Correspondence Column"—1. Where can I get "Dietrichsen's and Hannay's Astronomical Almanac" [no longer published.—ED.] and "The Nautical Almanac" for 1882, and the price of each (where are they published)? [Murray, price 2s. 6d.—ED.]; 2. The publishers of "Middleton's Celestial Atlas" and of "Gall's Atlas," and the price of each?—W. HARDY.

HE that wyll wryte well in any tongue, muste folowe thys councel of Aristotle, to speake as the common people do, to thinke as wise men do: and so shoulde euery man understande hym, and the iudgment of wyse men alowe hym. Many English writers haue not done so, but vsinge straunge wordes as latin, french, and Italian, do make all thinges darke and harde.—ROGER ASCHAM, 1545.

Replies to Queries.

[55]—GREEK FUTURES.—Mr. Ernest J. Wernham points out, in answer to "Castor and Pollux," that the rules for forming Greek futures are given in Matthiæ's Greek Grammar. He kindly makes an extract, but we cannot afford space for grammar rules occupying so much space.—ED.

[105]—PRESERVATION OF FUNGI.—"J. S." may preserve fungi in the following manner:—Take 2 oz. of sul.copper, or blue vitriol, and reduce it to powder, and pour upon it a pint of boiling water, and when cold add half-a-pint of spirits-of-wine; cork it well, and call it "the pickle." To 8 pints of water add $1\frac{1}{2}$ pints of spirits of wine, and call it "the liquor." Be provided with a number of wide-mouthed bottles of different sizes, all well-fitted with corks. The fungi should be left on the table as long as possible, to allow the moisture to evaporate; they should then be placed in the pickle for three hours, or longer if necessary; then place them in the bottles intended for their reception, and fill with the liquor. They should then be well corked and sealed, and arranged in order, with their names in front of the bottles.—J. G. PATTERSON.

[109]—RAILWAY COLLISIONS.—In the worst of these accidents the carriages are "telescoped," the seats of the compartments are driven together, causing fractured legs. To avoid this, draw the legs on to the seat and clasp the knees tightly with the arms. I know of cases where this has been successfully tried.—ENGINEER.

[116]—JOHN BULL.—Dr. Arbuthnot, in his ludicrous "History of Europe," represented an Englishman as a bluff, kind-hearted, bull-headed farmer. The character he called John Bull, and since it has become the national nickname.—J. J. W.

[123]—HIGH FERMENTATION.—In this process, which is the one used in the manufacture of English beer, the yeast rises to the surface of the fermenting liquid; hence its name. It is carried on by running a wort prepared from malt, or from a mixture of malt and other saccharine bodies, into a circular vat, partially covered on top to maintain proper temperature, and to prevent access of excess of air, at about 70° Fahr. Yeast is now added, and, having a plentiful supply of the food necessary for its growth, it soon converts some of the soluble albuminous matter of the malt into protein bodies of its own structure, while at the same time it converts a small portion of the glucose sugar present into the cellulose necessary for the construction of its cells. The mother yeast, while thus reproducing itself, not having sufficient oxygen for its action, decomposes the glucose, changing it into alcohol and carbonic acid gas according to the following equation:—

$$\underset{\text{Glucose.}}{C_6 H_{12} O_6} = \underset{\text{Alcohol.}}{2 C_2 H_5 HO} + \underset{\text{Carbonic Acid.}}{2 CO_2}$$

Small quantities of glycerine, succinic acid, and other products are also formed, and the action continues, unless checked by reduction of temperature, until the whole of the saccharine matter is decomposed. "Low Fermentation." This process commences at about 50° F., and the yeast on reproduction sinks to the bottom of the liquid. It is the process mainly employed on the Continent, and beers so fermented cannot be preserved in warm or temperate weather, unless surrounded by ice. The decomposition of the saccharine matter is the same as in "high fermentation." Stahl, Willis, Liebig, and other writers considered fermentation to be due to the oxidation of complex albuminoid bodies which decompose the saccharine matters present, in order to obtain sufficient oxygen for such oxidation; but, according to Pasteur and the greatest of other modern authorities, it is due to the action of living organisms which fall accidentally into the liquid from the air, or are purposely added, as in the case of adding yeast to wort. The yeast organism is the one which sets up alcoholic fermentation, and the reason why it is artificially supplied to wort is to supersede other fermentations that may be induced by germs of another nature gaining access to the liquid by means of air. The other most common ferment germs are those which set up the lactic and butyric fermentations.—E. M. D.—[Answered in the same sense by T. G. Browne.]

[133]—I observe a correspondent inquiring where he can find the Rev. W. H. Dollinger's papers. If he will read the index to the recent volumes of the *Popular Science Review*, he will find papers by that gentleman on microscopical subjects therein noted. The "Proceedings of the Royal Society" should also give him Mr. Dollinger's papers.—ANDREW WILSON.

[137]—HUMBLE BEES.—I beg leave to state that in December, 1880, at the request of some persons in New Zealand, I shipped eighteen fertile humble bees (*Bombus Lucorum*) by the *John Elder*, one of the Orient line of steamers, to Melbourne, Messrs. F. Green & Co., the owners, kindly instructing their officers to take all needful care of them, and see to their re-shipment in the *Arawata* to New Zealand. From a newspaper (the *Timaru Herald*) sent me, I learn that two out of the eighteen arrived alive, and when released, on the morning of Feb. 5, 1881, flew away briskly to seek, as we may hope, nests in which to multiply and increase, and thus bring about that long-desired work, the fructification of red clover. I may mention that these bees were searched for and sent to me by Mr. Duncan Keir, an intelligent nurseryman at Paisley. I packed them in small boxes, and supplied a little sugar in case they might require food in a warmer latitude; but the great point is if possible to keep them dormant during the voyage, and for this purpose I placed the package under the care of the butcher, to put in his ice-house. It is well known that none other than fertile mothers hybernate. Three other humble queens were sent Jan. 20 of last year by the steamship *Norfolk*, which sailed direct to New Zealand, under precisely similar circumstances, and the supply was obtained from the same source, but no tidings concerning them have yet reached me. The experiment has not been repeated this winter, owing to the very scanty encouragement received of these and previous efforts. Your correspondent, no doubt, alludes to an attempt made some years since by the late Mr. Frank Buckland, in which I had the pleasure of giving some assistance.—ALFRED NEIGHBOUR.

[140]—ICE.—Ice contracts and expands as other solids do, by variation of temperature. This is best seen in travelling over the ice on a large lake (say Lake Winnipeg) in winter. If a cold "snap" suddenly comes on, and the temperature falls 15° or 20° in the course of the night, loud noises, like pistol shots or distant thunder, are heard; if encamped near the shore, on resuming the journey in the morning, large cracks, several feet wide, caused by contraction, will be met with, and are often difficult to cross; if the severe cold continues for a day or two, these cracks freeze up. Milder weather comes, the ice expands, and there being now more ice on the lake than before, ridges are forced up. Another period of great cold occurs, there are fresh cracks formed, with subsequent ridges when the temperature rises. These contractions and expansions, caused by changes of temperature, I believe to be an important element in the motion of glaciers.—J. RAE.

[146]—CHEMICAL.—(1). It is a property of red blood-corpuscles to absorb oxygen. This absorption changes them to bright red. Carbonous oxide can displace O, and thus acts as a poison. Nitrogen has no such power. (2). The value of carbon hydrates as food can only be estimated thus in compounds of the same class; *e.g.*, we cannot compare ether with its 22 per cent. of O, with sugar having 51 per cent., the fact being that sugar, &c., are more assimilable than many substances having less oxygen.—C. T. B.

[146]—CHEMICAL.—E. M. must remember that the "Carbohydrates" are just those bodies which contain the hydrogen and oxygen in the proportion of water—that is, in a saturated condition—none free. Cane sugar, for example, is $C_{12} H_{22} O_{11}$, in which "E. M." will find eleven times H_2O, leaving 12C to answer his purpose.—LEWIS ARUNDEL.

[147]—B.Sc. EXAMINATION, EDINBURGH UNIVERSITY.—In reply to "A Philosophical Brushmaker," I may say that attendance upon the University classes necessary for the above degree (or upon classes conducted elsewhere, but recognised by the University Court), is imperative upon candidates. Full information may be obtained in the University *Calendar*.—ANDREW WILSON.

[152]—NICKEL PLATING.—In the first part of "Amateur Work" there is a recipe for this:—Make a bath of tin tartar, boil with some grain tin, and after cooling, throw in some red-hot nickel oxide. When the solution turns green, dip in your articles (brass or copper, of course, and perfectly clean) and in five minutes they will be coated. Though I understand chemistry well, I should be glad to know what tin tartar is.—LEWIS ARUNDEL.

[153]—DOUBTFUL ORGANISMS.—The creatures you allude to are called Protista; they partake equally of the nature of the lowest animals and the lowest plants.—LEWIS ARUNDEL.

[153]—There are certain living beings—if these are what "H. J. C. W." means by "doubtful organisms"—which present in themselves a singular combination of the characters of animals and plants. Such are the Monads. If "H. J. C. W." will read Huxley's lecture on "The Border Territory between the Animal and Plant Kingdoms" (to be published in his new volume of essays, "Science and Culture"—Macmillan), he will find therein a full statement of the likenesses which exist both to animals and plants in certain of the lower forms of life—ANDREW WILSON.

[154]—Frogs are excluded from the class Reptilia (as any ordinary primer of zoology would have shown "H. J. C. W.") because they possess gills in early life. No *reptile* (*i.e.*, tortoises, snakes, lizards, and crocodiles) possesses gills at any period of existence, but breathes from the first by lungs. Frogs, newts, toads, &c., are *amphibians*. They all begin life with gills, and afterwards develop

lungs; the gills either disappearing when lungs appear (as in the frogs, toads, and newts) or persisting (as in proteus, the axolotl, &c). Frogs and other amphibians further differ from reptiles in undergoing a *metamorphosis* during their development, and in the want of scales or bony plates on the skin.—Andrew Wilson. I find what "I had always supposed" (viz., that the class Reptilia included the Amphibia, and therefore the Batrachians) is an error. (It was not given, be it noticed, as a reply.) I know, of course, that some naturalists regard the Amphibia and Reptilia as distinct classes; and I see that in Prof. Newton's primer they are so given. I know also that Linnæus's mistake in classing the abranchiate reptiles as amphibia had been corrected. But there must have been some change in classification of late, if that I mentioned has been definitely rejected; for I find Prof. Owen, in "Brande's Dictionary of Science" (1867), writing (1) under head "Reptilia," that those which retain gills during a part of their existence are called Batrachians; (2), under head "Amphibia," calling those which retain their gills during the whole of their existence peribranchiate reptiles; and (3), defining Batrachia as "an order of Reptilia, including all reptiles which, like frogs and toads, have naked skins and external branchiæ in the early stage of existence."—Ed.]

[155]—I have known of a tortoise living ten years; but I should say the duration of life is longer, especially in the larger species. I should imagine they do not remain "under the earth," in ordinary circumstances, longer than the winter or cold season.—Andrew Wilson.

[157]—Aluminium.—Any good Chemistry, as Fownes', or Watts', or Miller's, gives a full account. It is too much to expect in these pages. Spell aluminium with two i's, and emphasize the "min."—Lewis Arundel.

[170].—"E. M.," in Knowledge, for Jan. 6, thinks that the existence of parasites in meat is an argument for vegetarianism. Permit me to remind "E. M." that parasitically-infested meat is not normal meat. If "E. M.," as a vegetarian, acquired a tapeworm guest from a lettuce, he would not abjure his vegetable food, I suppose, because of his liability to infestation therefrom, any more than he would cease drinking water because some waters contain young flukes. The lesson taught by my paper is not the abjuration of flesh as an article of food, but the careful selection of healthy flesh; and, I will add, of healthy and normal food of all kinds—vegetables and drinks included. The *pros* and *cons* of vegetarianism lie quite outside your correspondent's letter and my article.—Andrew Wilson.

[180]—"An Amateur" inquires the "use" of bugs, fleas, flies, and other "apparently useless insects." He should first learn that the word "use" has a sole meaning and application (as he employs it) to human life. He should learn next that each animal and plant exists for its own sake, and independently of any "use" which men may conceive it adapted to serve. Thus "An Amateur" might as legitimately ask the use of seals, and might receive the reply "to furnish sealskin jackets for ladies;" and humming-birds might similarly be regarded as existing for the purpose of decorating ladies' hats. In a word, science can take no heed of such a question as that put by "An Amateur." Like the Smith of Perth, each animal and plant fights "for its own hand," and lives and exists independently of all human ideas of use and no use.—Andrew Wilson.

Answers to Correspondents.

*** *All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of* Knowledge, *the increasing circulation of which compels us to go to press early in the week.*

Hints to Correspondents. 1. *No questions asking for scientific information can be answered through the post.* 2. *Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries.* 3. *No queries or replies savouring of the nature of advertisements can be inserted.* 4. *Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge.* 5. *Correspondents should write on one side only of the paper, and put drawings on a separate leaf.* 6. *Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

W. A. C. Mr. Hutton points out that if we cease to eat meat we shall destroy animals more certainly and more cruelly than at present, by leaving them no vegetable food; and he is an anti-vivisectionist of the most pronounced type. We had better not insert your objections to the toad-pressing story, lest boys should try the very experiments you say the story suggests—which certainly would not have occurred to us.—A. St. Clair. We know of no French educational paper whose editor would take English stamps in payment.—W. H. H. Soames. Certainly the moon occults the planets. Such phenomena are announced in the "Nautical Almanac." The outer satellite of Jupiter often passes considerably above or below the planet. In an article we wrote in 1867 for the *Popular Science Review*, we discussed the question fully.—Fred. Blackett. Our price is small, our modesty great; beyond sending specimen copy, we would not force ourselves on your society's notice.—W. R. Bland. The proprietors consider that such notice should appear as an advertisement.—W. H. Pertwee. Arctic explorers want, I suppose, to find what there is at the Pole—land or water, greater cold or less cold, and so forth. As to the other question, evolutionists may or may not believe in the statement you refer to, or some of them may and some may not; it is no business of ours. If you had asked me what I believed on that or kindred subjects, I might have replied that it was no business of yours, which, though it would have sounded abrupt, implies something which may be usefully remembered. A man says he believes a certain scientific fact, and he is asked—without rhyme or reason—whether, so believing, he can believe something else which the inquirer says he and others regard as a truth of religion. What sensible answer can he make to a question so absurd, without being somewhat plain-spoken? To such a question, as to my belief, asked me in public at New York in 1874, I answered, "My belief is that there is a deal of nonsense in the world," and I believe still that I could not have answered the question more precisely, unless for "nonsense" I had used a stronger expression.—Frank R. Thomas. It certainly appears that "the mind is only partially active, and that the sounder part of it—the reason—is dormant when we are dreaming." You ask, "to what does this point?" We are not quite sure that we understand you. It seems to us what might very naturally be expected.—E. H. Thanks for pointing out that Newton, in his work on fluxions, described the Witch of Agnesi, calling it a "conchoidal." We agree with you that the curve cannot properly be called a quadratrix.—F. Wilson. The laws of perspective are purely geometrical, and the slightest acquaintance with geometry would show you that perspective cannot possibly account for the disappearance of a hull of a ship before its masts. The hull is unseen because there is something in the way, namely, the rotundity of the earth.—Wm. H. Allen. Thanks for extract on actinium. Very little is known yet respecting the properties of the new element. Several have been discovered since spectroscopic analysis was invented.—Desideratum. The delay you refer to is explained by the circumstance that we receive so many letters like the one signed "Desideratum."—A. Champness. We cannot reply by letter to queries, even when a stamped and directed envelope is sent.—An Inquirer. If we put in your query about cats falling on their feet, we shall have all our school-boy readers trying experiments—applying the inductive method, with projective illustrations.—Æolus. No; the Americans do *not* (we believe) "fire their storms at us out of a gun." Ships reaching America give news of storms travelling eastward across the Atlantic, which had been already traced across part of the American continent. The prediction is based on the belief that such storms will travel farther east before they die out. You are more correct as to solar heat being the cause of storms; but they may arise without the sun being "in some vagaries." The heat he pours on the earth is tolerably constant.—One who wants Knowledge asks for information respecting the manufacture of Portland cement, or titles of books relating thereto.—E. S. We have not room for your letter on primary colours. If a definition of primary colours were given, which should carefully distinguish what is physical in the matter from what is physiological, we might get more satisfactory statements. As to your questions relating to religion, I reply that to exclude religion, in its wider and nobler sense, from our columns would be to exclude science. But dogmatic religion we cannot away with. One might as reasonably speak of a Mussulman spectroscope, or of Brahminical hydrogen, as of Christian science. Science is neither Christian nor un-Christian, but extra-Christian. We do not want such matters to be treated in a calm, philosophic spirit, but simply left altogether untouched. They have no proper place here. As a mere matter of detail, we may note that they never are treated in a calm, philosophic spirit, perhaps because no calmly philosophic person would be so unwise as to treat of them at all.—Daleth. About comets' nuclei later.—Mercury. For names of Mr. Wallace's books apply to Messrs. Macmillan. They will well repay study. Read also Darwin's "Origin of Species" and "Descent of Man."—Mabel. W. Laing recommends "E. H." to read Dr. J. Reade's "Experimental Outlines for a New Theory of Colours, Light, and Vision," 1818, and W. Crum's "Experimental Inquiry into the Number and Properties of the Primary Colours," 1830 (books entirely out of date); also, if he reads Dutch, N. Folmer's "Alpha van het Alphabet der Kleuren,"

Groningen, 1875. Prof. Ogden Rood's book on "Modern Chromatics" (Kegan, Paul, & Co., price 5s.) is far better worth studying.—Ernest J. Wernham. There are many proofs, and as many disproofs, of the theory that character can be learned from the handwriting. The method has no scientific interest.—B. Donbavand. We insert one of your letters, but your last, on the colours of animals, is too long, and we have not time to abridge it. You take three pages of MS. for initial sarcasms against a valued correspondent, who has really shown a very kind desire to explain matters; another to show that "a tank naturalist must be contemptible in all the ins and outs of him"; then *possibly* you come to business. We cannot say—life is too short to get through more of such letters. Stay. We will not at once consign your letter to W.-P. basket, but only the first four pages, keeping the rest for another trial when we have refreshed ourselves with matters more *ad rem*. Understand, you are as free to say in so many words that Prof. Wilson seems angry, as he was to say that a remark of yours seemed to him silly. But we cannot find space for elaborate sarcasms. We want to get at facts, and invite our correspondents to join in the work, not to try who can say the smartest things.—M. E. Pendred. It would take much more time than we can afford to go through your letter of some score of closely-written pages, scoring out all that is not to the point; and we can only insert what is to the point.—J. H. Symington. We misunderstood you about the Collie. Excuse us.—H. A. Bulley. Lunar influence on weather is conceivable, though never shown to be really effective; but planetary influences, or the absurdities called Astrometeorology, we cannot even discuss here. We must draw the line somewhere.—Zares. Dr. Ball's experiment, of dropping one of his namesakes on the floor of a railway carriage, has altogether the advantage over yours of firing a bolt from a catapult. How did you test the horizontality of the bolt's flight, and how eliminate effects of atmospheric resistance? We are sure, when we drop a ball in a railway carriage, that its only initial motion is horizontal, and that air-resistances are the same as on a body let fall from rest.—Pilula. You are evidently not aware that advertisements of the kind cannot be refused.—C. J. Brown. "Assuming the earth's diameter to be 8,000 miles," (or 8, or 8 millions, if preferred,) the pressure is greatest at the centre.—R. W. If the solid be transparent, farther edges should be shown like nearer. The cases are different. Science finds no evidence of man's having become degraded. It does find evidence that some creatures have.—Jas. Elias. Your letter is too long for insertion; but your idea is well worth considering, that, in some cases, frog's spawn might have been deposited in some fissure where running water passed, and so a tadpole develope there, which, adapting its mode of living to its narrow surroundings, would become a frog, and might live comfortably enough. A quarryman, as you say, would not be apt to notice the fissure, and the stone would naturally split in a plane running through the cavity.—H. D. Kingdon. Quite impossible to appoint meeting.—Daniel Jackson. Gambling on the Stock Exchange is undoubtedly no better than gambling elsewhere. The two books you refer to are the "Expanse of Heaven" and "Infinities Around Us," published by Chatto.—J. K. Mellor. Thanks, but fear we can find no space for biographies at present.—Jas. Douglas. The change of eccentricity of earth's orbit, and not the precessional reeling *per se*, causes changes of climate you mention.—E. W. Will try to find room for your letter in full. In the meantime, we may note that the applications of the differential calculus to Physics are so much more difficult than those to ordinary mathematical problems, that the course pursued in books seems natural enough. Do you mean to say that, given the linear dimensions of a curve, and the length of the limits between which you integrate, you find difficulty in ascertaining the number of square inches, feet, or miles in the area? I cannot see where the difficulty comes in. In a series of papers I once wrote on the calculus for the *English Mechanic*, I showed how a number of problems in everyday life may be dealt with by means of it. The translation of the symbols into concrete quantities should be one of the first, not one of the last, things to which the student's attention is directed.—A New Subscriber. We shall presently give a description of some comets of the present century; but we must refer you to treatises on comets for an account of all, or even of the principal comets.—Pleiades. (1). It is better for querists to give their real name (not for publication), but not essential. (2). We may presently give weekly notices of astronomical phenomena. (3). No. 1 of Knowledge has now been reprinted for the third time; the proprietors are not likely to reprint again, so that if you wish for No. 1 you should apply in good time. (4.) "Abstract" in headings of letters means that we have had to abridge them.—One Wishful to Learn. Heat is not generated at the sun by his attractive action on planets. When a cord is pulled, or a bar either pulled or pushed, the heat is generated by the impressed forces, *i.e.*, comes from without.—E. B. T. Thanks, but the idea is much older than Babbage's time, or R. F. Gardiner than Rev. Mr. Hitchcock's. W. Hardy. "Dietrichsen's Almanac," no longer published; "Nautical Almanac" for 1882, 1883, 1884, and, probably, 1885, can be obtained of Murray, price 2s. 6d. each.—Florence E. Boyce. Pray excuse us for leaving your interesting communication so long unnoticed. It got lost in our troubled sea of letters, MS., &c. The proof for sum of squares is very neat.—Arthur Vizard. Your remark answered by last number. But the analysis of chess openings need not be hurried. We must not make a toil of pleasure. Chess and whist are our scientific recreations.—F. H. S. Have been obliged to limit answers to magic square questions.—J. Russell. How far should we be advanced if we agreed to regard comets as having "the same place in the inanimate solar system as is occupied by jelly-fish in the animal world?" J. Sharp. You article somewhat too diffuse, and much of its contents generally known.—Ursula. Reply to query about rainbow on page 212, second column, lines 11, &c.—Lewis Arundel. Your remarks about my replies to 153, &c., remind me somewhat of Molière's "*Nous avons changé tout cela.*" I was not answering "according to Cuvier," but according to Owen and other more recent authorities. In explanation of a certain property of worms, I referred to their being articulated. Do you conceive that when worms were formed into a sub-kingdom Vermes, they ceased to be articulated, or that the chain of ganglia I mentioned ceased to be present in their annelidan bodies? They have no articulated limbs, but they are articulated animals whether classed as Arthropoda or Vermes, whether called Abranchiate Annelidans, or common earthworms. Equally, classing toads and frogs as Batrachian Amphibia has not made them change their reptilian habits.—D. C. Jones. Recently answered.—A. T. C. Pardon me for repeating that there must have been something near or far off between the sun and the holes. In saying that the sun's light ceased to pass through the holes (there being nothing between the holes and the opposite wall at the time), you in effect say that something intercepted the sun's rays. If you insist on it that there was nothing between the sun and the blind to cast a shadow—cloud, flight of birds, or of dust, or of leaves, or flying object of some sort, near or far off—all one can say is that nothing can explain what you saw. No shadow ever yet existed without something to cast it.—Major. The illusion about letter S is well known to proof correctors. The lower half looks very much larger upside down.—C. F. B. The reason why the sun and moon appear larger when near the horizon is, I take it, because the heavens appear to form a flattened not a spherical dome, and the sun or moon subtending really the same angle when near the horizon (appreciably) seem to be nearer than the sky beyond. The eye seems to misinterpret what it actually sees, making the sun seem nearer instead of the sky seeming farther.

Notes on Art and Science.

Mr. J. H. A. Macdonald, Q.C., the late Solicitor-General for Scotland, has constructed an "electric holophote course indicator," which he has lately been exhibiting in Edinburgh. An electric light with a reflector is placed in a prominent position on the deck of the vessel, and is controlled by the movement of the helm. The direction of the powerful beam of light indicates the course of the ship, and at the same time shows whether or not the sea is clear over a large area. The model is to be shown at the Crystal Palace Exhibition.

Mr. Jacob Reese, in a paper read before the Engineers' Society of Western Pennsylvania, remarks: "The great want of the present age is a process by which the static caloric of carbon may be set free by non-luminous combustion, or, in other words, a process by which coal or oil may be oxidised at a low degree within an insulated vessel." This cannot be too prominently brought forward. "If it can be accomplished," as Mr. Reese says, "we would be able to produce from twelve to fifteen million foot pounds of electricity from one pound of petroleum, or from ten to twelve million foot pounds of energy from one pound of good coal."—*Athenæum.*

Are Bees a Nuisance?—An unusual case is being tried in the Cumberland County (Penn.) Court this week, that of testing by a jury whether the keeping of a large number of bees in a town or borough is a public nuisance or not. The case is from West Fair-

[illegible], a small town on the opposite side of the river from Harrisburg. Two citizens had about 130 skeps of bees, and as the summer was scarce of material such as the bees feed upon, they came in large numbers into the houses, stores, grape arbours, and wherever there was anything for them to feed upon. In one instance they swarmed in a neighbour's kitchen, and were there for days, he not being able to hive them, the queen being killed. They were especially bad about canning and preserving time, compelling the housewife to do her preserving in the evening, and in one instance the wife had to climb in and out of the window for days, not daring to open the doors, for the bees would go in by hundreds; persons were stung passing along the streets and highways; entire houses became infested with bees, so much so that the inmates could not retire to rest at night without being stung by the bees; trays of fruit put out for drying were entirely consumed. Indeed, a reign of terror was experienced for several months, until a committee of citizens agreed to abate the nuisance, and, after several efforts, appealed to the court. The defence claimed that the raising and keeping of bees was an industry, and as such could not come under the head of a public nuisance, and that suit could not be brought nor damages recovered for the keeping of honey-bees. The attorneys on both sides presented the opinions of several judges and the law points in the case, after which the court decided the case should be tried, and the testimony was received. But one case seems to be on record in the State, and that was tried before Judge Pearson, in Dauphin County, years ago, in which the defendant was adjudged guilty, and had to pay a fine and abate the nuisance.—*Scientific American.*

THE TAPE-WORM. Most of my readers know that the domestic pig is subject to a disease known as "measles," in which the muscles are more or less filled with *cysts*, which render the pork unfit for food; but I think few are acquainted with its cause. Man, it is well known, is occasionally infested by a parasite—the so-called "tape-worm" (*Tænia solium*)—which may be described as having a tape-like body of varying length, with a differentiated "head," or *scolex*, at one extremity. This apparently single animal is in reality a colony of mothers and daughters, the scolex being the parent of all. This "head" is provided with a *rostellum*, or, as it might be called, proboscis, encircled by a crown of hooks, below which are the suckers; each segment added to the scolex is a complete individual containing a complicated and perfect reproductive system. The last segment—*proglottides*—which are filled with eggs, break off at intervals, and either the eggs are set free within the intestine of their host, when they are passed out with the fæces, or the segments themselves are evacuated. The tape worm feeds on the juices of the bowel by absorbing the nutriment through its skin, and does not appear to seriously inconvenience its host in any way. In Abyssinia *tænia helminthosis* is constant and general; indeed the animal is there regarded as a sort of hygienic agent, and cultivated rather than discouraged, yet the people are healthy; certain it is also that wild animals, almost without exception, harbour at least one species of tape-worm as a natural condition. But what has this to do with "measles"? Now to the point. Let us suppose one of the before-mentioned eggs taken into the stomach of a pig, either by its eating the excrement of a person affected or through the water or air; here it hatches, not into a tape-worm, but into an animal of oval form, transparent, contractile, in the middle of which are six stylets arranged in pairs; with these it cuts its way through the tissues until the muscles are reached, when, having arrived at its destination, it stops burrowing and surrounds itself with a sheath. Here the stylets atrophy, a new and quite different crown of hooks is produced, and the parasite becomes a *cysticercus*, or vesicular worm, the cyst being about the size of a hazel nut. This constitutes "measles"; the exhaustion or even death attendant on the disease is caused by the scores, hundreds, or even thousands of animals boring through the tissues. Once encysted there is no further suffering or danger. The cysticercus remains encysted for months or years, or until the piece of flesh enveloping it *is introduced into the stomach of man*, in which case it instantly quits its torpid condition, leaves its sheath, makes its way to the intestine, where, attaching itself by its suckers and hooks, it grows—or rather reproduces—so rapidly, that in a few weeks a tape-worm of several yards in length is formed, which reproduces eggs, and so *ad infinitum*—from pig to man, from man to pig. Should the eggs be introduced into man himself or animal other than the hog, the cysticercus penetrates the tissues in the same manner, but it is "not at home," and instead of resting in the muscles, it makes its way to other organs, such as the brain, heart, or eye, where its presence has caused in man several instances of insanity and death. Should a piece of meat containing a vesicular worm be eaten by a pig or animal other than man, a tænia is developed, but it also is "not at home," and does not attain its full development. Both eggs and cysticerci are killed by a temperature of 200° Fah., so there is no danger in eating well-cooked pork, even if it contains cysticerci. To prevent hogs contracting "measles," it is only necessary to prevent them having access, either through their food or water, to the secretions of man, and they will not suffer. Throughout the genius *Tænia* we find this dual life; for instance, the cat has a tape-worm, the cysticercus of which she gets from the mouse; and the dog one which he obtains from the sheep.—*Scientific American.*

Our Mathematical Column.

ALGEBRAICAL EQUATION. — In reply to "E. H.," there is no method of solving the equation

$$\sqrt{100-y^2} + \sqrt{8y-64} - 6 = 0$$

other than by reducing it to a cubic, and applying one of the approximate methods to the resulting equation. We get by squaring both sides, &c.,

$$y^4 + 16y^3 - 192y^2 - 3200y + 25600 = 0$$
$$\text{or } y^3(y-8) + 24y(y-8) - 3200(y-8) = 0$$
$$\text{Whence } y = 8, \text{ and } y^3 + 24y - 3200 = 0$$

As "E. H." points out, 9·74 is an approximate root of this equation. The other roots are imaginary.—ED.

[12]—"F. B.," admitting that if $\Sigma_n = \frac{2n\,(2n-1)\,\ldots\,(2n+1)}{1\,.\,2\,.\,3\,\ldots\,n}$,

$$\Sigma_n + 1 = \Sigma_n \left[\frac{2(2n+1)}{n+1}\right]$$

asks whether we might not at once conclude from this that if

$$S_n = 1 + n^2 + \left[\frac{n(n-1)}{1.2}\right]^2 + \&c. + n^2 + 1,$$

and it can be shown that

$$S_n + 1 = S_n \left[\frac{2(n+1)}{n+1}\right]$$

then $\Sigma_n = S_n$.

We might, if we could prove the relation in question, but we must do this first. How does "F. B." propose to show that when n becomes $n+1$ in the expression for S_n, the result, or $S_n + 1$, is equal to S_n multiplied by $\frac{2(2n+1)}{n+1}$? It is easy to infer this after showing that $\Sigma_n = S_n$, but as a step towards proving this it is not at all easy.—ED.

SQUARE AND CUBE NUMBERS.—J. A. Miles sends the following, respecting some curious properties of square and cube numbers:—

The first term of an arithmetical progression of n terms having a common difference d, and whose sum is n^a is equal to

$$n^{a-1} + \frac{d}{2}(1-n).—$$

If $S = n^2$, the first term is $= n + \frac{d}{2}(1-n)$—

Every square n^2 is the sum of an arithmetical progression of n terms, the first term of which is unity, and the difference 2.

Every square n^2 is the sum of an arithmetical progression of n terms, the first term of which is $\frac{n+1}{2}$ and the common difference 1.

If $S = n^3$, the first term is

$$= n^2 + \frac{d}{2}(1-n)$$

Every cube n^3 is the sum of an arithmetical progression of n terms, the first term of which is unity, and the common difference $2.(n+1)$.

Every cube n^3 is the sum of an arithmetical progression of n terms, the first term of which is the root n, and the difference $2n$.

Every cube n^3 is the sum of an arithmetical progression of n terms, the first term of which is $n^2 - n + 1$, and the difference 2.

Every cube n^3 is the sum of an arithmetical progression of n terms, the first term of which is a triangular number $\frac{n^2+n}{2}$, and the difference $= n$.

Every cube n^3 above 1 is the sum of an arithmetical progression of n terms, the first term of which is $(n-2)^2$, and the difference $= 8$.

THE LEAD (*Continued*)

LEADING AN ACE (PLAIN SUITS).

WE omitted to mention one case—quite exceptional—when an Ace is led from Ace, King, and others. This is dealt with in the next section.

LEADING A KING (PLAIN SUITS).

From a long suit, or from a suit of three at least, King is only lead under two conditions, viz:—

(1) From Ace, King, and others.

(2) From King, Queen, and others.

In the case of a forced lead from King and one other, the King is always led.

Here we may answer a question often asked by young players when corrected for leading Ace from Ace, King, and others. What difference can it make, they ask, seeing that both cards are of equal strength? To this they add sometimes that as it is a recognised rule to lead the highest of a sequence (following suit with the lowest) there seems a disadvantage in making what appears like an unnecessary exception.

So far as making the strong cards of your suit is concerned, it is a matter of indifference whether you lead Ace or King. But if you follow the rule of leading King from King, Ace and others, you enable your partner to understand you better. You make your Ace leads more intelligible. If you led Ace uniformly from Ace King, an Ace lead might mean any one of three things; (i.) Ace four or more, (ii.) Ace, Queen, Knave, with or without others, and (iii.) Ace, King, and others. Your partner would often be in doubt which of the three you led from; whereas he can scarcely ever be in doubt which of the two ordinary cases is in question, even though you should be unable to follow up your lead.

As for the lead of King from Ace, King, and others being an exception to the useful general rule, "lead the highest from a sequence," the point is of no importance; for the exception is not one that can ever cause any confusion. In fact, it is becoming a recognised whist principle, that one of the great uses of general rules is that they afford an opportunity for giving your partner information, by departing from them in certain recognised cases. Of this we saw an example last week, in the lead second round from Ace, Queen, Knave, with or without others. After winning with the Ace, the Queen would be the proper lead, if we followed the general rule of leading the highest of a sequence. When the original suit is only of moderate length, (three or four) the Queen is led; but when the suit is of more than average length (five or more) we depart from the rule, and lead Knave second round. Thus, whether we follow the general rule, or depart from it, we give our partner information, yet without in any way affecting the strength of our suit.

There is one case, and one only, in which from Ace, King, and others, Ace should be led:—

If, before getting the lead, we have trumped in one suit, and should then lead King of another suit, our partner, if he had no cards in the suit (a contingency always to be considered) might see an opportunity of establishing a cross ruff or see-saw, by which, perhaps, four or five tricks might be made. He would, therefore, trump your King, considering that Ace might lie with fourth player, and lead the suit which you had trumped. To avoid this, you lead in such a case your Ace first, then your King.

When a King has been led first round, your partner knows from the way the cards fall whether the lead was from Ace, King, and others, or from King, Queen, and others. If you have led from King, Queen, and he does not himself hold Ace, one of the opponents will cover your King with Ace. If it passes, he knows you have Ace. But as a matter of fact, no one at the table remains in doubt about the meaning of a King lead, unless the King is trumped. For if the King makes, Ace follows at once if the lead was from Ace, King; and a small card if the lead was from King, Queen (in which case, of course—the first round having passed—the Ace is with partner).

Thus, just as when the Ace is led, in any case except that of a forced lead, the second round at once shows which of those two suits from which Ace should be led has actually been opened; so is it when a King is led—we can always tell from the second round at latest what suit has been led from—Ace, King, and others, or King, Queen, and others.

There is one exception—very seldom advisable in plain suits—viz., when the King is led from Ace, King, Knave, with or without others. Then leader sometimes changes suit, that he may be led up to and finesse with the Knave.

LEADING QUEEN (PLAIN SUITS).

The Queen is led from a long suit, or from a suit of three, at least, only in the following cases:

(1) Queen, Knave, ten, with or without small ones.

(2) Queen, Knave, and one small one.

In the case of a forced lead from Queen and one other, the Queen is always led.

After Queen from suit (1), Knave is led, if there is only one card or none below the ten; ten if there are more.

LEADING KNAVE (PLAIN SUITS).

The Knave is led from a long suit, or from a suit of three, at least, only in the following cases:

(1) Knave, ten, nine, with or without others.

(2) Knave, ten, and one small one.

In the case of a forced lead from Knave and one other, Knave is always led.

After Knave from suit (1), ten is led if there is only one card or none below the nine; nine if there are more.

LEADING TEN (PLAIN SUITS).

Ten is only led in the case of a forced lead from ten one other, or from ten two others.

LEADING A SMALL CARD (PLAIN SUITS).

A small card is led from Ace, two or three small ones (except by continental players, who lead Ace, as already mentioned, from Ace three small ones); from King and others, not including Queen; from Queen, Knave, and small ones (two or more), from Queen or Knave and small ones; from ten and small ones (three at least); from a suit of four small ones, when the lowest is played; and from a suit of fewer than four (a forced lead), when the highest is played. N.B.—From a suit of five cards or more, not headed by the Ace, the lowest but one is played. This lead is called the *Penultimate*.

2. B. to K.B.3.	2. P. moves, or takes Kt.
3. B. or Kt. Mates acc.	

Problem No. 8, p. 190.

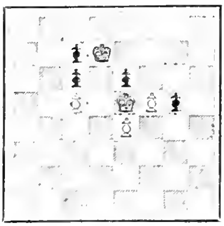
White.	Black.
1. B. to Q Kt.6.	1. P. takes B.
2. B. to Q.B.1.	2. P. moves.
3. B. Mates.	

TWO END GAMES.

THE following end-game has been sent to us by Mr. A. J. Maas. We leave it for awhile as an exercise to our readers. It occurred in actual play:—

Problem, No. 9.

Black.



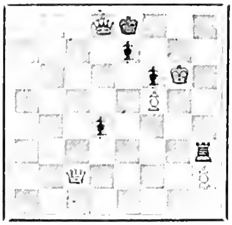
White.

White to play and win.

[T]he following end-game, Mr. Morphy (white), who had given [o]dds of a rook, drew the game.

PROBLEM No. 10.

BLACK.



WHITE.

White to play and draw.

GAME No. 6.

Played in the International Tournament at Berlin, on the 15th of September, 1881.

RUY LOPEZ.

WHITE.	BLACK.
Herr S. Winawer.	Dr. C. Schmid.
1. P. to K.4.	P. to K.4.
2. Kt. to K.B.3.	Kt. to Q.B.3.
3. B. to Q.Kt.5.	Kt. to K.B.3. (a)
4. Castles.	Kt. takes K.P.
5. Q. to K.2.	Kt. to Q 3 (b)
6. B. takes Kt.	Q.P. takes B.
7. Q. takes P.ch.	Q. to K.2.
8. Q. to Q.R 5 (c)	B. to K.3.
9. P. to Q.3.	Kt. to B.4. (d)
10. B to B.4. (e)	Castles (f)
11. Q takes R.P.	Q. to Q.Kt.5.
12. Kt. to K.5 (g)	Black resigns.

(*Sonntagsblatt*, Berlin.)

NOTES BY MEPHISTO.

(a) The defence of P. to Q.R.3. justly deserves preference to the move in the text. It leads to a safe development, for after 4. $\frac{\text{B. to R.4.}}{\text{Kt. to K.B.3.}}$ 5. $\frac{\text{Castles.}}{\text{Kt. takes P.}}$, this Knight, on being attacked, can retire to B.4., attacking the Bishop, and thereby gaining time.

(b) This move must be condemned on principle; it blocks Black's game entirely. Kt. to K.B.3. is the proper move.

(c) This move, which to some might look rather strange, was played to prevent Black from Castling on the Queen's side, as that was his intention; it will be seen that this, though only a small amount of forethought on the part of White, opened the door to a large amount of luck.

(d) As pointed out by the *Sonntagsblatt*, it would not have been feasable for Black to play 9.P. to K.Kt.3 with the intention of preparing to Castle on the King's side, as White would have replied with 10. $\frac{\text{B. to K.Kt.5}}{\text{P. to K.B.3.}}$ 11. $\frac{\text{Kt. to Q 4}}{\text{P. takes B.}}$ 12. $\frac{\text{Kt. takes B.}}{}$ and the Queen cannot retake on account of R. to K.sq. If in reply to 10 B. to K Kt.5. Black should play Q. to Q.2, then White continues with B. to B.6. Black's best course would have been to play P. to Q.R.3. and then Castle.

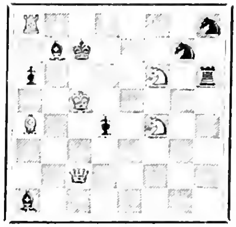
(e) Taking proper advantage of the position. The Knight back to Q 3. was about the only thing to save the Pawn, for if P. to Q.Kt.3., then the Pawns on the Queen's side would be weakened still more by Q. to R.4.

(f) The idea of Black in giving up the Rook's Pawn was to play Q. to Q.Kt.5. thinking that the Bishop would be compelled to retire, which Black would follow up by B. to Q.B.4. getting an attack. Checking with the Queen would obviously have been bad, *i.e.*, 11. $\frac{\text{Q takes R P.}}{\text{Q. to Q.Kt 5}}$ 12. $\frac{\text{Q to R.8.ch.}}{\text{K. to Q.2.}}$ 13. $\frac{\text{Kt. to K.5.ch.}}{\text{K. to K.sq.}}$ and White would lose a piece. Black, however, overlooked the force of 12. Kt to K 5. at once, which proved fatal. The whole idea of Black of exposing himself to the great danger of the position, for the purpose of extricating his game, was unsound. In chess, as in everything else, you must not indulge in such risky speculations; no move ought to be made but what a sound judgment would approve, as otherwise an unseen danger, or an overlooked resource, is almost sure to aid your adversary in demolishing your unsound speculation; though in many instances, it might be highly ingenious, and, in a few instances, might succeed, only as an exception to prove the rule.

(g) There is nothing to save Black's game. This is a remarkable collapse of a first-class player, of which there were a good many instances at Berlin. Dr. Schmid played Black, and we apprehend he must have also looked black, after White's 12th move—a rather remarkable instance of a Smith turning into a Blacksmith during a chess game of 12 moves.

Problem No. 11. By Herr Gunsberg.
(From the "Westminster Papers.")

BLACK.



WHITE.

White to play and mate in three moves.

Solutions of problems 6, 7, and 8, by G. W. Middleton, T. H. Symington, J. K. L., Gamma, Try Try Again, S.D.P., R.M., Afternoon, Etoniensis, correct. Of problem 8, by J. A. Miles, Arcadian, and See Saw, correct.

ALPHA BETA.—The solution you send of problem 5 is based on an incorrect idea as to the nature of chess problems. When mate is to be given in three moves, what is meant is, that against the best possible defence White is to give mate on his third move. You have shown how, after a certain move by White, and a certain reply by Black, White can mate. But after White, 1.B. to K.R.3., Black can play Knight to K.R.5.ch., and there is no mate either on the move, or in several more moves.

Contents of KNOWLEDGE *No.* 10.

NOTICES.

The Publishers beg to announce that in future Monthly Parts of KNOWLEDGE will be issued. The following are now published:—

PART I.—(November, 1881.) Containing the first four numbers. Price 10d. Post-free, 1s.

PART II.—(December, 1881.) Containing five numbers. Price 1s. Post-free, 1s. 2d.

The Back Numbers of KNOWLEDGE are now in print, and can be obtained from all booksellers and newsagents, or direct from the Publishers. Should any difficulty arise in obtaining the paper, an application to the Publishers is respectfully requested.

TERMS OF SUBSCRIPTION.

The terms of Annual Subscription to KNOWLEDGE are as follows:—

	s.	d.
To any address in the United Kingdom	10	10
To the Continent, Australia, New Zealand, South Africa, Canada, and the United States of America	13	0
To the East Indies, China, &c. (*via* Brindisi)	15	2

All subscriptions are payable in advance.

P. O. Orders and cheques should be made payable to the Publishers, MESSRS. WYMAN & SONS, London, at the High Holborn District Post-office.

Contents of No. 12.

PROFESSOR YOUNG ON THE SUN.

PROFESSOR YOUNG, although no one would imagine it from the book before us, is one of those to whom we owe some of the most important of the discoveries which, during the last few years, have added so much to our knowledge of the sun. It is well that we should have treatises such as this from the workers themselves to whom our knowledge is due. For, though the most skilful observers are not always the ablest either in dealing with known facts and deducing sound theories from them, or in presenting them to the unscientific world, there is always in their writings a special value and something of the charm which we find in accounts of travel by those who have seen what they describe. Professor Young, however, possesses much more than mere observing skill. He is a sound and careful reasoner, and if there is a certain terseness and preciseness (more than mere precision) in his writing, which detracts a little from its literary charm, this has probably been rendered necessary by the limited nature of the space at his disposal, and in no sense deprives his work of its claim to be regarded as exceedingly well written. This treatise possesses also another quality, very important, we conceive, in astronomical writing.* Professor Young is a mathematician, and the formulas he gives, even when they are not of his own devising, are given with adequate understanding of their meaning and value, which, unfortunately, has not been the case with all the treatises on astronomy recently published.

Taking first Professor Young's treatment of the dimensions, mass, and power of the sun, we note that he adopts for the sun's distance an estimate very near that which the labours of his countryman, Professor Newcomb, seem to indicate as nearest to correctness, viz.: 92,885,000 miles, with a probable error of about a quarter per cent., or 225,000 miles. This would correspond with a mean equatorial horizontal solar parallax of 8″·80, or, in untechnical terms, the earth seen from the sun at his mean distance, would have an apparent maximum diameter of 17″·60 (about one 106th part of the apparent mean diameter of the moon or of the sun as we see these orbs from the earth.)* We may note in passing, that in comparing the methods of determining the sun's distance by observations of Mars on the stellar heavens and of Venus in transit, Professor Young omits to notice that whereas the full displacement of Mars, as seen from different parts of the earth, is available, the displacement of Venus on the sun's disc is only a part of her actual displacement, the sun himself being displaced (roughly, only about seven-tenths of the displacement of Venus is available). His account of the American photographic method of observing the transit of Venus is full of interest, though calculated to make Englishmen somewhat ashamed of the relatively unscientific method which (despite good advice to the contrary) was adopted at the English stations.

The mass of the sun, deduced from this estimate of the distance, is about 330,000 times that of the earth. Expressing this in tons, Professor Young uses what we take to be the erroneous American system of notation, saying that the earth's mass amounts to about two octillions of tons, where we should say two thousand trillions of tons. Respecting the sun's attractive power, as exerted on the earth, Professor Young quotes the following impressive illustration from a recent calculation by Mr. Warring:—"We may imagine gravitation to cease, and to be replaced by a material bond of some sort, holding the earth to the sun, and keeping her in her orbit. If, now, we suppose this connection to consist of a web of steel wires, each as large as the heaviest telegraph wires used (No. 1), then, to replace the sun's attraction, these wires would have to cover the whole sunward hemisphere of our globe about as thickly as blades of grass upon a lawn. It would require nine to each square inch."

It should be added, however, and still further enhances our conceptions of the sun's might, that were the connection between the sun and earth of this nature—that is, by steel wires—more than three hundred days would be required to make the pull of the sun felt at the earth. The action of gravity is exerted certainly in less than a second. In fact, the most careful observation of the planet's motions reveals no evidence that gravity takes even any appreciable time at all in traversing the spaces separating the various members of the solar system from each other. This apparent instantaneity of the action of gravity is one of the greatest mysteries known to science.

Sir John Herschel has well remarked that Giant Size and Giant Strength are little without Giant Benevolence. It is the light poured forth by the sun on the planets, the heat whereby he nourishes them, more than his vast bulk and his mighty mass which fit him to be the central ruler

"The Sun." By C. A. Young, Professor of Astronomy in the College of New Jersey. (Messrs. Appleton & Co., New York.)

* "To borrow the curious illustration of Professor Mendenhall," says Professor Young, "if we could imagine an infant with an arm long enough to enable him to touch the sun and burn himself, he would die of old age before the pain could reach him, since, according to the experiments of Helmholtz and others, a nervous shock is communicated only at the rate of about 100 feet per second, or 1,637 miles a day, and would need more than 150 years to make the journey. Sound would do it in about 14 years if it could be transmitted through celestial space, and a cannon-ball in about 9, if it were to move uniformly with the same speed as when it left the muzzle of the gun." These illustrations are striking—we have seldom used them in lecturing on the sun without noticing that they produce a strong impression on the audience. But we find another illustration in the book before us, still more impressive. While the earth is travelling 20 miles along her circular path, her path deviates from the tangent at the first point of the arc of 20 miles by only one-eighth of an inch. This is the distance which the sun, with all his tremendous attractive energy, draws the earth towards him in a second of time.

of a scheme of circling worlds. It is estimated that the intensity of sunlight at the sun's surface exceeds 19,000 times that of a candle flame; 5,300 times that of metal in a Bessemer converter, 146 times that of the calcium light; 3·4 times that of the electric arc at its greatest attainable brilliancy. The heat emitted by the sun in every second of time is as much as would be obtained by the consumption of 16,136 billions (millions of millions) of tons of coal per second.

Passing to the consideration of the aspect of the mighty globe, which thus rules, lights, and nourishes the earth and her fellow planets, we find in this treatise one of the most complete, though concise, accounts of telescopic study of the sun which has yet been published. The nature and appearance of the spots, the faculæ and the granules, the way in which the spots are formed, vary in structure and disappear, their motions in different solar latitudes, and other phenomena of interest, are described succinctly and reasoned upon with skill and caution. We must leave, however, our remarks on this important part of Professor Young's subject to another occasion.

PRECESSION OF THE EQUINOXES.

By the Editor.

Since the whole globe of the earth reels in the way described in No. 11, while the sphere of the fixed stars remains all the while unchanged in position, the poles of the heavens (the points towards which the axis of the earth is directed) must move in circles around the poles of the ecliptic (the points towards which a perpendicular to the plane of the earth's motion is directed). The inclination of the earth's axis being about $23\frac{1}{2}°$, the circles thus described by the poles have an arc diameter of about 47°. In our illustrative map we show a part of the circle described by the north pole of the heavens around the pole of the ecliptic. This part shows the course pursued by the pole from between five and six thousand years B.C. to about 8500 A.D.

We must, however, note two circumstances in the part of the North Pole's path thus given. There is a reeling motion due to what is called nutation, a sort of small reel executed in about eighteen and a half years, the effect of which is to make the course of the pole wavy, instead of the simple circular path we have shown; this does not much affect the accuracy of the picture. There is another and somewhat more important correction, which would not, indeed, make much difference in our map, but in a map of the pole's course, on a larger scale, would have to be taken into account. The pole of the ecliptic is itself moving. The plane of the earth's path is slightly inclined to the median plane—the so-called invariable plane—of the solar system. This invariable plane is nearly coincident with the plane of Jupiter's orbit, but not quite. It crosses the ecliptic ascendingly, in about longitude 103°, and is inclined to that plane at an angle of about 1° $35\frac{1}{2}'$ (the plane of Jupiter's orbit crosses the ecliptic ascendingly in longitude 99°, and is inclined to it at an angle of about 1° $18\frac{2}{3}'$). The pole of the ecliptic describes then a small circle about the pole of the invariable plane, this small circle having a diameter of about 3° 11′. The time of circuit is not as yet known, because of uncertainties which exist as to the exact masses of the members of the solar system. Suffice it here to notice that, owing to this change, it is calculated that, during the last 3,000 years, the pole of the ecliptic has diminished its distance from the pole of the equator by about 25′. That the physical theory is not far from correctness is shown by the circumstance that, from observations made by Tcheou King 1,100 years before the Christian era, the obliquity would seem to have been then about 26′ greater than at present.

Apart from this slight change, the path shown for the pole in our illustrative map is sufficiently near to correctness. We note that the only conspicuous star which has been very near the pole during the last five or six thousand years is the star Alpha Draconis, or Thuban, yet this star must have been far more conspicuous in Bayer's time (still more, therefore, in all probability, in the time when it was the Pole Star) than it is in our own; for Bayer lettered the stars in each constellation in the order of their brightness, as nearly as he could estimate that order with the comparatively rough light-measuring methods available in his time; and the most cursory study of the stars of the Dragon shows that both Beta and Gamma are now much brighter than Alpha.

Thuban was nearest the pole about 2,700 years ago; but, of course, it was the Pole Star for a long time before and after the period when it was nearest the pole (just as Alpha of the Little Bear is now the Pole Star, though some 300 years will elapse before it is at its nearest to the pole). In dealing with the Great Pyramid, and trying to determine when it was built, it is not the time when Thuban was nearest the pole that we have to consider, but the time when it was at a certain definite distance (about 3° 10′) from the pole. Now, a study of the pole curve in our map shows that the star Thuban was at this distance from the pole (about $\frac{11}{15}$ths of the distance between the successive circular lines in the map) at two epochs. We open out a pair of compasses to the distance just named, and placing one point on α Draconis, describe with the other a circle; this will cut the path of the pole in two points, one corresponding to about 3350 B.C., the other to about 2170 B.C. Either of these would correspond with the position of the descending passage in the Great Pyramid; but Egyptologists tell us there can absolutely be no doubt that the later epoch is far too late. If, then, we regard the slant passage as intended to bear on the Pole Star at its sub-polar passage, we get the date of the Pyramid assigned as about 3350 years B.C., with a probable limit of error of not more than 200 years either way.

Be this as it may, we know that in the past the constellation of the Dragon was at the pole or boss of the celestial sphere. In stellar temples, like those of which Rawlinson gives examples, the Dragon would be the uppermost or ruling constellation. And here, in passing, it may interest the reader to note that some find evidence in this relation, that when writers of old spoke of the Old Dragon as having been cast from heaven, carrying two-thirds of the celestial

---

* Fellows of the Astronomical Society will remember, with some amusement, how, a few years ago, Lieut.-Col. Drayson (a mathematician of some skill) gravely told astronomers of the observed diminution of the ecliptic obliquity, as if it were some unexplained change, instead of being one of the most beautiful confirmations of the theory of gravity. On the one hand are the calculated effects of the perturbing action of the several planets; on the other, an observed change, precisely corresponding with calculation; yet, instead of "confirmation strong" of accepted views, Col. Drayson could only find a source of perplexity. On this imaginary difficulty he based an entirely impossible theory of the glacial period. Yet, when he described his views about the changing obliquity of the ecliptic, one of the greatest mathematicians living explained to him that the change he found so perplexing was a necessary consequence of the action of gravity. He had been too many years fostering his delusions to give them up. Such is the birth and growth of paradoxes: an error which could have been readily corrected at the outset, sets a man wasting years of labour in developing a false theory; and when, at last, his error is corrected, he is too much in love with his own work to give the error up.

beings with him, reference was made (unconsciously, perhaps, on the narrator's part) to some tradition of the passing away or fall of the Dragon from its former ruling position among the constellations. Those who thus interpret ancient records (much more ancient than Jewish history) find in Hercules, with his heel assailed by the serpent, as in our constellation figures, the first Adam; in Ophiuchus, the serpent holder, the second Adam. In Argo they find the Ark—in fact, in a whole series of constellations they find the story of the Flood. In Aquarius, with the streams pouring from his water jug, they find the beginning of the Flood. In the river Eridanus and the seas in which Pisces and the great sea monster, Cetus, seem to swim, they see pictured the prevalence of deep water over the whole earth. The Raven of the heavens is the Raven of the Flood-narrative. Argo is the Ark, shown as if only the stern half of a great ship lodged in the mountain. The Centaur, bearing sacrifice, as Aratus says, to Ara, the altar, is Noah offering sacrifice after he had left the Ark; and the Bow of Sagittarius in the smoke (the Milky Way) which seems to ascend from the altar,—

Ara ferens thuris, stellis imitantibus, ignem,—

is the Bow of the Promise.

These may, of course, only be fancies, but it is singular how closely these constellations, which are among the few really seeming to picture recognisable objects in the heavens, correspond in sequence and in range of right ascension with the events recorded respecting the Flood. For my own part, I am not of those who wonder that the ancients should have seen figures of the animals and other objects with which they were familiar in the heavens. From my boyhood upwards (and the boyhood of the individual is like the childhood of the race) I have seen figures among the stars, the figures being always such as I was familiar with. Even so late as my recent visit to the southern hemisphere, I found that almost despite myself the novel-looking star groups formed figures* with which I was ever after compelled to associate them; and I cannot doubt that it was the same with the childhood of the human race. There is certainly a well-shaped ship where Argo was seen by the ancients; the water streams of Aquarius and Eridanus are distinctly visible; Ara is a well-shaped altar; and though at present the figure of the Centaur (the man part) is not so upright as it was before precession had tilted it over (as it has the ship), we can still see there the figure of a portly man bearing something towards the altar. The bow is clearly seen, and nothing can be better in accidental picturing than the curling streams of smoke (figured in the stars of the Milky Way), which seem to ascend from the flat summit of the altar.

But precession has altered the configuration of all the star-groups as seen when most favourably situated for observation. Take a star globe, and, holding it with one forefinger near Thuban (Alpha Draconis), and the other at the opposite point of the sphere, notice the constellations as they slowly rotate. Note how steadily the ship sails past its highest point, on upright keel; how upright the Centaur and the Altar;* and how many groups, now almost unrecognisable, are seen in their new aspect to be fairly entitled to the names which the ancients bestowed upon them.

* I had always expected, from Sir John Herschel's description, to find Orion when inverted, as we see him in the southern skies, a very noble and impressive figure. But the very first time I so saw it, I immediately recognised in the figure, Clive Newcome's picture of Fred Bayham, and I never afterwards saw the constellation without at once seeing in it that ridiculous figure. When people tell me they cannot see a Bear in Ursa Major, I can only wonder at their blindness; the head of the bear being to me as obvious and as obviously ursine as a group of stars could well be.

* Only the modern figure of the Altar is absurdly drawn upside down. In old globes and charts we find it properly drawn.

SEEING THROUGH THE HAND.

AN OPTICAL ILLUSION.

By Thomas Foster.

There is a series of illusions affecting the apparent shapes and positions of solid figures—not only regular geometrical figures, as prisms, parallelopipeds, &c., but all solids whatever—drawn as if formed of a transparent material, so that their farther as well as their nearer outlines or edges can be seen. It can be readily shown that there is a law connecting in every case the false figure with the real figure. I have prepared a paper on illusions of this sort, with suitable illustrations, and another paper with illustrations on some curious cases of apparent motion in sets of concentric circles. But these and other papers on illusions are, it appears, kept over for the present by the pressure of other matter. [Circles next week.—Ed.]

In the meantime, I wish to submit to readers of Knowledge (as occupying less space) an illusion which seems to me exceedingly instructive, as bearing on the question how we see. Everyone knows that the eye itself is simply the organ by which the optical nerve is affected by light, and that it is by this nerve that the brain becomes cognisant of these light effects, the brain interpreting the messages brought along the optical nerve into information respecting the objects of sight.

Now the two eyes, and the optical nerves which extend to each, convey at all times different messages to the brain, which yet, as a rule, combines the two sets of messages into a consistent account (so to speak) of what is seen with both eyes. Even when the eyes differ in focal length, so that, as separately analysed, the views obtained by the two eyes are utterly unlike, the mind is very seldom perplexed by the two different accounts conveyed to it. But in the following experiment the eyes entirely deceive the mind, conveying to it the absurd impression that there is a hole right through the palm of the hand, or of a book or other opaque object which may replace the hand in the experiment.

Roll a sheet of card or paper (or the number of Knowledge now in your hand) into a tube nine or ten inches long, and about an inch in diameter. Holding this tube with the right hand, say, look through it with the right eye, while the left hand is held six or seven inches from the eye, the palm facing you, and touching the tube a little below the lowest joint of the little finger, that is, at about the level of the middle of the palm. Then, if both eyes are open, the tube being held touching or close to the right eye, while the left eye looks at the left palm (at about the nearest distance for distinct vision), the appearance presented is as though there were a circular hole about an inch in diameter through the palm of the left hand.

Now, in this case, the mind does not need to be told that it is deceived. The observer knows as well as possible that while he seems to be looking with the left eye through the palm of the hand at objects beyond, he is in reality looking at those objects with the right eye through the tube. Yet the mind does not correct the illusion, clearly though it recognises that there is illusion and its nature. The illusion is as preposterous as that experienced when

crossing the second finger over the first, we feel the tip of the nose with these fingers thus interchanged in relative position. In this case the observer seems to feel two nose tips, though he knows certainly that he has but one; he knows, too, just how the illusion is occasioned, but for all that the illusion remains.

The two most trustworthy senses, sight and feeling, being thus able to deceive—to palm off upon us, so to speak, what each of us knows to be false,—we see (and feel) how very far from the truth is the saying that seeing or feeling is believing. If these senses deceive us when we know precisely what they are doing (as when conjurors explain and illustrate in action the manner of their tricks), is it to be supposed that they do not often deceive us, and still more thoroughly when we have no means of testing what they tell us by what we already know?

INTELLIGENCE IN ANIMALS.

IN the case last considered, we see that a dog, belonging to a species not distinguished for keenness of scent, was not long deceived by a picture, even under circumstances favouring the deception—as his previous sleep, the position of rest from which he saw the figure, and the strong light shining upon it. As this was the only instance known to one who was familiar with the ways of dogs, the negative evidence respecting the recognition of pictures by animals is rather strong. However, there have been cases where animals, if not actually deceived by a picture, seem certainly to have understood what it was intended to represent. The following case seems to me full of interest. It is related by Mr. Chas. W. Peach, of Edinburgh. He remarks, first, that in certain publications dogs are said never to have recognised a painted likeness. "During my residence in Cornwall," he goes on to say, "I had a most intelligent and faithful dog for fifteen years. I had him when a month old. His mother was a beautiful liver-coloured spaniel, rather large; his father, a black Newfoundland; my dog took after him in colour and shape. In 1843, a young and self-taught artist asked me to allow him to paint my likeness in oil colours, and I consented. His studio was in the next town, three miles distant, and, as often as required, I went over. I, however, did not take my dog with me. It was done in "kitcat" size, and he succeeded so well in the likeness and artistic work, that, when exhibited at the annual meeting of the Polytechnic Society at Falmouth, a medal was awarded for it; and, as well, it was highly commended. The artist was so grateful that he presented me with the painting, and I still have it. When it was brought to my house, my old dog was present with the family at the "unveiling"; nothing was said to him nor invitation given him to notice it. We saw that his gaze was steadily fixed on it, and he soon became excited, and whined, and tried to lick and scratch it, and was so much taken up with it, that we, although so well knowing his intelligence—were all quite surprised; in fact, could scarcely believe that he should know it was my likeness. We, however, had sufficient proof after it was hung up in our parlour. The room was rather low, and under the picture stood a chair; the door was left open without any thought about the dog; he, however, soon found it out, when a low whining and scratching was heard by the family, and on search being made, he was [found to be] in the chair trying to get at the picture. After this I put it up higher, so as to prevent its being injured by him. This did not prevent him from paying attention to it, for whenever I was away from home, whether for a long or short time—sometimes for several days—he spent most of his time gazing on it, and as it appeared to give him comfort, the door was always left open for him. When I was long away he made a low whining, as if to draw attention to it. This lasted for years, in fact so long as he lived and was able to see it. I have never kept a dog since he died: I dare not, his loss so much affected me."

A similar anecdote is related of a painting by the elder Phillips. "Many years ago," says the lady who narrates the tale, "my husband had his portrait taken by T. Phillips, sen., R.A., and subsequently went to India, leaving the portrait in London to be finished and framed. When it was sent home, about two years after it was taken, it was placed on the floor against the sofa, preparatory to being hung on the wall. We had then a very handsome, large, black-and-tan setter, which was a great pet in the house. As soon as the dog came into the room, he recognised his master, though he had not seen him for two years, and went up to the picture and licked the face. When this anecdote was told to Phillips, he said it was the highest compliment that had ever been paid to him."

We have seen how a bull-dog, the least intelligent, perhaps, of all dogs, behaved in presence of a portrait. We have now to consider the behaviour, under similar circumstances, of the British mastiff, a more intelligent animal than the bull-dog, though not regarded as standing by any means first among dogs in this respect. The particular mastiff in question is one to whom I had the pleasure of being introduced some five years since, Dr. Huggins' dog Kepler. He is worthy of a brief biographical sketch. He was a son (that is, Kepler was) of the celebrated Turk, and was born about the year 1871. "He stands," wrote Mrs. Huggins of him, towards the close of 1876, a few months before his lamented decease, "thirty inches high, and is lion colour on the body; his face, the tips of his ears, and the tip of his tail, are marked with black. In disposition he is usually exceedingly affectionate and gentle, though he can be otherwise. Probably he thinks [though here I must confess that, strongly though Mrs. Huggins's opinion would support my case, I cannot altogether agree with her] that the words of George Herbert may apply to dogs as well as to men, and so reasons that—

He is a fool who cannot be angry,
But he is a wise *dog* who will not.

He has a clear idea of his duty in life. As Mr. Carlyle would say, 'he has found his work to do,' and considers it to be—to borrow the expression of an old writer—'to kepe his mastre and his maistirs hous.' To this end he is continually on the watch, barking in quite different ways as different comers approach. He has a bark of welcome for those he loves; of courtesy for mere acquaintances; of inquiry for strangers; of warning against enemies," an approach here, one may say, to language.

Kepler first attracted scientific attention by a peculiarity which, most probably, must be regarded as a result of instinct, or as, at any rate, inherited, since nothing in Kepler's own life explains it as the result of any process of reasoning. "When he," that is Kepler, "was very young," writes Mrs. Huggins, "his master discovered on taking him for a walk one day, that he" (Kepler, not Dr. Huggins) "was very much frightened at the sight of a butcher's shop, and some little time afterwards, when he was out with a servant, the feeling again showed itself, but in a much more marked manner. On this occasion Kepler threw himself upon the ground near the butcher's, exhibiting every appearance of terror, and as no amount of coaxing could induce him to pass the shop, the servant was at last obliged to bring him home again. His master, upon this, wrote to Mr. Nicholls, from whom he had purchased

Kepler, asking if he could throw any light upon this strange dislike. Mr. Nicholls replied that it had been strongly marked in Kepler's father and grandfather, and was unusually strong in one of his brothers, so much so, indeed, that he would fly at a butcher, even when dressed in plain clothes. These facts being very striking, Mr. Huggins Kepler's master wrote details of them to Mr. Darwin, who was so much interested, considering the circumstances a clear instance of inherited antipathy, that he sent an account of them to *Nature*. The facts attracted much attention at the time, and various theories were put forward to explain them. In connection with this dislike to butchers shown by Kepler and his relations, it is interesting to notice that a similar antipathy is noted by Jesse to dog killers, as mentioned both by Lord Bacon ('Sylva Sylvarum'), and Sir Kenelm Digby ('Treatise on the Nature of Bodies'), as having been common among dogs in their times. The passage from Sir Kenelm Digby's Treatise runs thus: 'We daily see that dogs will have an aversion from glovers, that make their ware of dogs' skin; they will bark at and be churlish to them, and not endure to come near them, though they never saw them before.' Dog-killing was an old custom in August." Perhaps, after all this intense aversion to butchers, dog killers, and others who may be supposed to bear about them some scent of blood, suggesting to the dog-mind the slaughter of his kindred, may be an effect of reasoning, not, as I have suggested above, of instinct only. A dog may argue that the scent can only be explained in one way, and that the explanation is such as to suggest danger to himself—"*hinc illæ lachrymæ*."

EXCAVATIONS AT THE PYRAMIDS.

(From *The Academy*.)

The Tombs, Gheezeh Pyramids. *Nov.* 26, 1881.

DURING the past six weeks excavations have been carried on by me here, under the authorisation of M. Maspero, not for obtaining portable antiquities, but for deciding questions of architecture and measurement. Many points of interest have been uncovered for the first time in modern history, though the work was not on a large scale, and the number of excavators never exceeded twenty. There have been over 280 holes sunk, varying from a foot deep to shafts twenty feet deep and trenches ninety feet long.

A brief notice of the work done may be worth giving at once, without waiting for the complete publication of it, along with my survey of the pyramids (made during five months of last season), to which it is a necessary sequel, for fixing the exact fiducial points of the ancient constructions.

At the Great Pyramid, the entrance passage has been cleared enough to examine it throughout, and to enter the subterranean chamber freely. Some of the loose gravel in the "grotto" of the well has been moved, showing that there is a natural vertical fissure filled with the gravel. The casing and pavement of the pyramid have been found *in situ*, at about the middle of the west, east, and south sides; it was already exposed on the north side, on which alone it has been hitherto known. The outer edge of the rock-cut bed of the pavement has been cleared in parts of the sides, and at the north-east and south-west corners. The great basalt pavement has been cleared in parts, and the edge of the rock-cut bed of it has been traced along the north-east and south sides; but its junction with the limestone pyramid paving (which is at the same level) could not be found, as both are destroyed at that part. The ends of the great trenches around the basalt pavement have been partly cleared. The bottom and sides of the east-north-east trench have been cleared in parts to show the form. No bottom was found under nine feet of sand in the north trench. The small north-north-east trench has been cleared in parts up to its inner end at the basalt paving, where it is much smaller, and forks into two. The various rock cuttings and trenches north-east of the pyramid have been cleared and surveyed, but refilled, as the road passes over them. A piece of the casing of the pyramid, found near the base on the west side, has Greek inscriptions, apparently Pto . . . . Sôt . . . . (perhaps Ptolemy VIII., as the s is round); and Markos K . . . . over which is hammered roughly . . . . in a p . . . . in Arabic. Nothing, besides a few fragments with single letters, had been previously discovered of the many inscriptions that existed on the casing.

At the second pyramid the corners have been all cleaned. The site of the edge of the casing has been found in six places near the corners, and the casing itself uncovered at the south-west. The edge of the bed of the pavement has been found on the north and west sides. The peribolus walls of the pyramid have been cleaned in many parts, showing that they are all carefully built, and not of "heaped stone rubbish," as had been hitherto supposed. Also, the so-called "lines of stone rubbish" on the west side of the pyramid prove to be all built walls, forming a series of long galleries about sixty in number, each about 100 ft. long, 9 ft. wide, and 7 ft. high, with ends and thresholds of hewn limestone. They would suffice to house two or three thousand men, and I can only suppose that they were the workmen's barracks. Fragments of fine statues in diorite and alabaster were found here, like those in the temple of this pyramid. The great bank of chips on the south side of the cyclopean wall north of the pyramid proves to have retaining walls built in it to hold up the stuff. The peribolus wall on the south-south-east of the pyramid is of fine limestone, of good workmanship, like most of the tombs of the period. The enormous heaps of rubbish south of this wall were slightly cut, and found to consist of tipped out, stratified, clean chips of limestone, like the rubbish banks of the Great Pyramid, but inferior stone.

At the third pyramid, the granite casing has been uncovered at its base in five places near the corners. The peribolus walls have been cleared in many parts all round, and found, in every case, not to consist of heaped stones, but to have carefully-built vertical faces, like the second pyramid peribolus, but of inferior work; and the wall on the south side is better built, and very wide.

The small pyramids have not been cleared for lack of time, as they are rather deeply buried; but a part of the rock-cut bed of pavement of the northern one near the Great Pyramid was accidentally uncovered close to the edge of the bed of the basalt pavement.

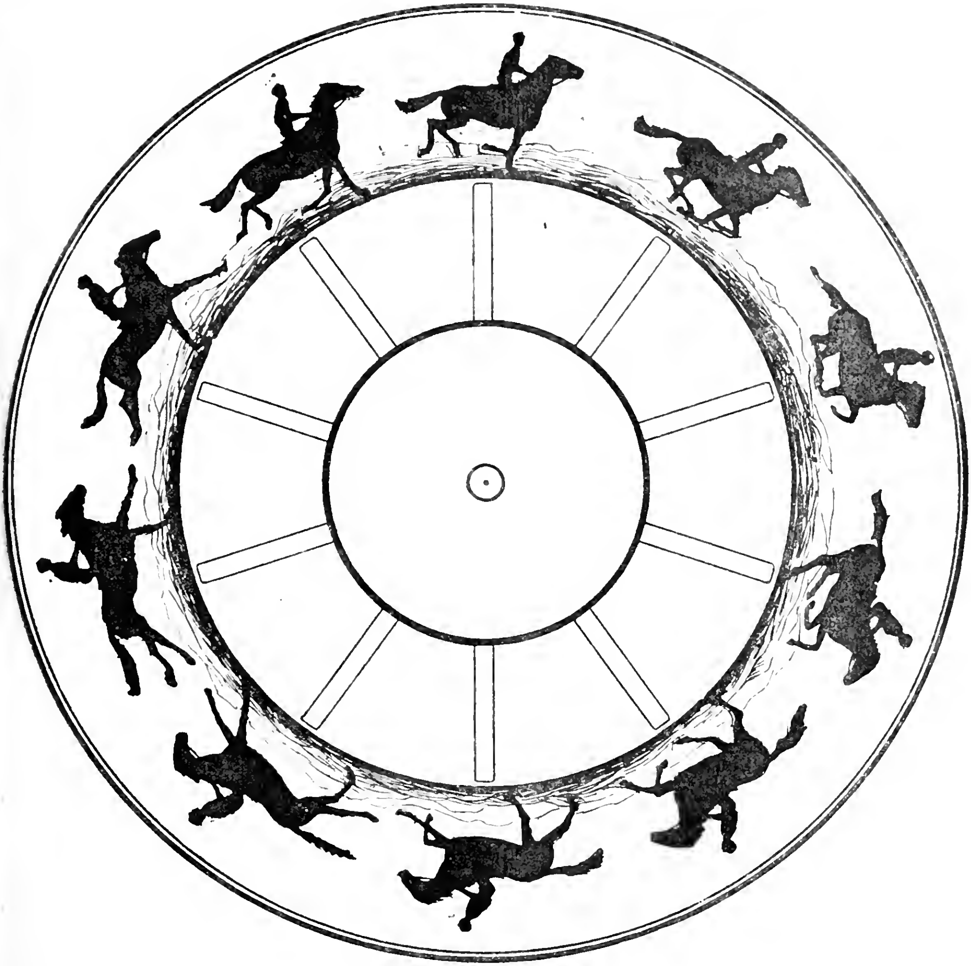
Though I am obliged to suspend work here at present, yet I shall be very glad to receive any suggestions of points needing examination (addressed to Poste Restante, Cairo); and, if they are practicable, I may find an opportunity for further work two or three months hence.

When all the paper work of this survey is finished, we shall know the sizes and distances of the pyramids within a quarter of an inch; and there will be fresh soil for the growth of theories, *as the Great Pyramid proves to be several feet smaller than hitherto supposed*, the sockets not defining the casing at the pavement level, though defining it, perhaps, at their own respective levels.

W. M. FLINDERS PETRIE.

[Let not pyramidalists despair. It will be just as easy to find all the features of the solar system in the Pyramid with the new measures, as it was before. The new coincidences will be worth just as much, too, as the old ones.—ED.]

MANUFACTURE OF GAS FROM WOOD.—When wood is burned, the chief product of the combustion is a gas called carbon dioxide or carbonic anhydryde (CO_2), *i.e.*, one of carbon united with two of oxygen. The gas is the same which gives the effervescence to soda-water, &c. This fact is made use of in New York, by a process called Wilkinson's, for the manufacture of wood-gas. CO_2 is itself a non-supporter of combustion, extinguishing a light when plunged into a jar of this gas, when it is inhaled destroys life, as in the fatal valley of Java (Johnston's "Chemistry of Common Life"), or anywhere else where persons have got into an atmosphere where it predominates. If we, however, get rid of one of oxygen in CO_2, *i.e.*, reduce CO_2 to CO, or carbonic oxide, we obtain the "Wood-gas" now used in New York. This is done "by forcing the gas through red-hot charcoal" (abs. *Chem. Soc. Jour.*). By doing this we get rid of the one of oxygen which was in excess, and so obtain a gas which has different properties—for it is now a "supporter" of combustion. The gas needs very little purification, the dangerous, obnoxious, and otherwise objectionable products being absent. The wood is only drawn from the retorts twice a day, "to prevent too great an accumulation of charcoal," whereas coke is withdrawn each time. "53,832 cub. feet of gas are produced from a cord of wood, costing 5·25 dollars (about 21s.) per cord of 3,300 lb. The quantity of gas alone is thus *four times as great* as that which can be obtained from coal, costing an equal sum per ton as wood does per cord." In New York, wood-gas is sometimes mixed with an inferior coal-gas, forming what is known there under the name of "commercial," which has a great candle power.—F.C.S.



THE MAGIC WHEEL.

We give, this week, the series of pictures of a galloping horse. We have to notice, however, that the instructions given in the *Scientific American* are erroneous. If a slit is cut exactly beneath each figure of a horse, we get a view of a horse galloping without advancing. Eleven slits should be cut (which the reader will find no difficulty in doing), at equal distances, when the horse will not only be found to move his legs, tail, &c., but to advance, as might reasonably be expected from a galloping horse. The same remarks apply, of course, to the trotting horse, in number 10, in fact, the trotting horse alone is taken from the *Scientific American*, the ten views of a galloping horse being from a series kindly supplied to the editor by Mr. Muybridge, of San Francisco, who photographed them. Twelve slits will produce the desired illusion even better than eleven, a correspondent notes, and their places are more easily measured.

THE MOON AND THE WEATHER.

It is held by a large number of educated people that a belief in the influence of the moon on the weather is a remnant of a past and now discredited system of divination by which all the events of life were referred to the influence of the heavenly bodies. It should, however, be borne in mind that the germs of truth may be found in every system of religion and philosophy, and that the interests of truth are served better by seeking for the truth underlying any particular theory, than by denouncing it as false because it lies beyond the range of superficial observers.

In the first place, the theory of lunar influence upon the atmosphere stands apart in a great degree from the old system of astro-meteorology; for, as may be seen in the text-books containing the

data on which predictions were founded, notably Ramesey's "Astrologia Mundi," it was the conjoined influence of the sun and planets, rather than the moon's position relative to the earth, which was mainly relied on as causing atmospheric changes, and whatever nucleus of truth the system contained was necessarily obscured and rendered almost valueless by the imperfect observation and boundless credulity of the times. And, in the second place, it must be clear to every tyro in natural science, that if it be rational and in accordance with the verifications of science, to assert that the moon's influence acts upon the waters of the ocean, it cannot be foolish and irrational to hold that the same influence affects the waters of the clouds and the air in which they float—both ponderable bodies equally subject to the laws of gravitation. So much may be taken for granted.

But the most tangible objection urged against the theory of lunar influence is that atmospheric changes are not coincident—or, if so, only accidentally—with changes of the moon, and, therefore, it is unreliable. This reasoning, however, is in itself fallacious. Those who predict changes in the weather from the moon's influence, allege that the disturbing force is felt when she is on the equator, crossing from north to south declination, or, *vice versâ*, arriving at one of the stitial colures at its extreme north or south declination. And, of course, she may or may not at such times be at the points called syzygies (the new or full moon), or at the quadratures. Thus, an atmospheric change is not necessarily to be expected at every change of the moon; but it may reasonably be when she arrives at one of the cardinal points, and it is found by experience almost invariably to occur.

But, without the knowledge of what the theory really is, the most acute critics must fall into error in judging a system whose principles they misapprehend. To give a striking instance—It is asserted by no less an authority than Professor Jevons, in his Science Primer, "Logic," that the belief in lunar influence on the weather is an illustration of "fallacy." He says:—"In one sense it is a fallacy that the moon governs the weather, because long and careful enquiries have shown that there is no correspondence between changes of the moon and changes of the weather." This reasoning clearly shows how the subject is misunderstood by those who accept the popular notion of the theory. Certainly, a change need not be expected if the syzygies and quadratures are alone regarded. The same writer says further:—"There are at least twelve new moons in each year, and changes in the weather take place in this country at least once a week on an average. It is, therefore, quite likely that a new moon and a change of weather will happen together now and then." To this the reply is that it is quite likely, for the moon usually, in the course of each week, either crosses the equator or arrives at one of the stitial colures.

And those who have made atmospheric changes a subject of special observation, are compelled to admit that the theory of lunar influence cannot be tabooed as unworthy of attention. In a number of the *Journal des Débats*, published last summer, M. de Parville, in an article on the temperature of the present year, says:—"A very long series of observations has also shown that the moon, which passes every month from one hemisphere to the other, influences the direction of the great atmospheric currents. The changes in those currents, in consequence of the prevailing moisture or dryness, are intimately connected with the relative position for the time being of the sun and moon."

Admitting that the time of atmospheric changes, taking local and climatic conditions into account, may be approximately known, it remains to be seen how far the relative positions of the other members of our solar system affect the character of the change; whether, for instance, the chemical rays of one planet, when stationary, or in conjunction or opposition of the sun, incline to heat, and those of another to cold, is a legitimate matter of investigation, always remembering that the wider the scope for surmise and assumption, the more carefully must hastily-propounded theories be tested by verified conclusions. To formulate into a system the effects of solar, lunar, and planetary aspects and motions, requires long-extended and careful observation, but, on the other hand, it must not be too hastily assumed that an error in detail proves the principle to be false—a sweeping condemnation which no logical mind should accept. When mathematical or scientific demonstration cannot be given off-hand, and when, consequently, so much depends on the even balance of the judicial faculties, scepticism is as dangerous to the interests of the truth as credulity. SOMETHING ABOUT THE POTATO.

HOW few of us ever give any thought to the food we eat, beyond the fact of its being well or badly cooked. Very few know that the potato for years past has, amongst other articles of food, received the earnest attention of investigating chemists at home and abroad. A few of the facts resulting from their work during the last few years, I now propose to try without going into that part of the researches which can only be of interest to the chemist, such as giving the results of analyses, or the names of the various *alcohols* which we are able to extract from the potato—and put before you as an interesting article.

I daresay some, or rather most, of you have heard of potato spirit, to obtain which, potatoes may be mashed either with mull or sulphuric acid. Mull, if anything, gives a trifle better result. In manufacturing this spirit we obtain an oil, called fusel oil, from which we can extract *nine* different alcohols, as well as other organic substances, the names of which I will not trouble you with. Besides the spirit and ether we obtain from potatoes, we may soon advantageously obtain pressed yeast. At present there is a little difficulty to be overcome in the working of the process, the difficulty being that the yield of spirit is less in proportion to the yield of yeast; but in a short time the chemists, who are working the solution of this problem out, expect to overcome this obstacle.

Another important produce manufactured from the potato is potato starch, which, by the action of acid, is converted into glucose-sugar, or syrup, which is chiefly made in America and Germany, though we have, at the same time, some important works in this country, and one quality is, from the samples which I have seen, for brewing and sweet manufacturing purposes, the purest. Owing to the large amount of sulphuric acid present in some of the prepared syrup in America, it has been found to have had an injurious effect on the health of those people who have taken the syrup, but this acid should not be present in so large an amount as this. Some samples I have tasted were perfectly free from it, and you could only taste the very sweet taste of glucose. On the other hand, other samples have really been unbearable, owing to the large amount of acid present—in one case, in the form of sulphurous acid, which leaves the same taste in the mouth as a mouthful of burnt sulphur would do, if inhaled. As glucose is one of the chief ingredients required for brewing, it is easily seen what an important substitute for malt this must be to the brewers, though a few years ago brewers would not acknowledge using it! Its use has since then become more general, so brewers are not ashamed to own to using it. Without going into detail, I will here give a general average analysis of the potato:—

Water.	Nitrogenous substances.	Oil.	Non-Nitrogenous Substances	Cellulose.
75·77	1·79	·16	20·56	·75

A full analysis of the above, giving the names of all the non-nitrogenous substances, &c., with their percentages, would take up a good deal of space, without making the general reader any the wiser than he was at the beginning.

The next thing to be considered is the general cultivation of the potato, as made known to us by the chemists who have been studying this branch of the tuber. Generally speaking, large seed produces more large potatoes than small seed. Most people might take this for granted, without corroborating the supposition by numerous experiments, as the chemist does, for the chemist must bring forward positive results only to bear out his suppositions.

The influences of the blossoms makes a great deal of difference in the yield of the crop, as the following results show. 208 centrs. 19 lb. of tubers were obtained from plants from which the blossoms had been removed, and only 181 centrs. 48 lb. from plants not so treated. I do not think many readers of KNOWLEDGE would have thought that the difference could have been so great.

It has been found that the growth of sprouts on potatoes depends on their nearness to the apex of the tuber; if they are treated with water in sunlight, the growth increases forty or fifty times, although this not the case in the dark. Absence of light is necessary for the growth of young tubers.

Heat produces very beneficial results to the growing plant. On this account too early planting is injurious, for potatoes require the same total heat to bring out the leaf buds; so, should the plants be planted too soon, it would require, as experiment shows, perhaps forty days instead of fourteen to bring them to this stage, but it is well, at the same time, to bear in mind the fact that if they are left too late, the ground will become equally unsuitable.

Potato rot is the next point to be considered, of which there are three kinds—viz., dry, wet, and sweet rot. In the dry and wet rot it has been found that the potatoes with the maximum starch resist the disease most effectually. Potatoes grown on moist soils and soils containing much organic matter are most liable to the disease. The starch in diseased potatoes is yellow, but can be used for manu-

facturing a second quality of dextrin. In dry rot the tuber is loose and spongy, coated on the outside with mould. The disease is originally due to Bacteriæ, and another parasite is often present at the same time. Wet rot, I forgot to say, differs from dry rot in this respect, the interior of the tuber is partially liquid and the outside coated with mould. During rotting, the potato loses half its nitrogenous constituents and the whole of the sugar.

The Sweet wort is formed by a parasite called *Mucor mucedo*. The mycelium of the parasite travels to a certain distance inside of the potato, and then disappears. Bacteria rapidly destroys the plants. There is another parasite, called *Aspergillus niger*, which produces a similar result. It seems rather uncertain as to whether cane sugar or glucose is formed; some chemists say the one, others the latter.

We all are familiar with frozen potatoes, but not many of us know in what manner the frost affects them. Frost has the effect of doubling the amount of sugar in the tuber, the starch diminishing in proportion; part of the protein passes from the coagulable to the soluble form.

To prevent rot in potatoes, the tubers, whether sound or diseased when taken from the ground, are left in a weak solution of calcium chloride—one part to a thousand of water—for half-an-hour. They are then transferred to a soda solution of the same strength, after which they are washed with clean water and air dried. Half kilo of calcium chloride and the same amount of soda is sufficient for 250 kilos of potatoes. A kilo is a little over 2 lb. 3 oz.

Even though potatoes are badly diseased, they are still useful for cattle food. They are best cut up and boiled or merely scalded, mixed with chopped straw or chaff, and stored in narrow trenches covered up with clay. So stored, they will keep for many years. If steamed, they should be kept in casks, as there is more adhering moisture. If it is not convenient to heat them as above, they should at once be sent to the distillers.

With regard to the best kind of potato for yield and quality, there seems to be a good deal of difference in opinion, as the following examples will show. 1. For quality and quantity: Champion, Richter's Imperator, Eos, &c. 2. Richter's Imperator for yield is far the best; is of a hardy nature, smooth, and the stalk is tall and straight. Next in order are Violet, Victoria, Irlachin, Richter's Snowrose, &c. 3. For starch and yield: Eos, Aurora Alcohol; lower in yield but very high in starch, Achilles and Ceres. Richter's Imperator Early Rose, &c., very heavy yields. The above forms three opinions of three chemists; they all seem to agree that the Imperator is the largest yielder.

I think I have now put before the readers of KNOWLEDGE the most important points in the potato which have received the attention of chemists during the last few years. There is one more branch of the researches on which a few words may be said, and that is on a few of the results obtaining through *manuring*. At the same time it must be mentioned that experiments on large scales are still being carried out with respect to numerous manures on different kinds of ground.

The most successful way of manuring is to partially dig the manure into the ground. The application of nitrogenous and phosphate manures without farmyard manure is much less to be trusted on a poor soil than on a rich one. Manuring on fertile soil is not productive of any great gain. Sheep-dung produces a yield of 50 per cent. higher than any other artificial manure, and 60 per cent. higher than if no dung be applied at all. Extra supplies of ammoniacal and superphosphates produce no increase. Compost has the same effect as if the land were unmanured, except that there is an increase of starch. The unmanured plots are highest in disease. A good mixture is Chili saltpetre and Baker's superphosphate in the proportion of one of the former to two of the latter mixed with stable manure. Bone meal, one author says, increases the weight of product, and it is also very likely that the whole plant likewise increases in weight. There is another substance which has been tried, viz., peat, and good peat is found to give even better results than good stable manure.

If I have interested, and at the same time shown the readers of KNOWLEDGE that there is a good deal of matter for reflection, even in the use of every-day articles of common food, such as the potato, I am satisfied. F. C. S.

THE PURPLE OF THE ANCIENTS.

FROM the interesting "Notes on the Purple of the Ancients," by Edward Schunk, Ph.D., F.R.S., the following abstract, which may be interesting to the readers of KNOWLEDGE, is taken:—

After briefly referring to the works of Pliny and Aristotle as containing accounts of the shell-fish used in their days for the purpose of dyeing, and also of the processes incidental to same, the author proceeds to lay before the Fellows of the Chemical Society the history of this interesting dye as known to modern authors and investigators.

A shell-fish from which this dye can be extracted is found on our own coasts, Cole, in 1683, having discovered on the coasts of Somersetshire and South Wales a species of fish which, by proper treatment, could be made to dye linen and silk a *fine purple*. Reaumur, in 1710, discovered the same animal on the coast of Poitou.

The shell-fish is known to conchologists by the name of *Purpura capillus*.

The results of the various observers—Cole, Reaumur, Duhamel, (1736), and Bancroft (1803), may be summed up as follows:—

1. The colour-producing secretion, which resembles pus in appearance and consistence, is contained in a small whitish cyst or vein, placed transversely under, but in immediate contact with, the shell, and near the head of the animal.

2. This pus-like matter, either diluted with water or undiluted, on being applied to bits of white linen or calico, and exposed to sunlight, rapidly changes its colour, passing from yellow through light green, deep green, and "watchet-blue," to purplish, red or crimson. While these changes are in progress, a strong odour like garlic or asafœtida is given off.

3. To produce this change of colour, the light of the sun is essential. It is effected more rapidly by the direct action of the sun's rays than by that of diffused light, but it does not take place in moonlight, or in artificial light. If the linen or other fabric to which the secretion has been applied is kept in the dark, it remains unchanged, but when exposed to the sun it becomes purple, even after the lapse of years, though a little more slowly than at first. The metamorphosis which the change of colour indicates is not sensibly promoted by heat. It proceeds in a vacuum and in hydrogen or nitrogen gas as speedily as in air, on exposure to light. It seems to be hastened by the addition of certain chemical reagents, though these cannot replace sunlight, which is indispensable for initiating the change.

4. The colour produced is remarkably stable, resisting the action of soaps, alkalies, and most acids; being destroyed by nitric acid and chlorine.

Bizio, in 1855, experimented with the *Murex branduris*; the conclusions deduced were similar to previous observations. A. and G. de Negri, in 1875, experimented with the *Murex branduris* and *M. trunculus*.

They state that the purpurogenic secretions of these two species are not identical, the secretions of the former being photogenic, *i.e.*, not coloured when protected from the action of the light, whilst the latter becomes violet, even in the *dark*, by the sole action of the air.

Observers on the subject say that the action of light is indispensable in the action of colouring matter in mollusca.

The author conducts his experiments with the *Purpura capillus*, which he found on the rocks at low water near Hastings. He worked them up immediately after collecting, as it is necessary to use only live animals.

Breaking the shell, he easily found the pale yellow vein at the back of the animal, which may easily be cut out for examination. Putting some of the yellow viscid secretion on linen, the following changes occurred: the colour changed from yellow to green, and then to purple—emitting during the process the peculiar odour referred to in No. 2 of the summary of previous observations. The author finds that on linen, at least, the colour is not such a very brilliant purple, though it seems permanent, resisting the action of a strong soap liquor.

A temperature of 100° had no effect, either in retarding or hastening the formation of colouring matter.

Besides the above, the author found that sunlight was *not* the only agent which would bring out the deep colour, for hydrochloric acid likewise possesses this property on the veins of this remarkable shell-fish; but he thinks, at the same time, that it is open to doubt whether the action in this case is similar to that produced by insolation. It is interesting to watch the changes which occur in colour through a microscope, and if any of the readers of KNOWLEDGE desire to pursue the interesting investigation of the properties of this shell-fish, I shall be glad, at any time, to furnish them with particulars of the author's observations on this point.

Although we have, in the Old World, long since left off using the shell-fish as an article for dyeing, it is still used, to some extent, in America for this purpose, more especially on the Pacific coast of Nicaragua and Costa Rica.

The following is one of the interesting accounts, given in the paper, of the process as practised in Central America:—

"Some of the cotton fabrics manufactured by the Indians are very durable, and woven in tasteful figures of various colours. The colour most valued is the Syrian purple, obtained from the murex shell-fish, which is found on the Pacific Coast of Nicaragua. This colour is produced of any desirable depth and tone, and is perma-

nent, unaffected alike by exposure to the sun and to the action of alkalies. The process of dyeing the thread illustrates the patient assiduity of the Indians.

"It is taken to the seaside, when a sufficient number of shells are collected, which, being dried from the sea-water, the work is commenced. Each shell is taken out singly, and a slight pressure upon the valve which closes its mouth forces out a few drops of the colouring fluid, which is then almost destitute of colour. In this each thread is dipped singly, and after absorbing enough of the precious liquid, is carefully drawn out between the thumb and finger, and laid aside to dry. Whole days and nights are spent in this tedious process, until the work is completed. At first the thread is of a dull blue colour, but upon exposure to the atmosphere acquires the desired tint. The fish is not destroyed by the operation, but is returned to the sea, where it lays in a new stock of colouring matter for a future occasion."

The author had some of this fabric sent him, but the colour did not quite realise his expectations. The yarn and calico were of a *dull purple,* which is rather different from the general idea of the famous Syrian dye. They were harsh to the touch, and emitted a peculiar smell. A shell was sent with the articles; it resembled the *Purpura capillus* of our coast, but is much larger, belonging, the author says, to the *Purpura patula* of conchologists. The author informs us that in the process which the natives who dyed the goods used (samples of which he received), the whole animals were picked out with a pin. So we see there are various ways of making use of the animal. F.C.S.

METEORIC ORGANISMS.

By CARL VOGT.

THE organisms in meteorites (chondrites), announced by M. Hahn, have no existence; what has been described and drawn as such, results from crystalline conformations, which are absolutely inorganic. None of these imagined organisms has the microscopic structure belonging to the organisms with which they have been associated. In particular, the asserted sponges do not show the structure either of existing or fossil sponges; the so-called corals do not show that of polops or anthozoa; and the imagined crinoids do not show the structure of known crinoids. The observed structures are due to an opaque crust, or result from optical illusions, caused by an incomplete method of conducting microscopical researches. Apart from pulverulent masses, metallic substances, and non-crystalline encrusting matter, ordinary meteors are composed of crystalline elements collected into granules, as is shown by their disaggregation, either by wearing down, or by the use of acids. —*Les Mondes.*

INTELLIGENCE IN ANIMALS.

AN acquaintance of mine, Mr. H., is the possessor of a cat that is a great admirer of birds as an article of food, and he has more than once devoured a chicken, for which he received condign punishment. A short time ago Mr. H. placed a number of eggs under a duck, but the only result was a single, weakly duckling. This my friend laid on the fender before the kitchen fire, and tended the little creature for some time. Eventually he put it into the garden, in order that it might get its own living, and then resumed the sowing of some seeds. On looking round in a few minutes, he saw the cat seize the duckling and dart into the house. Mr. H. followed with the intention of punishing the thief, but he found that the cat had set the duckling in its accustomed place on the kitchen fender, and was caressing and carefully licking some dirt stains from the down of his new friend. Mr. H. frequently afterwards took the duckling into the garden in the presence of some of his neighbours, and the cat invariably carried its little favourite back to the kitchen fire. I think this is a remarkable instance of the suppression of a strong instinct on the part of the cat, and may it not also have learnt a lesson of kindness?

STUDENT.

THE EFFECT OF SEWAGE ON OYSTERS.—Many people have complained of feeling ill after eating what they have afterwards thought were stale oysters. But the microscope has now shown that this has been caused by "germs" present in the liquid of the oyster. These "germs" are similar to those found in sewage hence the deduction that the presence of sewage pipes near oyster beds has a poisonous effect upon the oysters "especially the northern side of Dublin Bay" (Abs. *Chem. Soc. Jour.*—C. A. Cameron). When the oysters were submitted to analysis it was found that the fact asserted by the microscopist was fully corroborated. This now accounts for the reason of people complaining that the oysters were stale.—F. C. S.

Letters to the Editor.

[*The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.*]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

⁂ All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

Our Correspondence Columns.

VEGETARIANISM.—COMMUNICATION WITH THE MOON.—LIGHT AND LANTERN.—CHOANITES.—THE NAUTILUS.—CELESTIAL MAPS.

[207] Those amiable fanatics, the vegetarians, seem determined to force their way into the columns of KNOWLEDGE; and there, as elsewhere, to insist upon every one, high and low, rich and poor, young and old, adopting their panacea on pain of being branded as idiots for rejecting it. Now, I have no particular faith in the "whole hog" system, and believe that I may eat a cutlet without tomato sauce; and even drink a glass of claret or sherry without imperilling either my longevity, my digestion, or my intellectual powers. May I express a hope, then, that some of those who would send all mankind back (like Nebuchadnezzar) to graze, will listen to what Dr. Wald says, in Carper's *Quarterly Journal*, as quoted by Dr. Drysdale in the *Echo* newspaper. "Some prisoners in a castle at Waltenburg, who had a mortality from 1846 to 1851 of 18 per 1,000, in 1852 had a mortality of 380 per 1,000, the causes of death being diarrhœa, scurvy, and dropsy. Dr. Wald, on investigation, found that, as the potato crop had failed, these prisoners, on theoretical chemical grounds, had been fed principally on white and grey peas and lentils with bread. The mortality increased terribly on this diet, and more leguminous food was supplied, so that in 1854, beans were given five times a week, when the mortality still increased whole troops of the prisoners becoming blind and dropsical. Wald at once dropped this theoretically nutritious food, and gave milk, bread, rice, meat, and coffee, and the normal mortality soon reappeared." I have eaten meat for upwards of forty years, and certainly have not spent twopence in medicine during the last ten of them. Moreover, I will do the hardest day's walking, shooting, rowing, riding, or thinking, against any man whatever of my age who has lived upon potatoes and turnip-tops for an equal time; with the moral certainty that, in sporting slang, I should "beat him off his head."

I have no book of reference at hand, but in connection with letter 206 (p. 233), would say that, unless my memory is more than usually at fault, it was Gruithuisen, of Munich, who proposed to communicate with the Selenites by the erection of the familiar diagram to the 17th proposition of the First Book of Euclid, on some extensive plain or desert on the earth's surface.

Mr. J. W. Stow (query 169, p. 234) should obtain vols. xxxii. and xxxiii. of your contemporary, the *English Mechanic*, running through which he will find a series of articles by Mr. Lewis Wright, under the title of "Optics with the Lantern," which supply the very thing he requires.

Query 171 (p. 234) may be answered by saying that the fossil choanite must have been nearly related to the modern family of Alcyonidæ, to which the common organisms, called "Dead Men's Fingers" by the fishermen, belong. It has no affinity with the sea anemones at all. It is the polypidom of a zoophyte. I have seen a large number of choanites in my time, but "the spiral worm round the body" is something new to me.

Assuming that by "gut" in Query 177 (p. 231) Mr. Webb means the siphuncle of the nautilus, the most plausible explanation yet given of its use is that by Mr. Searles Wood- that, passing right through all the closed and isolated chambers of the shell, it serves to maintain the vitality of the entire organism during the animal's certainly long life.

In answer to Query 181 (p. 234), Middleton's "Celestial Atlas" is, or was, published by Jarrold & Son, of Norwich, and costs, with the "Companion," about 15s. Gall's is, I fancy, published by Gall & Inglis, who are Scottish publishers, I forget whether in Edinburgh or Glasgow. The price of this I have forgotten too.

In "Nights with a three-inch Telescope," in Fig. 5 the smaller star should be at the bottom. In Figs. 6 and 7 the rings of Saturn and the disc of Jupiter are *grey* in the engraving. The rings and all Jupiter's disc not covered by belts should be *white*. The small star beneath ε Persei, also in Fig. 8, is to the *left* of a perpendicular let fall from its primary, instead of slightly to the right of it.

A Fellow of the Royal Astronomical Society.

CHEAP TELESCOPES SUNLIGHT ON FIRES—TEMPERATURE OF INTERSTELLAR SPACE—ICE—TIME OF THE GLACIAL EPOCH HEAT FROM THE STARS.

[208]—If "R. I. P." (query 135, p. 188) will take my advice, he will make no attempt to construct any telescope, cheap or dear, himself. At any rate, five guineas would be the lowest price at which he could obtain anything whatever worth looking through, and that would not be a weariness to the flesh. I presume that by 2½" and 3" he means 2½ and 3 *inches* respectively; but " really signifies seconds of arc, and, legitimately, nothing else whatever.

"X." (query 136, p. 188) may rest assured that it is a mere vulgar superstition that bright sunlight interferes with combustion. It renders flame almost invisible, and so gives an ordinary fire the aspect of going out; but anyone who will take the trouble to shut the shutters will see at once that the seemingly decaying fire is burning as brightly as ever. As for cigars, I can not only always keep one alight, but never, to my recollection, has one gone out, in brilliant sunshine.

In answer to query 139 (p. 188) estimates of the temperature of interstellar space not unnaturally differ considerably. Hopkins's was − 39·5 deg. centigrade (No. 15, "Monthly Notices," Vol. XVII., p. 192, Fownes estimated it at −50 deg. cent., and Pouillet as low as −142 deg. cent. These are all mere deductions from theoretical considerations, as of course the temperature of space has never been actually measured.

One single fact will suffice to show that ice (Query 140) does not vary in volume, as other solids do, with variation of temperature; since it *contracts* during liquefaction.

There can be very little doubt that Dr. Croll's Theory (Query 141) is substantially correct. No other theories exist which are worthy of scientific attention. Adhémar's is worthy of Jules Verne; while Colonel Drayson's well, his is worthy of Adhémar.

It may interest "Student" (Query 161, p. 211) to hear that Mr. E. J. Stone, the present Radcliffe Observer, in 1869 determined the heating effect of Arcturus to amount to 0.0000137 deg. Fahr., about equivalent to that radiated by a 3-inch Leslie's cube of boiling water 400 yards off! Curiously the heat from α Lyræ is *less* than this; in fact, it is only equal to that emitted by a 3-inch cube of boiling water at a distance of 600 yards.

A Fellow of the Royal Astronomical Society.

INTELLIGENCE IN ANIMALS.

[209]—A pony belonging to a gentleman in this neighbourhood showed great unwillingness to carry any one on his back. One day he was being ridden by a young lady; he seemed to be very spirited, and galloped along the drive at a good pace for some distance, when he suddenly stopped, stretched out his neck and threw the lady over his head.

For some time after this he was not ridden, but the fright gradually wore off, and his back was once more called upon to bear the burden, until the following incident occurred, after which I don't know what became of him. He was trotting briskly along the road with his young master on his back, when, on coming to a shallow pond on the right-hand side of the road, he abruptly *turned at right angles*, took a step or two into the pond, then came to a stand, throwing his rider into the centre of it. He stood for a moment and looked at his unseated rider, then trotted quietly home.

I don't know whether this will be considered *reasoning* or not. The pony seems to have thought that if he got off for so long by throwing his rider on the ground, he might get off for a longer time if he threw him in the pond; certainly he must have considered it more disagreeable to be thrown into the pond than on to the ground, seeing he turned into the pond to accomplish it.

Edinburgh. J. B.

ASTRONOMICAL CURIOSITY:—EVOLUTION.

[210]—I have seen somewhere the following paradox, as I suppose I must call it. Granting (1) that the stars are on the average as bright as our sun, (2) that their number is practically infinite, and (3) that light travels without loss (all of which premises appear to me perfectly reasonable); it follows that the sky should *always* be as bright as if full of suns, and square suns, so as to fit closely. For a star's greater distance is compensated by the greater number that can shine near together, and the theory supposes that in any direction we should reach stars sooner or later. This result is, however, so different from reality, that I should be glad to be shown where the fallacy lies. [In our next.—Ed.]

I venture to point out to Mr. Donbavand (Letter 183), first, that biologists should no more be expected to account for the origin of any "first-born animal," than that astronomers should be called upon to point to the origin of the nebulous globe, from which our solar system is derived, or theologians to explain whence came the material from which it was made (since we are told that "created" means "set in order"). Secondly, Pasteur, or any one else, has never disproved the possibility of "spontaneous generation;" all he proved related to his particular experiments, and similar ones. How do we know, for instance, that, *even now*, the process is not going on in our ponds and ditches, side by side, if you like, with the known modes? It is not possible to *disprove* a thing like this, and the *probability* of it must remain a matter of opinion. Thirdly, is it more astonishing that a fish should develope into a reptile by continuous slight modifications, in course of ages, than that a tadpole should become a frog, in the same individual, in a few hours? I think Mr. Donbavand should read Haeckel's "History of Creation," if he still feels interest in the matter.

Lewis Arundel.

LIQUIDS AND THEIR VAPOURS.

[211]—At what Mr. M. Williams has described (see Knowledge, No. 8) as the "critical temperature" of liquids, the mysterious disappearance of all visible distinction between the liquid and its vapour, is much misunderstood by many persons, who imagine that, when this temperature is arrived at, "the whole of the remaining liquid is suddenly converted into vapour."

We know that liquids expand (becoming lighter) as their temperature is raised, and, at the same time, the density (and elastic force) of their vapours increases at a very rapid rate, so that we might reasonably expect that, after a certain increase of temperature, the densities of the liquid and of its vapour would become equalised, and at this point, of course, the eye could no longer perceive any distinction between them. This, then, is "the critical state," which thus loses its "mystery." [Not quite.—Ed.]

No experiments, so far as I am aware, have been instituted with the object of testing this view. But some of those by Cagniard de la Tour (as in the following table) plainly point to the result I have mentioned above as regards "ether" (See Miller's "Chemical Physics," 1867, p. 366).

Temperature Fahrenheit.	Pressure in atmospheres of the vapour of ether. Volume of liquid = 7; " of vapour = 20.	Volume of liquid = 3½. " of vapour = 20.
257°	10·6 atmospheres.	14 atmospheres.
302°	18 "	22·5 "
324°·5	22·2 "	28·5 "
369°·5	37·5 "	42 "

On increase of temperature, as above, = 67°·5 (from 257° to 324°·5), the pressure (in *each* column) is *more* than doubled; whereas, with same increase of temperature = 67°·5 (from 302° to 369°·5), the pressure is *more* than doubled (by 7½° atmosphere) in the first column, while in the second column it is *less* than double pressure by three atmospheres. Hence, the conclusion that in the latter case, *all* the liquid having passed into vapour, the full pressure was not attained; whereas, in the former case, where some of the liquid still remained (though imperceptible), the tension continued to increase from addition of vapour, density of *both* liquid and vapour increasing *equally* with increase of temperature.

It would be desirable, if possible, to ascertain (by spectroscope or transmitted polarised light) if any "molecular change of arrangement or of motion" could be detected in these different states of liquid and gas co-existing at the same density.

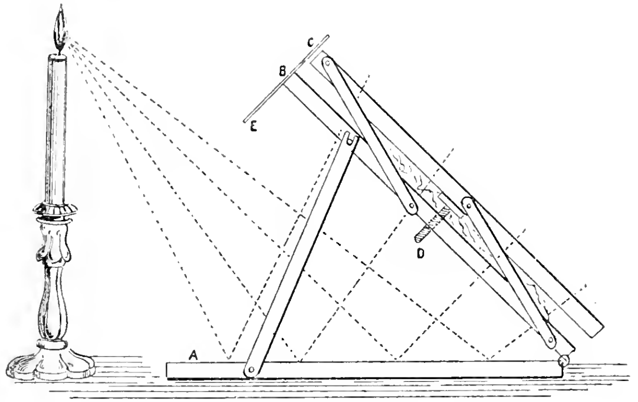
Henry Hudson, M.D.

TATTOO MARKS.

[212]—I have asked myself the question which your correspondent now asks (166), and I have answered myself in this manner:—The atoms inserted by tattooing are quite foreign to those constituting the human body; they do not form and disperse with them, but must be removed as mechanically as they were inserted. They were dead and foreign atoms when introduced, and so remain, uninfluenced by the living electrical changes that surround them. Might I compare them to a boulder thrown into a running stream? If the stream were strong enough, it would carry away the boulder. If an abscess were to occur where the tattooing took place, the powder would be carried away.—J. J. A.

BOTANICAL CONTRIVANCE.

[213]—Those of your readers who are students of botany may find the contrivance, of which I send you a diagram, useful for obtaining a correct outline of the specimens which they wish to draw. It was made for a friend, who wanted a means of copying flowers, &c., the exact size of nature. A is a looking-glass laid flat upon the table, B and C are wooden frames, each holding a square of plain glass. The flower to be drawn is laid between the glasses, which can be kept at any distance apart by means of the parallel links on each side, and the screws at D. A piece of paper is laid upon the upper glass, and by the light of a candle reflected from the mirror, the shadow of the flower is projected through the paper, and its outline can be easily traced. The paper can then be removed, and the shading and colouring copied from the object, which is held in the same position between the glasses. A skilful draughtsman may despise such aid, but it has been found useful for drawings aiming rather at correctness of shape and size than at artistic effect. The shadows will, of course, be very slightly larger than the object. The machine might also be useful to designers of Christmas cards, or floral patterns of any kind. It can easily be made with a common looking-glass and two picture frames, and a few pieces of brass wire. A cardboard screen should be placed at E to prevent the light from falling directly upon either side of the paper. Everything must have a Greek name nowadays, so we call it the SKIAGRAPH.



BOTANICAL CONTRIVANCE.

COLOURS OF STAMENS.

[214]—I have read Mr. Grant Allen's interesting and clever paper in the *Cornhill Magazine*, in which he considers yellow to be the original colour of flowers, founding his theory on the fact that most flowers have yellow stamens. This is scarcely borne out by an examination I have made of twenty-three flowers in a conservatory, of which I found eleven had yellow, seven white, and five red or pinkish stamens. I presume Mr. Allen in speaking of stamens means the filaments and not the anthers only, which are certainly almost always yellow. As Mr. Allen is a contributor to KNOWLEDGE, he may be disposed to give further explanations, and to furnish more details in that periodical. Some orders of plants appear to have nearly always yellow stamens. In others they appear to come near the colour of the throat of the corolla. It is, however, too early in the year to investigate the subject thoroughly.

T. HOWSE.

MARINE BOILERS.

[215]—With reference to "Crankshaft's" letter, 114, p. 167, I can tell him that in marine boilers it is not merely the incrustation of salt which prevents heat passing from the furnace or tubes to the water. As a rule, marine engines are surface condensing, and the grease used for lubricating the cylinders passes with the steam into the condenser, and thence into the boiler. It here, apparently, enters into chemical combination with solids mechanically held in suspension in the water, and deposits this upon the fire-box and tubes in a thin, hard scale. This is a most extraordinary non-conductor of heat—so much so, that I have known boiler-plates almost heated to redness without maintaining the steam higher than 100 lb., the scale being only as thick as one's thumb-nail. If this scale be taken out, pulverised, and rubbed on the hand, and water poured on it, the water will assume a spheroidal shape, and run off without wetting the dust, showing the presence of grease in large quantities.

Another experiment is—spread some of the scale, when moist, upon a tin plate, and place a drop of water on same, and hold the same over a lamp. A very long time will elapse before evaporation takes place. Tilt the plate so that the water runs on to a portion which has not been covered by the scale, and the water will at once evaporate.

The above will perhaps be more readily noticed as occurring with water containing silicate of lime, or lime in some shape.

Letter 115, p. 167.—Undoubtedly there is a tendency to vacuum on the following side of a screw-propeller when revolving; this, however, does not affect the *power* of the steam-engine, but the *speed* of the vessel. The former depends upon the pressure of the steam and the speed of the piston. The latter depends upon the slip of the screw-propeller, *i.e.*, as to whether the propeller is passing a body of water equal to its own pitch. The freer the access for the water to approach the propeller, the greater the quantity of water passed, the less the amount of slip, and the greater the speed of the vessel. Hence, although in designing vessels for screw propulsion it is, of course, necessary to study to a certain extent the form of the bow, it is far more important to have a clean run aft.

Letters 114 and 115 contain questions of deep import to engineers, and you would do great service to the profession if you could publish what information you can obtain upon these points.

Thanks for answers to my former queries on "Gravity." Am not quite sure I agree with one small part, but have not yet had time to go fully into the matter.—Yours truly,

W/g.

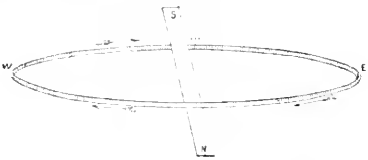
MAGNETIC NEEDLE.

[216]—Referring to query 90, p. 123, to say that a magnetic needle turns to the north, owing to the northern terrestrial mag-

netism being of an opposite name to that magnetism which resides at the north-pointing end of the needle, and, therefore, attraction ensues, would be little to W. H. P.'s purpose. He desires, most probably, to know how the terrestrial magnetism got there.

It seems to me the following view (touched upon in some text-books) is the most satisfactory:—Whenever heat flows in a closed circuit, there is a flow of positive electricity with it. If, therefore, a positive current passes in the direction indicated by the arrows in Fig. 1, the piece of soft iron would become—so long as the heat or electricity circulated—an electro-magnet. If to the upper end, marked S, of the soft iron, we were to present that end of a magnetic needle which pointed southward (geographically speaking), we should find that would be repelled, while the north-pointing end of the needle would be quite violently attracted.

The earth, during her daily rotation, offers successively parts of her surface to the warming action of the sun, and a slight consideration will show that this is practically the same as heat continually passing round the earth in a westerly direction, therefore well representing a closed circuit. We



have then all that is necessary for the state of things above noticed. The wire (Fig.) E.W.w. may well show or represent the surface of the earth exposed to the warming action of the sun (for the current will be in the same direction, viz., E.W.w.), the bar, SN, the iron contained in the earth. This iron becomes converted into a huge electro-magnet. We should then have towards the northern part of the earth the same-named magnetism as at position S in the figure. The behaviour of a needle under these circumstances we have shown; so a needle on the earth will act in precisely the same manner—that is to say, its N-pointing pole turns to the north, because the different-named magnetisms (if I may use the term) attract. Strictly speaking, there is a fourfold force acting, two on either pole of the needle, one pulling, the other pushing, not in the sense of moving merely directive; but, in order to simplify, we have neglected the other three. Their action needs no explanation, for they are all additive to the result.—G. F. J.

THE DESCENT OF MAN.

[217]—Mr. Donbavand's method of criticism, regularly adopted, would cripple scientific inquiry. He asserts the first difficulty of the evolution theory to be its foundation, complaining that it cannot give an exact definition of the period and the form in which the first living organism appeared upon our planet. Now I submit that a similar argument could be advanced, and with equal force, against the fundamental facts and theories of almost every branch of knowledge. The chemist bases most intricate calculations upon a hypothesis of atoms and molecules, of which not one has ever been seen isolated, weighed, or defined. The electrician speaks habitually of magnetic fluids which have never tangibly revealed themselves. No definite origin can be assigned either to molecules or to magnetism. Instances of this kind might be multiplied *ad infinitum.*

Science cannot and does not, as yet, pretend to any knowledge of the beginnings of law, matter, or life. Its present task is to procure and to sift evidence, to arrange and to explain known facts, and thereupon to formulate certain theories which shall enable us, reasoning by analogy, to acquire a more correct and comprehensive view of the subject of inquiry.

Darwin and his followers are stated by the highest authorities to have effected much in this direction. But, in any event, I contend that there is no scientific reproach to their theory in the circumstance that it fails to demonstrate the absolute origin of life. It is no evidence against the continued straightness of a line that our vision cannot extend to its extremities. E. BURKE.

"A GLIMPSE THROUGH THE CORRIDORS OF TIME—LIGHT AND HEAT WAVES."

[218]—A writer in *Nature* calls attention to a paper published by Kant, when he was thirty years of age, in which he states, "If the earth were a perfectly solid mass, without any liquid, the attractions of the sun and moon would not alter the rate of rotation round the axis . . . . If, however, the mass of a planet includes a considerable amount of liquid, the attraction of the sun and moon, by moving this liquid, impress upon the earth a part of the vibrations thus produced. The earth is in this condition." He then goes on (says the writer) to state that the moon produces the greatest effect and the tide running round the earth in a direction opposed to that of rotation. "We have here a cause on which we can count with certainty, incessantly reducing this rotation by as much as it may be capable of." . . . "When the earth steadily draws nearer and nearer to the end of its rotation, this period of change will be completed when its surface is, relatively to the moon, at rest, *i.e.*, when it rotates round its axis in the same time in which the moon revolves round it, and will, consequently, always show the same face to the moon. . . . If the earth were entirely fluid, the attraction of the moon would very soon reduce its rotation to this minimum. Herein we at once see a cause why the moon always shows the same face to the earth. . . . From this we may conclude with certainty that when the moon was originally formed and still fluid, the attraction of the earth must in the manner above described have reduced the speed of rotation, which then, in all probability was greater, to the present measured limit."

The writer considers that Kant had given a glimpse through the corridor of time a century earlier than any of the authorities mentioned by Professor Ball.

Do light and heat travel at the same pace? Do the waves of light and heat coincide? which, I suppose, may be only another way of asking the same question.—A. T. C.

[Light waves are, for the most part, heat waves, and *vice versâ,* though the luminous effect of different ether waves is not proportional to the heating effect. Of such waves we may say that they do not coincide, being identical. The same things cannot coincide, any more than a horse can run a dead heat with himself.—ED.]

PLATING ALKALOIDS.

[219]—Mr. Lewis Arandel has failed to answer the point in query 152 that I wanted elucidating, viz., how to plate on iron. Having tried silvering on iron in the wet way, first coating with copper, and failed in this, I am anxious to try nickel. In Supplement II., Watts' "Dic. Chem.," the neatest method of nickel-plating on copper and brass is given. With regard to the letter on alkaloids, Watson Smith (Bericht's "Deut. Chem. Gesellschaft," xii., 1,420) gives antimony or bismuth trichloride as a test for several alkaloids, including aconitine, which gives a bronze-brown colour. Again, last year (Thresh gives in "Pharm. J. Trans." [3], X., 809, a method of estimating the quantity of this, and of other alkaloids present, by precipitation with iodide of potassium and bismuth.—C. T. B.

THE HEALTH OF NAVVIES.

[220]—After reading your abstract from the *Times* on the above, it occurred to me that M. Colin might now very advantageously try what the effect the betel nut would have in warding off the malarias, &c., contracted in marshy grounds. I think Johnson, in his "Chemistry of Common Life," informs us that the betel chewer, whether native or stranger, has an invaluable treasure in the use of this narcotic, which is a perfect safeguard against fevers, agues, and all other maladies incidental to marsh life. If this is the case, is it not worth a trial during the extensive canalisation soon to be done in France? M. Colin, should he try it, would be able to see if the effect of betel by itself is the same as when chewed with the betel pepper leaf, and quicklime. F. C. S.

SCIENTIFIC PARADOX.

[221]—The difficulty of "Eclecticus" (p. 202) may possibly arise from his conception of the manner in which the pressure of a gas or vapour arises. Liquids have a tendency to give off vapour to a greater or less extent. This tendency varies with different liquids, and in the case of the same liquid, varies with differences of temperature. But vapours have a tendency to condense into the liquid form dependent upon their nature and the conditions to which they are exposed. When these two antagonistic influences are in equilibrium, a state of stability arises. Now, although there may be an atmosphere of ether-vapour present, water will continue to evaporate either until the tendency of the water to vaporise is counterbalanced by the tendency of the water-vapour to liquefy, or until no liquid water remains. It is evident the ether-vapour takes no part in producing this equilibrium, merely retarding the formation of vapour, and going to increase the total pressure.

It may be added that the total pressure exerted in the case of the vapours of ether, alcohol, and water is very much less than the sum of their individual tensions. This only holds good for liquids which do not dissolve in one another. W. S. C.

ALUMINIUM.

[222]—With reference to query 157, I give the following method of extracting aluminium, as it may be of general interest to your readers of KNOWLEDGE :—

A mixture of ground aluminous clay (ordinary clay, but of a good quality, and soda ash (carbonate of sodium) are heated in a furnace, aluminate of soda and silico-aluminate of soda being formed. The fused mass is then broken into pieces and thrown into an iron tank containing water; the mass is frequently stirred, and finally allowed to settle.

The aluminate of soda (being soluble in water) is dissolved, while the silico-aluminate of soda (being insoluble in water, sinks to the bottom of the tank, with any peroxide of iron that may be present in the clay.

The liquid is then drawn off, and carbonic acid gas passed through the solution. This decomposes the aluminate of soda, forming carbonate of soda and pure alumina hydrate. Thus :—

$$\underbrace{2\,AlNaO_2}_{\text{Aluminate of Soda.}} + \underbrace{CO_2}_{\text{Carbonic Acid Gas.}} + \underbrace{3\,H_2O}_{\text{Water.}} = \underbrace{Na_2CO_3}_{\text{Carbonate of Soda.}} + \underbrace{2\,Al\,(OH)_3}_{\text{Alumina Hydrate.}}$$

The alumina hydrate is then dried, mixed with chloride of sodium (common salt) and charcoal or coke, and formed into balls about the size of an orange. These balls are then taken and put into a vertical earthen retort, and heated to redness; then a stream of chlorine gas is passed through them. The chlorine combines with the alumina (being greatly helped by the charcoal), and forms chloride of aluminium, which unites with the sodium chloride (common salt), and distils over or sublimes as double chloride of aluminium and sodium thus :—

$$\underbrace{Al_2O_3}_{\text{Alumina}} + \underbrace{2\,NaCl}_{\text{Common Salt.}} + \underbrace{3\,C}_{\text{Coke.}} + \underbrace{3\,Cl_2}_{\text{Chlorine}} = \underbrace{3\,CO}_{\text{Carbonic Oxide Gas.}} + \underbrace{2\,AlNaCl_4}_{\text{Double Chloride of Aluminium and Sodium.}}$$

Ten parts of the double chloride of aluminium and sodium thus formed is mixed with 5 parts of kryolite (a double fluoride of aluminium and sodium, found in Greenland), which serve as a flux, both in a state of fine powder, and to this mixture is added 2 parts of (metallic) sodium in small pieces.

The whole is now introduced on to the hearth of a reverberatory furnace, previously heated to the required degree, when a violent reaction ensues. The dampers are then closed, and all parts of the furnace kept as close as possible, to prevent access of air. This causes the mass to completely fuse. When the action has subsided and the decomposition is completed, the furnace is tapped, and the metal and slag are run into suitable moulds. Most of the aluminium collects in the bottom of the mould. Above this are two layers of slag, the top layer being sodium chloride (common salt), the middle layer being less fusible than the top, and consisting chiefly of fluoride of aluminium, in which small globules of aluminium are mechanically held, which are recovered by pulverisation and sifting of the slag.

The following equation will show the reaction that takes place in the above reduction. Thus :—

$$\underbrace{AlNaCl_4}_{\text{Double Chloride of Aluminium and Sodium.}} + \underbrace{AlNaF_3}_{\text{Kryolite, or Cryolite.}} + \underbrace{6\,Na}_{\text{Sodium.}} = \underbrace{2\,Al}_{\text{Aluminium.}} + \underbrace{4\,NaCl}_{\text{Common Salt.}} + \underbrace{4\,NaF}_{\text{Fluoride of Aluminium.}}$$

There are other methods, but this gives the purest metal, and is one generally used in England and France. Messrs. J. Lowthian Bell & Co. (or Messrs. Bell Bros.), at Washington, near Newcastle-on-Tyne, manufactured aluminium on a large scale for several years, but gave it up a few years since, owing to it not paying so well as was first anticipated, and also on account of the limited demand for the metal. I think they used the above method.

Gateshead. G. W. GRAY.

DESCENT AND DARWINISM.—VEGETARIANISM.

[223]—I wish to protest against the large amount of space M. Doubavand has taken up in stating his ideas. He says that he sometimes ventures on the labour of thinking. May I venture to suggest that before he again trespasses on your space, he should think over what he means to say, and the shortest and clearest method of saying it ?

E. M. (letter 170) argues that because uncooked diseased meat is apt to produce tapeworm and trichinosis, therefore we should abstain from animal food altogether. Does he not see that his own argument might be turned with equal force against himself ? Because uncooked unripe fruit, if eaten at all, and all uncooked fruit, if eaten in quantity, is likely to produce diarrhœa, and so forth, therefore abstain from vegetable food altogether. EXON.

Queries.

[185]—COLD SATURATED SOLUTIONS.—Can you inform us as to the best method of making and of ascertaining the quantity of salt present in a saturated solution at 60° F ? We have tried a number of experiments, none of which are satisfactory. F. GAUBERT and C. A. SEYLER.

[186]—THE CALCULUS. Is a knowledge of the differential and integral calculus gained from, say, Boucharlat's or Hall's treatises sufficient to begin studying the Mécanique Céleste ?—TRIA. [It would be far from sufficient. A complete course of study of the higher mathematics must intervene, unless you are a born analyst. ED.]

[187]—FLAME. What are the modifications of the ordinary theory of a gas or candle flame introduced by (I think) Frankland ? Perhaps you could sometimes give us an article or two on flame, explaining why one kind of burner is better than another. I take it that for a given expenditure of gas, heat + light is constant. Is there a theoretical maximum to light, and what principles require attention in our attempts to attain it ? —L.

[188]—INTRA-MERCURIAL PLANET.—Leverrier formed a theory of an intra-mercurial planet, for which he surmised some three or four orbital periods. Oblige by informing me exactly what these periods were. I do not refer to Lescarbault's Vulcan, but to the prior hypotheses and periods of theory.—JOHN JONES. [The only periods that Leverrier dealt with, to the best of my belief, were calculated after Lescarbault's Vulcan was announced, though Leverrier attempted to reconcile prior supposed observations of planets in transit across the sun's face. —ED.]

[189]—EYE-PIECE.—Can you please give me an easy way to find the power of an eye-piece of 2 plano-convex lenses, both ½ inch focus, and sliding one into the other, at a distance from one another, say ¼ inch and ½ inch ? I want this information, so I may know the power of my telescope.—J. W. C. [The lenses should be set ½ inch apart. The power is then four times that of either lens alone.—ED.]

[190]—THE PRESERVATION OF SERTULARIAS, ZOOPHYTES, SEAWEEDS, &c.—Can the Editor of KNOWLEDGE, or a correspondent, inform me of a chemical preparation to preserve zoophytes, sertularias, and seaweeds, &c. ? and is there a book on the subject, and on British and foreign seaweeds, &c. ?—M. A. S.

[191]—ANIMAL LANGUAGE.—Do not the habits of swallows, prairie-dogs, &c., seem to prove that animals have some sort of language by which they can make themselves understood at least to members of their own family ? ARACHNIDA.

[192] THE ICE-AGE IN BRITAIN.—What proofs are there at the present time that there ever existed an ice-age in Britain ?—ARACHNIDA.

[193]—ACTION OF THUNDER-STORMS.—Why are beer and milk so frequently turned sour during a thunder-storm, although they will often stand as high a temperature without being affected when there is no thunder in the air?—F. A. S.

[194]—GRAVITY.—The editorial reply to query 114 is incomprehensible, if correct. If any force, however small, will overcome the inertia of any mass, however great, what then becomes of the law, that inertia is proportional to mass? I wish to know what force is necessary to overcome the inertia of one ton weight in a direction at right angles to the force of gravity ?—ZARES.—[We repeat, any force, however small. If a ton of matter were suspended as you described, or placed on a perfectly smooth table, the breath of a child would overcome its inertia. The velocity communicated to it would be very small, but you did not say how much velocity you wanted. ED.]

Replies to Queries.

[61]—STAR NUMBERS AND LETTERS.—"A Fellow of the Royal Astronomical Society" says (p. 164, No. 8): "Stars . . . . . are both lettered and numbered in their order of Right Ascension." There should be a comma in this reply, after the word "lettered." The stars are numbered in the order of their right ascension, and Bayer lettered them roughly in order of their brightness. This answers a query by "Winter."—ED.

[71]—NAMES OF FLOWERS. I would advise Querist 71, in sixth KNOWLEDGE, to get Bentham's "British Flora." He will find it everything he desires. Should he fail to get at the right name of a flower by means of this excellent work, I should then recommend him to send a perfect specimen of the "stranger" to the editor of

KNOWLEDGE, who, I am sure, will not consider it too much trouble to assist amateur botanists by giving names of flowers when requested to do so. J. E. GEORGE. We are not personally botanical, worth mentioning - better trust in the book. Though we would forward specimen to botanist. ED.

[130] KNOWN LANGUAGES. Horalacque calculates 199 language - how many more have been made *known* since he wrote I do now know. G. T. HARRAP.

[133] In addition to "Pangul's" references, "Querist" will find several of Mr. Dollinger's papers in the *Monthly Microscopical Journal*, vols. X., XI., XII., XIII., XIV., XVI., XVIII. B. J. AUSTIN.

146 CHEMICAL.- The reason why the O. of the air is utilised in the body, while the N. is rejected, is that the former is essential to those transformations which convert the potential energy of certain constituents of food into actual energy, while the latter is useless for that purpose. Fats and other carbohydrates, when taken into the body, furnish, by their oxidation, the actual energy which is in part transmuted into muscular power; and it is to this process of oxidation that animal heat is due. There being no other available source of O., the amount necessary for the said oxidation of the carbohydrates used as food must come from the inhaled air. It is only the heat and muscular-power-producing constituents of food - the carbohydrates - that get oxidised in the body, the nitrogenous or flesh-forming constituents, together with the phosphates and carbonates, being capable of performing their functions without undergoing the process of oxidation. Now, as the products of oxidation, CO_2 and OH_2, are exhaled, there cannot remain in the body anything that can be termed "food already oxidised." In fact, the utility of carbohydrates does not consist in their adding anything to the structure of the body, but in their producing muscular power and heat when being transformed into the gases exhaled in the breath. In starch and sugar, the O. and H. exist in the same proportions as they do in OH_2, and, as the whole of the O. and H. of those carbohydrates leave the body as OH_2, all the carbon is in a position to be oxidised by the inhaled O. of the air, and is, consequently, available to produce its full amount of force and heat.— E. M. D.

[157]—ALUMINIUM, page 211.—Cryolite (a fluoride of sodium and aluminium, which occurs in great abundance in Greenland) is powdered, mixed with half its weight of common salt, and either placed in alternate layers with two parts of sodium in a crucible, or roasted with the same quantity of sodium in a furnace. The chief advantage in using cryolite is that the costly and troublesome process of preparing the double chloride of aluminium and sodium is thus dispensed with. There was a process patented in Germany a short time ago, the main point in which consisted in fusing the sulphide of aluminium with iron; but surely other chemists thought of this process before: I did three years ago.—A GREENOCK STUDENT.

Answers to Correspondents.

**** All communications for the Editor requiring early attention should reach the Office on or before the Saturday preceding the current issue of* KNOWLEDGE, *the increasing circulation of which compels us to go to press early in the week.*

HINTS TO CORRESPONDENTS. 1. *No questions asking for scientific information can be answered through the post.* 2. *Letters sent to the Editor for correspondents cannot be forwarded; nor can the names or addresses of correspondents be given in answer to private inquiries.* 3. *No queries or replies savouring of the nature of advertisements can be inserted.* 4. *Letters, queries, and replies are inserted, unless contrary to Rule 3, free of charge.* 5. *Correspondents should write on one side only of the paper, and put drawings on a separate leaf.* 6. *Each letter, query, or reply should have a title, and in replying to letters or queries, reference should be made to the number of letter or query, the page on which it appears, and its title.*

J. CARGILL. Thanks for encouraging words. Your student friend who thinks we are too abstruse for the masses and too popular for scientific students is right enough; that is what we have aimed at. But he is unwise in calling it a fault. We do not write for science students, though among those who write for us are some who can teach the teachers of science students. Nor do we write for those who neither think nor care to think. J. D. M. I have never seen unusual feats of strength done under mesmeric influence, but Dr. Carpenter gives instances of the kind. They illustrate the influence of imagination, but they have not yet been explained.—J. WILLSON. Lardner's works are not absolutely out of date, but they would suit better one who was well up in all the modern views, so as to be able to distinguish at once what is obsolete.—J. PRESTON BATTERSBY. Many thanks. Your notes are very interesting. I return them as you desire. I think you are mistaken in imagining there is any prejudice about so-called mesmeric phenomena. They are treated very fairly by some of our most eminent physiologists.—M. If, knowing what the planets are, their distances, &c., the slightest reason for conceiving that they can influence our weather could be shown, it might be worth while to make such observations as you suggest; but none can be imagined. BRENTON. You are quite right; T. R.'s solution may be made by embodying his demonstration of the property on which it depends to all intents and purposes a solution within the limits of Books I. and II.; but with the extra matter you show to be necessary to complete it, it contrasts very unfavourably with either of the other proofs depending on books III. and VI.—ZARES. *What* series 0 to 1 do you mean? M. J. HARDING. Orion, on the cover of my "Easy Star Lessons," is "quite too utterly awful." I had nothing to do with it. It is the binder's conceit. Trying to correct it would be useless. In the present position of science, a work "containing a most exhaustive refutation of the Darwinian theory" must either be a very wonderful performance (as you say), or very bad. Science has not been profoundly stirred by the book. The sub-title seems open to objection, to say the least, as suggesting that the Newton of Biology is a sort of "devil's advocate."— A. G. P. We misread your letter; but our reply was not meant as you suppose. The absence of centrifugal force would produce a very slight but measurable increase of weight. W. A. C. We have no objection; you may prefer a dog to your nearest and dearest; you must allow us, though we like Rover very much, to prefer our dear ones of human sort. To be consistent, you ought not to breathe, for, at every breath, you destroy multitudes of "creatures belonging to races below us." —WINTER. Yes; he probably smiled: but "he laughs longest who laughs last."—VEGA. Yes; but the point really is whether the classification adopted by Owen is essentially wrong. For convenience, the other may be better; but it is a merely arbitrary distinction.- H. D. P. Not about Sorghum just now; so many things wanted and promised. Sorry am unable.—GRADATIM. The loxodromic curve approaches the pole by an infinite series of circlings, though the total distance is finite, each whorl bearing to the previous one a ratio less than unity. Thus your whole question involves a paradox, as no ship could follow such a course; no wonder no ship could leave the Pole on the loxodromic spiral. Remembering that the stereographic projection of the loxodromic curve on the equatorial plane with South Pole as pole of projection is an equi-angular spiral, and that this curve approaches the pole asymptotically, you will find no difficulty in interpreting your paradox.—B. DONBAVAND. Your letters at least five times too long for admission.—J. P. SANDLANDS. South cone is up, means that this weather signal is hoisted—viz., a cone with its point downwards. Mrs. Kingsford says the teeth of man indicate that he is a frugivorous animal; others regard them as showing him to be omnivorous. As a matter of fact, he is omnivorous, whatever his dental formula may be. The other query seems answered by what is stated in our review of Mrs. Kingsford's book. —ONE INTERESTED IN "KNOWLEDGE." No one asks you to believe that man is descended from monkeys—only that he is related to them; so that what you believe is closely akin to the scientific faith, for you think monkeys descended from men. The tone of your remark that "no theory will make you believe" so and so, is unscientific in the extreme. The student of science is prepared to believe whatever facts may prove.- J. R. See p. 170, where precisely such a problem is solved.—PETER KNOWLES. I return the twelve stamps. If I "published" the work you name I would send it, but I do not publish that or any work. I did not even write it, I only revised it. If I remember rightly the publisher is Baillière, King William-street, Strand. URSA MAJOR. A lunar rainbow is caused precisely as a solar rainbow is caused, only that the light comes from the moon instead of the sun. V. C. C. D. I do not see how reasoning so sound and moderate as that you quote can be answered. I should imagine few evolutionists would be so extreme as those who seem to be disposed of by this reasoning.— G. T. HARRAP. You "disagree with vaccination," but your letter would disagree with our readers. SALUTO. Yes, microscopy is as desirable in our pages as telescopy.- F. C. S. Many thanks: marked for insertion.- J. B. More rapid respiration, increasing the combustion, seems to account for the difference.—G. S. BODKIN. We point out mistakes (where we see them) frankly and without apology, because that is doing to others what we wish them to do to us.—J. MCNEILL. In issuing monthly parts, the publishers are endeavouring to meet the wishes of the public; when I note that reprints have been necessary to make up the first two monthly numbers, you will understand their price. The reprint of a newspaper always means loss of money, and the publishers have reprinted (setting up every line of contents and advertisements afresh) in some cases twice; and made up sets out of the back numbers which had been intended for volumes. Many thanks for good wishes.—C. J. BROWN. Gravity vanishes at the earth's centre, but pressure is there at its maximum. Apart from a very slight diminution, due to the greater or less rigidity at

different parts of the earth's interior, the pressure at any point within the earth is proportional to the total quantity of matter above that point, just as in the sea, where, though gravity is appreciably constant, pressure is proportional to the depth. If you ask where the force of gravity is at a maximum, I cannot answer, because I do not know according to what law density increases towards the centre. As to the other point, our circulation increased so that it became quite impossible to continue cutting the edges without unduly delaying publication. But we more than make up for that in other ways. In binding there would in any case have had to be another cutting, and most of our readers, we believe, intend to bind each volume as it is completed.—H. Fear cannot find space for paper on colours. Readers complain unless a certain proportion of space is given to original matter, and we cannot increase the total space beyond a certain range. Correspondents must not suppose we do not value letters which we are obliged to omit.—J. E. SHEPHARD. The writer of the article in question was not likely to consider the use of aconitine in homœopathic practice. It is seldom used by allopathic physicians, except as an external application. A GREENOCK STUDENT. Clouds are formed by the condensation of aqueous vapour into small water drops, which, however, do not fall rapidly like rain drops. It can be shown that the smaller a water drop, the slower its descent through still air. However, a cloud is also constantly changing, as you suggest. The light, feathery clouds consist of particles of ice or fine snow. Colonel Ross promised other papers on blowpipe analysis, but has apparently not yet been able to find time to write them. The blowpipes made on his plan will be rusting for want of use. TREBOR ROLAT. Short whist, played without counting honours, is, to all intents and purposes, the ordinary game with the element of chance as far as possible eliminated. It is in my opinion a much better game even than that which Clay thought would be perfect, in which the honours are counted at half the usual rate, one point for two by honours, two for all four honours. After playing the game for any length of time without counting honours, a real lover of whist feels something like shame in counting honours, or even half honours. At present we fear the star chart cannot be issued with the last week of each month, as we want one chart to appear each month. As soon as we can, the change shall be thought of. Have no space, for some time, for article on relation between mind and physical force.—DOUG. BRODIE. Your 2½ stamps received, but no paper on the Tides has yet appeared; we did not promise it for an early date, and if we had, we could hardly have kept our promise.—JAMES DEAS. Never heard before that the Star in the East was thought by any one to be the variable Mira. That star has been said to be a comet, a conjunction of planets, and a temporary meteor. Astronomy has nothing to say to any of these ideas.—S. DE MERVIGNE. The passages you quote show that where the conditions remain the same, races change little or not at all. What is there in the theory of evolution to suggest that they should change a great deal?—F. F. Your suggestion about the use of Jacob's ladder at fires seems excellent, but space should be found for it elsewhere. It does not belong so much to our subjects, as to those treated of in weekly newspapers or mechanical papers.—VIGNOLES. Many thanks; but your square has already been given.—ROBERTUS. We do not know the name of the secretary of the Society for Promoting the Abolition of Capital Punishment.—E. M. Not knowing the tables that you refer to, cannot tell precisely how the discrepancies arise. The date of your tables is so remote you could scarcely expect calculations made by them to correspond with the recent ones of the Nautical Almanack. We shall give such a map as you mention, relating to the transit of Venus. You must not expect to find in the "Nautical Almanack" all that is necessary to calculate phenomena. I had to work many hours and many days to get the results on which I based my investigations of the transits of 1871 and 1882.—J. N. DEVINE. Of course you are right. Our mistake was a natural one; but it was unquestionably a mistake. We have altered it, noting the error.—MEMBER OF THE ARCHÆOLOGICAL SOCIETY. Thanks; but it would be an obligation if you could briefly sketch for readers of KNOWLEDGE the essential ideas of Naville's book. The subject is a curious one, a little out of my own personal line of studies, but full of interest, and I am sure readers would be interested.

MR. W. H. H. HUDSON, late Fellow and Lecturer of St. John's College, Cambridge (Third Wrangler in 1861), succeeds Mr. Drew as Professor of Mathematics at King's College, London.

Notes on Art and Science.

FERMENTATION IN BEER.—"In Re" is evidently unaware of the lengthy explanation which his question involves. In the first place, different brewers have different ways of starting fermentations. The Germans, and a few English, mix their yeast with a little of the "wort" first, and then add the rest. The Japanese use rice must for starting. Then the "pitching" variations during process of specific gravities and temperature must be considered, also germs generated in fermenting healthy and unhealthy the preparation of the wort and yeast; in fact, I should advise "In Re" to get a book on brewing and read it through, for it will *all* be interesting, and will lead him up to his subject. If Dr. Graham, Professor at University College, London, has published his lectures delivered on the subject, I can only say that "In Re" will have a book written by one who has mastered thoroughly the whole subject of brewing. Mr. T. A. Tooley, B.Sc., F.C.S., editor *Brewers' Guardian*, has his articles on Brewing and Distilling, written for the "British Manufacturing Industries," published. His name needs no comment.—F.C.S.

THE EXPANSION OF WATER BY HEAT.—Herr P. Volkmann has in the *Annalen für Physik und Chemie* compiled the results of Hagen, Matthiessen, Pierre, Kopp, and Jolly, on the expansion of water, and has obtained the following mean results for the volume and density of water at various temperatures:—

Temp.	Volume.	Density.	Temp.	Volume.
0 degr. C.	1·000122	0·999878	15 degr. C.	1·000847
1 ,,	1·000067	0·999933	20 ,,	1·001731

SUNDAY LECTURE SOCIETY.—In the course of his lecture on "The Heart and its Work," on a recent Sunday, at St. George's Hall, Langham-place, Dr. Andrew Wilson gave some interesting details regarding the action of the central engine of the circulation. The heart, he showed, was merely "a hollow muscle," and the force which drives blood through our bodies is therefore similar to that wherewith we move our fingers in writing, or our legs in walking. Dr. Wilson showed also that the work of a man's heart in 24 hours amounted to 124 ft. tons; *i.e.*, if the heart's force for 24 hours were gathered into one stroke or lift, it would suffice to lift 124 tons 1 ft. high. The heart is ruled by at least three sets of nerves. In its own substance, there are masses of nerve-matter, or *ganglia*, which carry on the normal work of the organ. Then, secondly, there exists an important *vagus* nerve, which checks or slows the heart's action, as under the influence of fear or other mental emotion; and there is, thirdly, a *sympathetic nerve*, which causes the heart's action to increase in rapidity. The varying emotions of the mind thus influence the heart for good or for evil by disturbing its normal action.

NO ORGANIC MATTER IN METEORS.—A Louisville (Ky.) paper reports an interview with Prof. J. Lawrence Smith, of that city, in the course of which Mr. Smith gave reasons for discrediting the discovery of organic substances in meteors, as claimed by Prof. Hahn, of Berlin. Mr. Smith said:—"Although I have probably examined more microscopic plates of fragments of meteorites than any other person, still I have never discovered anything like organic remains in any of them. Besides, the well-known chemical composition of these bodies is averse to the existence of any such remains as spoken of by Prof. Hahn. Were these remains present, we should discern carbonate of lime in their interior. The two or three that have any carbonate of lime were discovered and analysed by myself, and in these cases the carbonate of lime was an accidental constituent of incrustation deposited on the surface after their fall. In the microscopic examination of these polished plates of meteorites, the two predominating minerals, enstatite and bronzite, will, by their fissures and forms, sometimes remind one of vegetable and other organic forms, but the merest tyro of an observer will trace here nothing but a rare resemblance. And furthermore, the nature of these minerals precludes the possibility of organic remains even in terrestrial minerals of similar kind. Not knowing of any eminent German geologist named Prof. Hahn, I thought it but reasonable and logical that I should inquire something about him from my friend Prof. Hawes, now in the employ of

the Smithsonian Institution, and the best lithological microscopist in this country, and who recently returned to this country after ten years' study with Prof. Rosenbaum and others into the microscopic character of rock. In answer to my inquiries, Prof. Hawes wrote me this letter:—"I read that paper of Prof. Hahn's. He is a kind of half insane man, whose imagination has run wild with him. These forms which he so accurately describes and figures have long been known to exist in meteorites, and have been frequently described by mineralogists and microscopists. They are mainly composed of enstatite or bronzite in radial forms, and fractured in such a peculiar manner as to give them the appearance of structure. Some of the American meteorites which I have examined show these forms in great beauty, but Prof. Hahn is the only man who has seen anything organic in them, and his paper has excited nothing but ridicule. It reminds one of the long and laborious research of a German professor who found a whole flora and fauna which he named with double Latin names, and which he found in his microscopic examination of basalt. It is very clear to my mind," continued the Professor, "that these cranky observations, viewed with the spectacles of the imagination of Prof. Hahn, have obtained more publicity than they merit."—*Scientific American.*

Our Mathematical Column.

MATHEMATICAL QUERIES.

[15]—ARITHMETICAL PROBLEM.—A and B have to build a wall one hundred yards long; A is to have five shillings a yard more than B. When the wall is finished A and B each receive £50. How many yards did each do, and at what rate per yard?—HAMILTON STUART.

[This leads to an indeterminate equation. Thus, if x be number of yards built by A, y the number of shillings received per yard by B, we have $x(y+5)+y(100-x)=2{,}000$; or $x+20y=100$.—ED.]

[16] In an old volume of problems, I came across the following: A messenger, M, starts from A to B (a distance a miles), at a rate of v miles per hour, but before he arrives at B, a shower of rain commences at A, and at all places occupying a certain distance, z, towards, but not reaching beyond, B, and moves at the rate of u miles an hour towards A. If M be caught in the shower, he will have to wait until it is over. He is also to receive for his errand a number of shillings inversely proportional to the time occupied in it, at the rate of n shillings for one hour. Supposing the distance, z, to be unknown, as also the time at which the shower commenced, but all events to be equally probable, show that the value of M's expectations, in shillings, is—

$$\frac{nv}{u}\left[\frac{1}{2}-\frac{u}{v}+\frac{u(u+v)}{v^2}\log.\frac{u+v}{u}\right]$$

Can you or one of your readers kindly solve this problem for me without using the differential calculus?—NO ANALYST. [We will leave this problem for a week. "No Analyst" has set us a hard one.—ED.]

[17]—TORTOISE PROBLEM. A hare and tortoise have a race, the hare gives the tortoise 100 yards start and runs ten times as fast; they start together, but while the hare runs the 100 yards, the tortoise has crawled ten yards; while the hare is running the ten yards the tortoise crawls one yard; while the hare runs that one yard the tortoise has advanced $\frac{1}{10}$ of a yard; and so on, *ad infinitum*, the hare, mathematically, never overtaking the tortoise.—TORTOISE. [The paradox was known to the Greeks as the problem of Achilles and the Tortoise. The explanation is that the distance run by either animal is divided into an infinite number of parts, forming a geometrical series, having a finite sum. Thus the hare runs 100 yards $+10+1+\&c. = 100\div(1-\frac{1}{10}) = 100\left(\frac{10}{9}\right) = 111\frac{1}{9}$ yards. The tortoise crawls $11\frac{1}{9}$ yards. Dividing up a finite distance into an infinite number of parts does not make it infinite.—ED.]

[18]—ARITHMETICAL QUESTION.—A man having a cask containing 300 gallons of wine takes out one gallon per day, putting in a gallon of water to refill the cask each day. After how many days will the mixture in the cask be half water and half wine.—YOUNG BEGINNER. —[Y. B. asks whether this problem can be solved without the aid of logarithms. Not readily. At end of one day the mixture is $\frac{299}{300}$ths wine, at end of second it is $\frac{299}{300}$ths of $\frac{299}{300}$ths wine or $\left(\frac{299}{300}\right)^2$ wine, and so on. If in x days the mixture in the cask is half water and half wine, we have $\left(\frac{299}{300}\right)^x=\frac{1}{2}$; or taking logarithms of reciprocals of each side, we have $x(\log.300-\log.299)=\log.2$, or $14501x=3010300$, $x=\frac{3010300}{14501}=207.59$; or up to the 208th day the mixture would contain more wine than water, after the 208th day it would contain more water than wine.]

A. M. R. points out a mistake on p. 191, where we put

$$1=(\sqrt{1+x}+x)(\sqrt{1+x}-x)$$

Of course, this relation does not hold; and the solution fails. We had found 0 to be the only root which could be obtained without a solution for cubic or biquadratic, and as the solution, after above mistake, led to root 0, we did not (as we should have done), run through the steps. The equation obtained just before the mistake occurs is

$$1=\sqrt{1-x}\,(\sqrt{1+x}+x)$$

this will be found to give $x=0$ and the biquadratic

$$x^4-4x^3+4x^2+4x+4=0.$$

"T. R." considers that the proposition $DM^2=AM.MB$, first figure, p. 211 (ADB a right-angled triangle, and DM perp. to AB), may be established without the use of books of Euclid beyond I. and II. Thus (we rather abridge his proof):

$$AM^2+MB^2+2AM.MB=AB^2=AD^2+DB^2=AM^2+MB^2+2MD^2$$
$$\therefore\ AM.MB=MD^2$$

We did not say otherwise. We said it neither is in those books, nor can be given as a *corollary* on any propositions they contain. Several of the propositions in Book III. can be as easily proved from Book I., but they are thrown, for convenience, into a separate book.

[19] SUM OF SQUARES. I do not know if the following simple method of getting at the formula for $1^2+2^2+3^2+4^2 \ldots\ldots + n^2$, is new or not, but I believe it is not the usual one, and so send it on the chance of your thinking it worth publishing:—

$$\begin{array}{ccccccccccccc}
 & 1 & 2 & 3 & 4 & 5 & . & . & . & . & . & n & A\\
 & 1 & 2 & 3 & 4 & 5 & . & . & . & . & . & n & \\
 & 1 & 2 & 3 & 4 & 5 & . & . & . & . & . & n & \\
C & 1 & 2 & 3 & 4 & 5 & . & . & . & . & . & n & B\\
 & 1 & 2 & 3 & 4 & 5 & . & . & . & . & . & n & \\
 & . & . & . & . & . & . & . & . & . & . & &
\end{array}$$

Here the horizontal line cuts off the series $\frac{n}{2}(n+1)$, and the zigzag line divides the figures forming the squares from the unnecessary ones below. The sum of the squares equals $A+B$.

Now, $B=2C$, as is readily seen from the above diagram. [Every vertical column in B sums up to twice the sum of a horizontal row in C.—ED.] And

$$B+C=(n-1)\times\frac{n}{2}(n+1)$$
$$\therefore\quad B=\frac{2}{3}(n-1)\times\frac{n}{2}(n+1)$$
$$=\frac{n}{3}(n-1)(n+1)$$
$$\therefore\quad A+B=\left(\frac{n}{2}+\frac{n}{3}(n-1)\right)(n+1)$$
$$=\frac{n(n+1)(2n+1)}{6}$$

FLORENCE E. BOYCE.

[9]—Several correspondents consider this problem incorrect, incomplete, or absurd. Others give incorrect solutions. It is, however, quite correctly stated. It is correctly solved thus, or to the same effect, by T. R., Charles Hammond, D. Kelley, Jas. Frobisham, K. Carlson, and others. We give Mr. Hammond's solution as one of the neatest in form:—

"Since the grass grows uniformly, its growth may be kept down by a certain number, independent of time, but varying directly as the area of the field.

"The remaining horses are required to consume the original stock of grass. Their number varies directly as the area, and inversely as the time.

"From this it is evident that in the first case 6 horses take 16 weeks to consume the original stock of 10 acres, and 6 keep down the growth.

"Now, by proportion, the number of horses taken to consume the original stock in a 40-acre field in 6 weeks is 64, and the number required to keep down the growth is 24.

$\therefore$ Answer, 88 horses.

N.B. For the general case of this, see Newton's "Arithmetica Universalis," page 90, 2nd edition, London, 1722.

Our Whist Column.

By "Five of Clubs."

THE LEAD (*Continued*).

Addendum to Plain Suit Leads.

The leads considered in the last two numbers were supposed to be either original leads from long or strong suits, or forced leads with no knowledge of your partner's strength in the suit led. Note that in every case of a forced lead from a short suit, where you have reason to believe that your partner has strength in the suit, the highest is played, so that from Ace two others you lead Ace in this case, following with the next highest. Similarly, from King two others you play King, then next highest; from Queen two others, Queen, then next highest: from Knave two others, Knave, then next highest. This last is the constant lead from Knave two others (as from ten two others, you play ten, then next highest): when your partner has not indicated strength, there is some use in leading lowest from Ace two others, King two others, or Queen two others; but manifestly keeping back the Knave or ten (with two others) can be of no use to you, while playing it may help your partner.

The Lead in Trumps.

We do not propose to consider here the important question (important in whist-play, at any rate) when to lead trumps, but what card is to be led when it has been decided to open the trump suit.

The lead in trumps differs in one important respect from the lead in plain suits,—there is no fear that a good card will be lost if kept back, by being trumped. We can, therefore, play with safety a waiting game; indeed, it is often advantageous to do so, because so much often depends on winning the last round in trumps.* Another difference between trump cards and others arises from the circumstance that you need not so carefully indicate your strength by playing an obviously winning card; for there is no possibility of your partner hurting you by trumping a card which he may mistake for a losing one. The chief variations of the trump lead from a lead in plain suits depend on these considerations—principally on the former.

Thus, in trumps, from Ace, King, and not more than five others, the smallest should be played; this ensures the numerical command in trumps, if you have five others, and is the best way towards obtaining it if you have less than five. Besides, by this course you give your partner a good chance of winning the first trick. Of course, if you have six small ones besides Ace and King, you have the numerical command, even if all the remaining trumps are in one hand; you therefore play King, then Ace.

Again, from Ace, King Queen alone in plain suits, you lead King, then Queen. In trumps, having no fear that Queen will be lost, you lead Queen first, then King. So with Ace, King, Queen, Knave, you lead King first in plain suits; in trumps you lead the lowest of the sequence, the Knave.

Again, in plain suits from Ace and four or more others, not including King, you lead Ace, because of the risk that in the second round it might be trumped. Having no such fear in the trump suit, you lead the smallest, unless you have more than six small ones, in which case, being sure of the numerical command, you lead Ace.

In trumps from King, Queen, and two or more small ones, the lowest is led, instead of the King, as in plain suits; but with more than five small ones, begin with King.

Some trump leads differ from plain suit leads and ordinary trump leads, on account of the trump card being of a particular value. Thus, from Ace, Knave, ten and nine, the nine would be led in plain suits: so, also, nine would be led in trumps, unless Queen is turned up on the left, when Ace should be played. Again, from King, Knave, two or more small ones, the lowest is led in plain suits, and ordinarily in trumps; but if ten is turned up to the right, the Knave is led. In trumps, from Knave, ten, eight, with one or more small ones, lead the lowest, as in plain suits, unless nine is turned up on your right, when lead Knave.

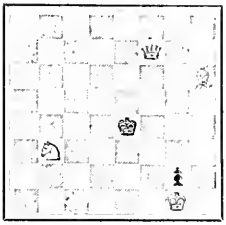
* We do not mean simply having the last winning trump, for this may be left in and the opponents' strong suits yet played out to the bitter end; but winning the last round of trumps, so as to be able to bring in a strong suit either of your own or your partner's.

Our Chess Column.

Problem No. 11 (From *American Chess Nuts*).

By E. B. Cook.

Black.



White.

White to play and mate in three moves.

TWO KNIGHTS' DEFENCE (*Continued*).

Another interesting form of this opening is where Black, on his fourth move, plays Kt. takes K.P. In most cases strong players will adopt this move with good effect against a weaker opponent. As it is chiefly our wish to instruct the student, we shall show him in full all the variations resulting disadvantageously, so that he might avoid them, at the same time also giving him the good replies for adoption.

1. P. to K.4. P. to K.4.	2. Kt. to K.B.3. Kt. to Q.B.3.	3. B. to B.4. Kt. to K.B.3.
4. Kt. to Kt.5. Kt. takes K.P.		

White has three modes of continuing, viz., Kt. takes K.B.P. or Kt. takes Kt., or B. takes P. ch. (best). Of these only the last move can be recommended, for if

5. Kt. takes K.B.P.
Q. to R.5.

6. Q. to K.2. Kt. to Q.5.	or 6. Castles. B. to B.4.	or 6. P. to K.Kt. 3. Kt. takes Kt.P.
7. P. to K.Kt.3. Kt. takes Q.,	7. Kt. takes R. Kt. takes B.P.	7. B.P. takes Kt. Q. to K.5.ch.
8. P. takes Q. Kt. to Q.5.	8. B. to B.7.ch. K. to K.2.	8. Q. to K.2. Q. takes R.ch.
9. P. to Q.3. Kt. to Q 3.	9. R takes Kt.ch. Q. takes R.ch.	
10. Kt. takes Kt.ch. B. takes Kt.	10. K to R.sq. B. to Q. 3.	

In all these cases Black obtains a decisive superiority. 5. ——— Q. to R.5 wins in any case, as the attack obtained thereby is very strong.

If 5. Kt. takes Kt. P. to Q.4.	6. B takes P. Q. takes B.	7. Q. Kt. to B.3. Q. to Q.sq.

and the game is even

If 5. B. takes P.ch. (best)
K. to K.2.

6. P. to Q.3. Kt. to K.B.3.	or 6. Kt. takes Kt. K. takes B.	or 4.
7. B. to Q Kt.3. P. to Q.4.	7. Q. to B.3.ch. K. to K.sq.	or 7. Q.Kt. to B.3. P. to K.Kt.3.
8. P. to K.B 4. B. to K.Kt.5.	8. P. to Q.4. P. to Q.4.	8. Castles. P. to Q.4.
9. Q to Q.2. K. to Q.2.	9. Kt. to Kt.5. Q. to B.3.	9. Kt. to Kt.3. B. to K.3.
10. Castles.	10. Q. takes P. Kt. takes P.	10. P. to Q.3. B. to Q.B.4.

It will be recognised that Black incurs the disadvantage of playing his K. to K.2., on account of the strong centre which he afterwards threatens to obtain, which, as second player, he could not get in the ordinary course. In all the three variations given above, White has no advantage, but Black has a great many chances of getting the better game. In the first variation the game is about even, although Black will have to take some care. We can best show the very attacking nature of the opening in spite of the unfavourable position of Black's King (which, as we have before said, is compensated by his

strong counter by giving the following additional variations, namely, if in the first variation, instead of 10 Castles, White play the tempting move 10. Kt. to B.7. Black gets the advantage as follows:—

10. Kt. to B.7. / Q. to K.2. 11. Kt. takes R. / P. takes P.dis.ch. 12. K. to B.sq. / Kt. to Q.5.

13. Kt. to B.3. / B. to Q.B.4. and Black has the better game, as he has an exceedingly strong attack. He chiefly threatens Kt. to B.6, which White cannot retake with the Pawn, on account of B. to R.6.ch. The Queen has no place to go to if attacked by the Kt., as Q. to K.8.ch. is thereby threatened. White would lose his Queen if, in reply to Kt. to B.6, he should play Q. to Q.sq., by Kt. takes P.ch.

Again, if in the first variation White does not play 8. P. to K.B.4. he will speedily be strongly attacked by Black. If, for instance, 8. Castles. / P. to K.R.3. 9. Kt. to K.B.3. / K. to B.2., with a good game, as Black has two good plans to pursue, firstly B. to Q.3., R. to K.sq., and K. to Kt.sq.; or, secondly, he might play B. to Q.3, B. to K.3., Q. to Q.2., and Q.R. to K.Kt.sq., so as to proceed with an attack on the King's side by P. to K.Kt.4.

Of course, statements of these kind are only general, and meant to show the nature of the position, but real play has, of course, to be modified, even according to weak replies of an opponent. But, whatever White should do, Black should obtain the better game, owing to his good position.

(4) 1. P. to K.4. / P. to K.4. 2. Kt. to K.B.3. / Kt. to Q.B.3. 3. B. to B.4. / Kt. to K.B.3.

4. Kt. to Kt.5. / Kt. takes K.P. 5. B. takes P.ch. / K. to K.2. 6. P. to Q.4.

This is the very best reply, we may say the only move which, amongst the numerous possible moves, gives White the advantage, which fact shows the dangerous nature of this opening. 6. P. to Q.4. breaks up Black's centre, and thereby obtains for White the better game.

In reply to 6. P. to Q.4. Black can play

6. — / P. to Q.R.3.	or 6. — / P. to Q.4.	or 6. — / Q.Kt. takes P.
7. Kt. takes Kt. / K. takes B.	7. P. takes P. / Q. Kt. takes P.	7. P. to Q.B.3. / Kt. to Q.B.3.
8. P. to Q.5. / Kt. to K.2.	8. Q. takes P. (best) / Q. takes Q.	8. B. to Q.5. / Kt. to K.B.3.
9. Q. to R.5 ch. / P. to Kt.3.	9. B. takes Q. / Kt. to K.B.3.	9. Kt. to B.7. / Q. to K.sq.
10. Q. takes K.P. / R. to Kt.2.	10. Kt. to Q.B.3. / P. to B.3.	10. Kt. takes R. / Kt. takes B.
11. Q. to B.4.ch. / K. to Kt.sq.	11. B. to Kt.3. / B. to B.4.	11. Q. takes Kt. / P. to K.R.3.
12. Q. Kt. to B.3.	12. B. to K.3.	12. Q. to K.4.
winning.	and White has a good game.	winning.

Besides these moves Black can also play

6. — / P. to Q.3.	6. — / P. takes P.	6. — / Kt. to K.B.3.
7. B. to Q.5. / Kt. to B.3.	7. Q. to K.2. / P. to Q.4.	7. P. takes P. / Kt. takes P.
8. B. takes Kt. / P. takes B.	8. B. to R.5. / etc.	8. Q. to K.2. / etc.
9. P. takes P. / etc.		

If 6. — / Kt. to Q.3. White wins the Queen by 7. Kt. to K.6.

Therefore, whatever Black may do, White, by 6. P. to Q.4., will invariably get the better game, which move, therefore, is the proper defence against this strong counter-attack.*

* To Mr. Gossip is due the credit of advocating this strong move and the ensuing variations.

SALFORD.—You have not transgressed the rules of chess, but your solution of Problem 6 is unsound. After Q. to Q.3 ch., B. takes Q., P. takes B., why should not Black take B. with P. in his turn? How would White mate then on the move?

JAMES MACALPINE.—If (1) Kt. to Kt.5. in Problem 6, 1. P. to Kt.4., 2. P. takes K.P., Black can play Q. to Q.'s 5th ch., and there is no mate.

CRYPTOTYPE.—If Q. takes K.B.P., in Problem 6, Black moves Q. to Q.R. square; then, if Q. takes Q., P. to Q.B.3., and there is no mate on the move.

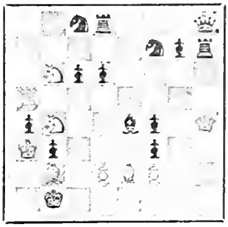
H. FITZ HART. Your letter forwarded to Hades, "Mephisto," being the author of the analysis in question. You should have addressed Chess Editor.

The *Chess Player's Chronicle* calls our attention to the following beautiful problem by Mr. Grimshaw, in which the idea underlying the second solution of his problem, No. 6, p. 190, is embodied.

PROBLEM, No. 12.

By W. Grimshaw.

BLACK.



WHITE.

White to play and mate in four moves.

Unfortunately there are two solutions, one beginning Q. takes P., the other (the author's) beginning Q. takes R. (at R.'s 2.). The *Chronicle* believes that the solution given in the *Illustrated London News* was not the author's; how, then, was it that no reference was made in the *Illustrated* to any other solution? The *Chronicle* appends a note of interrogation to our remark that if, in Problem 6, Queen goes at once to K.'s 6th, mate is only threatened in one way. How is mate threatened, except by B. takes P.? After 1. Kt. to K.B.5., 1. B. takes Kt. 2. Q. to K.'s 6th, mate is threatened also by Q. takes B.,—that is, as we said, in two ways.

Contents of KNOWLEDGE *No.* 11.

NOTICES.

The Publishers beg to announce that in future Monthly Parts of KNOWLEDGE will be issued. The following are now published:—

PART I.—(November, 1881.) Containing the first four numbers. Price 10d. Post-free, 1s.

PART II.—(December, 1881.) Containing five numbers. Price 1s. Post-free, 1s. 2d.

The Back Numbers of KNOWLEDGE are now in print, and can be obtained from all booksellers and newsagents, or direct from the Publishers. Should any difficulty arise in obtaining the paper, an application to the Publishers is respectfully requested.

TERMS OF SUBSCRIPTION.

The terms of Annual Subscription to KNOWLEDGE are as follows:—

	s.	d.
To any address in the United Kingdom	10	10
To the Continent, Australia, New Zealand, South Africa, Canada, and the United States of America	13	0
To the East Indies, China, &c. (*via* Brindisi)	15	2

All subscriptions are payable in advance.

P. O. Orders and cheques should be made payable to the Publishers, MESSRS. WYMAN & SONS, London, at the High Holborn District Post-office.

OFFICE: 74 & 75, GREAT QUEEN STREET, LONDON, W.C.

CONTENTS OF No. 13.

HYACINTH BULBS.

BY GRANT ALLEN.

IF we were not so familiar with the fact, we would think there were few queerer things in nature than the mode of growth followed by this sprouting hyacinth bulb on my mantelpiece here. It is simply stuck in a glass stand, filled with water, and there, with little aid from light or sunshine, it goes through its whole development like a piece of organic clockwork, as it is, running down slowly in its own appointed course. For a bulb does not grow as an ordinary plant grows, solely by means of carbon derived from the air under the influence of sunlight. What we call its growth we ought rather to call its unfolding. It contains within itself everything that is necessary for its own vital processes. Even if I were to cover it up entirely, or put it in a warm, dark room, it would sprout and unfold itself in exactly the same way as it does here in the diffused light of my study. The leaves, it is true, would be blanched and almost colourless, but the flowers would be just as brilliantly blue as these which are now scenting the whole room with their delicious fragrance. The question is, then, how can the hyacinth thus live and grow without the apparent aid of sunlight, on which all vegetation is ultimately based?

Of course, an ordinary plant, as everybody knows, derives all its energy or motive-power from the sun. The green leaf is the organ upon which the rays act. In its cells the waves of light propagated from the sun fall upon the carbonic acid which the leaves drink in from the air, and by their disintegrating power, liberate the oxygen while setting free the carbon, to form the fuel and food stuff of the plant. Side by side with this operation the plant performs another, by building up the carbon thus obtained into new combinations with the hydrogen obtained from its watery sap. From these two elements the chief constituents of the vegetable tissues are made up. Now the fact that they have been freed from the oxygen with which they are generally combined gives them energy, as the physicists call it, and, when they re-combine with oxygen, this energy is again given out as heat, or motion. In burning a piece of wood or a lump of coal, we are simply causing the oxygen to re-combine with these energetic vegetable substances, and the result is that we get once more the carbonic acid and water with which we started. But we all know that such burning yields not only heat, but also visible motion. This motion is clearly seen even in the draught of an ordinary chimney, and may be much more distinctly recognised in such a machine as the steam engine.

At first sight, all this seems to have very little connection with hyacinth bulbs. Yet, if we look a little deeper into the question, we shall see that a bulb and an engine have really a great many points in common. Let us glance first at a somewhat simpler case, that of a seed, such as a pea or a grain of wheat. Here we have a little sack of starches and albumen laid up as nutriment for a sprouting plantlet. These rich food stuffs were elaborated in the leaves of the parent pea, or in the tall haulms of the growing corn. They were carried by the sap into the ripening fruit, and there, through one of those bits of vital mechanism which we do not yet completely understand, they were selected and laid by in the young seed. When the pea or the grain of wheat begins to germinate, under the influence of warmth and moisture, a very slow combustion really takes place. Oxygen from the air combines gradually with the food stuffs or fuels—call them which you will—contained in the seed. Thus heat is evolved, which in some cases can be easily measured with the thermometer, and felt by the naked hand—as, for example, in the malting of barley. At the same time motion is produced; and this motion, taking place in certain regular directions, results in what we call the growth of a young plant. In different seeds this growth takes different forms, but in all alike the central mechanical principle is the same:—certain cells are raised visibly above the surface of the earth, and the motive power which so raised them is the energy set free by the combination of oxygen with their starches and albumens. Of course, here, too, carbonic acid and water are the final products of the slow combustion. The whole process is closely akin to the hatching of an egg into a living chicken. But, as soon as the young plant has used up all the material laid by for it by its mother, it is compelled to feed itself just as much as the chicken when it emerges from the shell. The plant does this by unfolding its leaves to the sunlight, and so begins to assimilate fresh compounds of hydrogen and carbon on its own account.

Now it makes a great deal of difference to a sprouting seed whether it is well or ill provided with such stored-up food-stuffs. Some very small seeds have hardly any provisions to go on upon; and the seedlings of these, of course, must wither up and die if they do not catch the sunlight as soon as they have first unfolded their tiny leaflets; but other wiser plants have learnt by experience to lay by plenty of starches, oils, or other useful materials in their seeds: and wherever such a tendency has once faintly appeared, it has given such an advantage to the species where it occurred, that it has been increased and developed from generation to generation through natural selection. Now what such plants do for their offspring, the hyacinth, and many others like it, do for themselves. The lily family, at least in the temperate regions, seldom grows into a tree-like form; but many of them have acquired a habit which enables them to live on almost as well as trees from season to season, though their leaves die down completely with each recurring winter. If you cut open a hyacinth bulb, or, what is simpler to experiment upon, an onion, you will find that it consists of several short abortive leaves, or thick fleshy scales. In these sub-

terranean leaves the plant stores up the food stuffs elaborated by its green portions during the summer; and there they lie the whole winter through, ready to send up a flowering stem early in the succeeding spring. The material in the old bulb is used in thus producing leaves and blossoms at the beginning of the second or third season; but fresh bulbs grow out anew from its side, and in these the plant once more stores up fresh material for the succeeding year's growth.

The hyacinths which we keep in glasses on our mantel pieces represent such a reserve of three or four years' accumulation. They have purposely been prevented from flowering, in order to make them produce finer trusses of bloom when they are at length permitted to follow their own free will. Thus the bulb contains material enough to send up leaves and blossoms from its own resources; and it will do so even if grown entirely in the dark. In that case the leaves will be pale yellow or faintly greenish, because the true green pigment, which is the active agent of digestion, can only be produced under the influence of light; whereas the flowers will retain their proper colour, because their pigment is always due to oxidation alone, and is but little dependent upon the rays of sunshine. Even if grown in an ordinary room, away from the window, the leaves seldom assume their proper deep tone of full green: they are mainly dependent on the food-stuffs laid by in the bulb, and do but little active work on their own account. After the hyacinth has flowered, the bulb is reduced to an empty and flaccid mass of watery brown scales.

Among all the lily kind, such devices for storing up useful material, either in bulbs or in the very similar organs known as corms, are extremely common. As a consequence, many of them produce unusually large and showy flowers. Even among our native English lilies we can boast of such beautiful blossoms as the fritillary, the wild hyacinth, the meadow-saffron, and the two pretty squills: while in our gardens the tiger lilies, tulips, tuberoses, and many others belong to the same handsome bulbous group. Closely-allied families give us the bulb-bearing narcissus, daffodil, snowdrop, amaryllis, and Guernsey lily; the crocus, gladiolus, iris, and corn-flag; while the neighbouring tribe of orchids, most of which have tubers, probably produce more ornamental flowers than any other family of plants in the whole world. Among a widely-different group we get other herbs which lay by rich stores of starch, or similar nutritious substances, in thickened underground branches, known as tubers; such, for example, are the potato and the Jerusalem artichoke. Sometimes the root itself is the storehouse for the accumulated food-stuffs, as in the dahlia, the carrot, the radish, and the turnip. In all these cases, the plant obviously derives benefit from the habit which it has acquired of hiding away its reserve fund beneath the ground, where it is much less likely to be discovered and eaten by its animal foes. For it is obvious that these special reservoirs of energetic material, which the plant intends as food for its own flower or for its future offspring, are exactly those parts which animals will be likely unfairly to appropriate to their personal use. What feeds a plant will feed a squirrel, a mouse, a pig, or a man, just as well. Each requires just the same free elements, whose combination with oxygen may yield it heat and movement. Thus it happens that the parts of plants which we human beings mainly use as food-stuffs are just the organs where starch has been laid by for the plant's own domestic economy—seeds, as in the pea, bean, wheat, maise, barley, rice, or millet; tubers, as in the potato and Jerusalem artichoke; corns, as in the yam or tare; and roots, as in arrowroot, turnip, parsnip and carrot. In all these, and in many other cases, the habit first set up by nature has been sedulously encouraged and increased by man's deliberate selection. What man thus consciously effects in a few generations, the survival of the fittest has unconsciously effected through many long previous ages of native development.

BRAIN TROUBLES.

Partial Loss of Speech.

Let us consider next a case where the almost complete loss of the power of fixing the attention was followed by the partial loss of the power of expression,—a sequence which would, we believe, be far more commonly noticed than usual were all the circumstances of each case carefully noted. The case also illustrates the danger resulting from the endeavour to over-tax the powers of nature:—"I was engaged this morning," says Dr. Alexander Crichton, "with a great number of people, who followed each other quickly, and to each of whom I was obliged to give my attention. I was also under the necessity of writing much, but the subjects were various, and of a trivial and uninteresting nature, and had no connection the one with the other; my attention, therefore, was constantly kept on the stretch, and it was continually shifting from one subject to another. At last it became necessary that I should write a receipt for some money I had received on account of the poor. I seated myself, and wrote the two first words, but in a moment found that I was incapable of proceeding, for I could not recollect the words which belonged to the ideas that were present in my mind. I strained my attention as much as possible, and tried to write one letter slowly after the other, always having an eye in order to observe whether they had the usual relationship to each other; but I remarked, and said to myself at the time, that the characters I was writing were not those which I wished to write, and yet I could not discover where the fault lay. I therefore desisted, and partly by words and syllables, and partly by gestures, I made the person who waited for the receipt understand that he should leave me. For about half-an-hour there reigned a kind of tumultuous disorder of my senses, in which I was incapable of remarking anything very particular, except that one series of ideas forced themselves involuntarily into my mind." The patient goes on to describe the various thoughts which occurred to him at this time, and how he tested his mental condition by thinking of the principles of religion, conscience, and the future life, finding to his relief that these principles he found "equally correct and fixed as before" (a degree of assurance which some do not possess who are quite free from mental disorder). Passing over these matters, as not bearing specially on our subject, we find that so soon as he tested his power of expressing his ideas, either by spoken or by written words, he found that for the time being the power was lost. "I endeavoured to speak, in order to discover whether I was capable of saying anything that was connected; but, although I made the greatest efforts of attention, and proceeded with the utmost caution, I perceived that I uniformly spoke other words than I intended. My soul was at present as little master of the organs of speech as it had been before of my hand in writing. Thank God, this state did not continue very long, for in about half-an-hour my head began to grow clearer, the strange and tiresome ideas became less vivid and turbulent, and I could command my own thoughts with less interruption." It is interesting to notice how the loss of the power of expression was associated thus with con-

fusion of thought and inability to fix the attention. "I now wished," proceeds the patient, "to ring for my servant, and desired him to inform my wife to come to me." (The power of correctly expressing his ideas does not seem to have been possessed in any very remarkable degree by this gentleman, even when his mind had fully recovered its usual health). "But I found it still necessary to wait a little longer, to exercise myself in the right pronunciation of the few words I had to say, and the first half-hour's conversation I had with her was, on my part, preserved with a slow and anxious circumspection, until at last I gradually found myself as clear and serene as in the beginning of the day. All that now remained was a slight headache. I recollected the receipt I had begun to write, and in which I knew I had blundered, and upon examining it, I observed, to my great astonishment, that instead of the words *fifty dollars, being one half-year's rate*, which I ought to have written, the words were, *fifty dollars, through the salvation of Bra*——, with a break after it, for the word '*Bra*' was at the end of the line. I cannot recollect any business I had to transact that could by means of an obscure influence have produced this phenomenon."

In this case it is obvious that the temporary loss of the power of verbal expression was occasioned by overwork; but it is noteworthy that the work was of a special character, involving the special exercise of the power which failed first (that of fixing the attention). It may be worth while to inquire whether that kind of mental confusion, which, when it has passed beyond a certain point is followed by impairment of the power of speech, is generally or often a consequence of distracting occupations. The following case seems to some degree to bear on this question. It is related by Dr. Watson. A patient who had had an attack of apoplexy seemed to be recovering under the influence of perfect quiet. But, "after a long and imprudent conversation with a friend, he suddenly lost the thread of his discourse, and could not recover it." Memory was affected first, be it observed: next went the power of attention. "Then he became confused." Thirdly, the power of speech was affected. "He misapplied words. I asked him how he felt. He answered, 'Not quite right,' and this he repeated very many times, abbreviating it at first into 'not right,' and and at length into 'n' ight.' Wishing to mention '*camphor*,' he called it '*pamphlet*.' I mention these as specimens." Afterwards, signs of bodily weakness, indicating paralysis, were observed. The weakness degenerated gradually into complete palsy, and before long the case ended fatally. In this case the patient had not suffered originally from undue mental work, the mental trouble being caused by an abscess. But the case seems to illustrate well the trying effect of distracting conversation on a wearied, weakened, or (as in this case) diseased brain.

The tendency to use one word for another, where, so far as meaning is concerned, there is no connection whatever, though there is some resemblance of sound, is one which probably most literary men have noticed at times, when they have been wearied or their attention has been much distracted. It is not by any means so alarming a symptom as temporary failure of the power of articulating words, or actual inability to write the desired words; but it is a circumstance which should not be overlooked. A little rest, or the substitution for awhile of some light reading for hard brain-work, will generally set matters right. If not, a longer rest or open-air exercise should be taken. Time will be gained by waiting till the brain is fitter for work. The present writer has repeatedly had occasion to time himself over certain forms of literary work, and his experience has been this, that where four or five hours are to be occupied in steady work, a good half-hour will often be saved by taking half-an-hour's sleep, when such signs of mental weariness are noticed as have been described above. There is, however, one point to be observed. Rest must be taken as soon as such signs are recognised, for if an effort is made to struggle against the occasion for rest, the power of resting may be lost. Precisely as an over tired pedestrian often tries in vain to sleep, when he has but a short time for rest, so the overwearied brain may be kept by confusing thoughts from obtaining rest.

DR. J. W. DRAPER.

BY THE EDITOR. (*With a Portrait.*)

AMONG the distinguished men whose acquaintance I have made during my lecture tours in this country America, and Australasia, few occupy a higher place in my recollection than Dr. J. W. Draper, whose death, at New York, has just been announced. His scientific researches and literary work are justly regarded by those whom we must consider as his fellow-countrymen (though he was an Englishman by birth) as most important and valuable, and his name is not honoured in America only, but throughout the world.

John William Draper was born at St. Helen's, near Liverpool, in 1811, and educated there and at the London University (to which he was sent to study chemistry when the University was first opened). He left England soon after for America, and completed his medical education at the University of Pennsylvania, graduating in 1836. He was soon after appointed Professor of Chemistry in Hampden Sydney College, Virginia, and in 1839 in the University of New York.

His earliest contributions to Science were on the chemical action of light, on which he published nearly forty memoirs. The following summary of his work on this subject is from a biographical sketch which appeared in the *Popular Science Monthly*, in January, 1874 (about the time when I first made Dr. Draper's acquaintance). I believe that though they may have been editorially revised by my esteemed friend Professor Youmans, they were in substance communicated by Dr. Draper himself, thus possessing a special value at the present time, when some of his most important researches are bearing fruit, which others are claiming as their own:—

"Of all the chemical actions of light, by far the most important is that of the decomposition of carbonic acid by the leaves of plants, under the influence of sunshine. On this the whole vegetable world depends for its growth, and the whole animal world, directly or indirectly, for its food. The decomposition in question is essentially a deoxidation, and up to about 1840 it was generally supposed to be due to the violet rays of the spectrum, which, in accordance with the views held at that time, were regarded as producing deoxidising actions, and were consequently known as deoxidising rays. But this was altogether an assumption unsupported by experimental proof. Professor Draper saw that there was but one method for the absolute solution of the problem, and that was by causing the decompositi tion to take place in the spectrum itself. In this delicate and beautiful experiment he succeeded, and found that the decomposition was brought about by the yellow rays, at a maximum by those in the vicinity of the Fraunhofer fixed line D, and that the violet rays might be considered as altogether inoperative. The memoir containing this result was first read before the American Philosophical Society, in Philadelphia, and immediately republished in London, Paris, and Berlin. It excited general interest among

chemists. Even so late as 1874 it furnished to the German experimenters the basis of a very interesting discussion in photo-chemistry.

"In 1842 Dr. Draper discovered that not only might the Fraunhofer fixed lines in the spectrum be photographed, but that there exists a vast number of others beyond the violet, which up to that time had been unknown. He also found three great lines less refrangible than the red, in a region altogether invisible to the eye. Of these new lines, which more than doubled in number those of Fraunhofer, he published engravings. He also invented an instrument for measuring the chemical force of light—the chlor-hydrogen photometer. This was subsequently extensively used by Bunsen and Roscoe in their photo-chemical researches. In their paper, read before the Royal Society in 1856, they say, 'With this instrument Draper succeeded in establishing experimentally some of the most important relations of the chemical action of light.'

"His memoir 'On the Production of Light by Heat,' published in 1847, was an important contribution to spectrum analysis. Among other things it gave the means for determining the solid or gaseous condition of the sun, the stars, and the nebulæ. In this paper he established experimentally that all solid substances, and probably liquids, become incandescent at the same temperature; that the thermometric point at which such substances are red-hot is about 977° Fahr.; that the spectrum of an incandescent solid is continuous, it contains neither bright nor dark fixed lines; and from common temperatures up to 977° Fahr. the rays emitted by a solid are invisible, but at that temperature they impress the eye with the sensation of red; that the heat of the incandescing body being made continuously to rise, other rays are added,

DR. J. W. DRAPER.

increasing in refrangibility as the temperature ascends; and that, while the addition of rays so much the more refrangible as the temperature is higher is taking place, there is an augmentation in the intensity of those already existing. This memoir was published in both American and European journals. An analysis of it was read in Italian before the Royal Academy at Naples, July, 1847, by Melloni, which was also translated into French and English. But, thirteen years subsequently, M. Kirchhoff published, in a very celebrated memoir, considered by many as the origin of spectrum analysis, and of which an English translation may be

found in the *London and Edinburgh Philosophical Magazine*, July, 1860, the same facts under the guise of mathematical deductions, with so meagre a reference to what Draper had done, that he secured the entire credit of these discoveries. In an historical sketch of spectrum analysis, subsequently published, Kirchhoff avoided all mention of his American predecessor.

"Dr. Draper was the first person who succeeded in taking portraits of the human face by photography. This was in 1839. He published a minute account of the process at a time when in Europe it was regarded as altogether impracticable. He also was the first to take photographs of the moon, and presented specimens of them to the New York Lyceum of Natural History, in 1840.

"'A Treatise on Human Physiology, Statical and Dynamical,' became a standard text-book in American colleges. It has passed through a great many editions, and was translated into several foreign languages. The Russian edition is used in the higher schools of that country. A yet more important work is his 'A History of the Intellectual Development of Europe,' thus described in the *Westminster Review*:—'It is one of the not least remarkable achievements in the progress of positive philosophy that have yet been made in the English tongue: a noble and even magnificent attempt to frame an induction from all the recorded phenomena of European, Asiatic, and North-African history.'" [Of this treatise, Dr. Draper's later work, "The Conflict of Science and Religion," may be regarded as in some sense an abstract. It is severe in its treatment of religious intolerance and dogmatism, and does not seem to do full justice to the motives which in many cases have actuated religious persecutions. But the book is the product of a healthy and vigorous mind, and, setting aside the undue hardness of its tone in certain places, it must be regarded as a work which has done, and is calculated to do, an immense deal of good.]

"Though in his earlier years Dr. Draper was a skilful mathematical analyst, he has published but few mathematical papers, the most important being an investigation of the electrical conducting power of wires. This was undertaken at the request of Prof. Morse, at the time he was inventing his telegraph. The use made by Morse of this investigation is related by him in 'Silliman's American Journal of Science and Arts,' December, 1843. The paper shows that an electrical current may be transmitted through a wire, no matter what the length may be, and that, generally, the conducting effect of wires may be represented by a logarithmic curve. Among electrical memoirs there is one on the tidal motions exhibited by liquid conductors, and one on the electro-motive power of heat, explaining the construction of some new and improved forms of thermo-electric batteries. An abstract of these improvements is given in the last edition of the 'Encyclopædia Britannica' (Art. Voltaic Electricity).

"Dr. Draper was the first person to obtain photographs of the diffraction spectrum given by a grating, and to show the singular advantages which that spectrum possesses over the prismatic investigations on radiations. In a memoir on the production of light by chemical action (1848), he gave the spectrum analyses of many different flames, and devised the arrangement of charts of their fixed lines in the manner now universally adopted. A memoir on phosphorescence contains the experimental determination of many important facts in relation to that property. Among purely chemical topics he has furnished a method for the qualitative determination of urea by nitrous acid."

[From 1860 to 1870 Dr. Draper did but little in scientific research, devoting himself mostly to historical works. During this time he published his "History of the American Civil War," in three volumes.]

"In the summer of 1870, Dr. Draper suffered a severe bereavement in the loss of his wife. Of Brazilian birth, she was connected with an ancient and noble Portuguese family. She had rendered his domestic life a course of unbroken happiness, and doubtless she was the exemplar before his eyes when he wrote that oft-quoted passage in his 'Physiology,' in which, after depicting the physical and intellectual peculiarities of woman, he says: 'But it is in the family and social relations that her beautiful qualities shine forth. At the close of a long life, checkered with pleasures and misfortunes, how often does the aged man with emotion confess that, though all the ephemeral acquaintances and attachments of his career have ended in disappointment and alienation, the wife of his youth is still his friend? In a world from which everything else seems to be passing away, her affection alone is unchanged: true to him in sickness as in health, in adversity as in prosperity, true to the hour of death.'"

Of their six children, one died in infancy; the survivors are three sons and two daughters. Of the former, the eldest, Dr. Henry Draper, Professor of Natural History in the College of the City of New York, is eminent as a physicist and astronomer; the second, Dr. John C. Draper, is Professor of Physiology in the University of New York; the third, Dr. Daniel Draper, is Director of the Meteorological Observatory in the New York Central Park, where he has exercised an important influence in developing the meteorological system of the United States. In recent years, Dr. Draper has published two short memoirs: one, on the "Distribution of Heat in the Spectrum," showing that the predominance of heat in the less refrangible regions is due to the action of the prism, and would not be observed in a normal spectrum, such as is formed by a grating; and that all the rays of light have intrinsically equal heating power; the second an investigation of the distribution of chemical force in the spectrum. The *Popular Science Monthly* notes to his credit that "these scientific researches, to which so many years of his life have been devoted, *have been at his own expense; he has never received any extraneous aid, though many of them have been very costly; he has never taken out any patent, but has given the fruits of his investigations and inventions freely to the public.*"

THE GREAT PYRAMID.

By the Editor.

IN No. 10 we showed how the builders of the Great Pyramid, in carrying out what obviously was their purpose, the exact orientation of the building, would have been led to construct those passages, descending and ascending, which actually exist in the building, with precisely the slopes we should expect to find; but we did not pass beyond the smaller of the ascending passages; and, indeed, it is to be noticed that in passing upwards from the upper end of this passage we recognise another plan. All the features thus far have been such as we should expect to find in a massive structure such as this, intended—for whatever reason—to be very carefully oriented. They are such, in fact, as could not but exist in a building oriented so successfully as the Great Pyramid unquestionably is, unless some utterly incredible chance had enabled the builders, by an imperfect method, to hit accidentally on so perfect an orientation. Even then, in passing from the ground level

to higher levels, they must inevitably have lost the perfection of their orientation, unless they had had such means of keeping their work correct as we find they had. This being so, the chances being practically infinite against their first obtaining, and afterwards retaining, such accuracy of orientation, without long, slant passages, such as we find within the Pyramid, we are logically justified in saying it is *certain* that the passages were used in that way, and were intended originally to subserve that purpose.

The case is somewhat altered when we reach the point C, where the ascending passage ceases to be of the same small square section as the descending one. Up to this point its purpose is obvious. But so far as *mere* orientation was concerned, there seems no reason why it should not have retained the same section to a higher level. It is true that the nearer it approached to the central line, LF,* the less effective its directive value; but certainly this value would not be increased by increasing the size of the they had considered this plane for the same reason that the modern astronomer considers it—viz., because this is the plane in which all the heavenly bodies culminate, or attain the middle and highest point of their passage from the eastern to the western horizon. They might have had only a fancy for exact orientation, though one can hardly tell why they should. Still, men of different races have taken strange fancies, and, unlikely though it seems, this might have been such an one, just as the building of colossal tombs seems to have been.

At the point C, however, all doubt ceases. The astronomical nature of the builders' purpose becomes here as clear and certain as already the astronomical nature of their methods has been. For from here upwards the small ascending passage is changed to one of great height, so as to command a long vertical space of the heavens, precisely as a modern astronomer sets his transit circle to sweep the vertical meridian. The floor, however, of the ascending

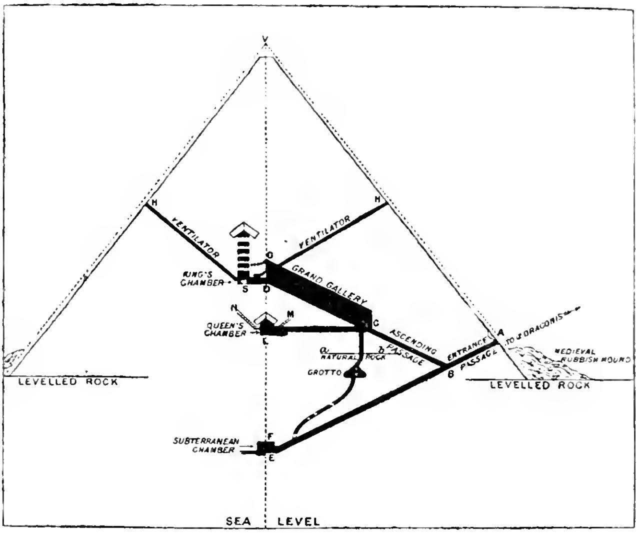

Fig. 1.

passage, whether in a vertical or a horizontal direction; and from and after the point C it is increased in both directions.

Now, we are certain that the builders of the Pyramid wanted to orient it very carefully, simply because we find that they did so. We do not know *why* they did. But it seems antecedently unlikely that *all* they wanted was to get the Pyramid perfectly four-square to the cardinal points. The natural idea is, that being, as we see by their work they were, astronomers of great skill, they had an astronomical purpose of some sort. They had thus far been working with manifest reference to the meridional plane, just as an astronomer of our own time would; and it looks very much, even from what we have already seen, as though

* This line is not vertically below the vertex, V, but central, in the sense of being the vertical line where the horizontal north and south line from the ascending and descending passages crosses the east and west plane through the vertex.

passage, and even its sides, are carried on unchanged in direction, right up to D, where the central vertical (see preceding note) meets the ascending gallery. So that from B to D, except where the horizontal passage CL to the so-called Queen's Chamber is carried off, the floor of ascending passage and gallery formed a perfectly uniform slant plane.

And here let us pause to inquire—seeing that the astronomical purpose of the passages is made manifest—what shape an astronomer, who was also an architect, would give to the great ascending slit, as it were, through which the transits of the heavenly bodies were to be watched. As an astronomer, he would like it to be very high and relatively narrow; but as an architect, he would see that the vertical section could not have such a shape as *ABCD* in Fig. 2; for then, not only would the side walls, *AB*, *BC*, be unstable, but the observer would not be comfortably situated. Yet, as an astronomer, he would know that such a shape as is

shown in Fig. 3 would be unsuitable. To mention only one case out of many, supposing he wanted not only to observe a transit of a heavenly body along such a course as p_1, p_2, or q_1, q_2, which during the short time the body was visible would be practically a horizontal line, but also by observations on successive nights to determine the course of a heavenly body on the star sphere along a path as P_1, P_2, which might be inclined: then, the slant of the walls would entirely defeat his purpose. He would require, as an astronomer, that the walls should be absolutely vertical

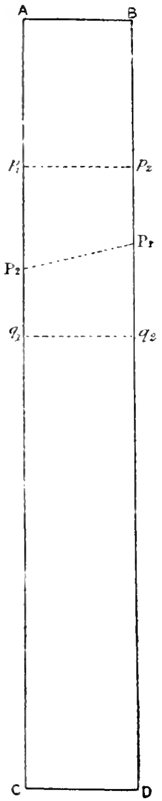

Fig. 2.

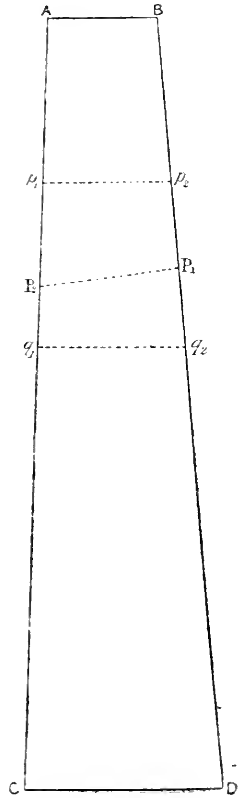

Fig. 3.

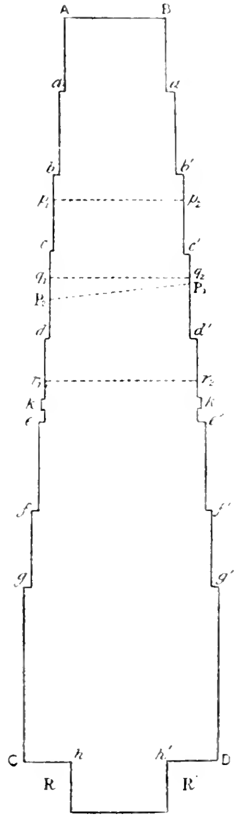

Fig. 4.

(note the difference between the paths p_1, p_2, q_1, q_2, P_1, P_2, in Fig. 2, and the similarly-lettered paths in Fig. 3), while as an architect he would know that they must be closer at the top than at the bottom of a passage so lofty as the great ascending gallery. Fig. 4, giving the actual shape of the vertical section of the great gallery, shows how the astronomical architects of the Great Pyramid combined both qualities. Every part of the walls is absolutely vertical, and yet the walls, regarded as wholes, are aslant.

If we had not seen from the beginning the astronomical plan of the Great Pyramid, and that such a plan indicated an astronomical purpose, we should find, I take it, in this double character of the ascending gallery, proof positive that it was intended for astronomical observations. Only an astronomer would have set the architect such a problem.

But it may be said, How are observers to be stationed along a slant gallery such as this, with smooth and much-inclined floor? Is not the idea that such an unstable place was intended for exact astronomical observation almost as absurd as the notion that the top of the Pyramid was meant for that purpose!

Certainly, if a modern astronomer were planning a slant gallery for transit work he would arrange for comfortable observation (the only observation which can be trustworthy).

Now the ramps, as Prof. Piazzi Smyth calls them—the long slant stone banks, shown in section at R and R' in Fig. 4—seem as if they had some reference to such a purpose. They are at a convenient height above the level of the slant floor, insomuch that Smyth pictures his Arabs leaning on them, stepping on to them, and so forth. But

they would not serve of themselves to make observations easy. The observer has to be set in the middle of the gallery (at whatever point of its length he may be), and he ought to be comfortably seated. I think, if I were planning for his comfort (which means fitness to make good observations), I should have seats set across from ramp to ramp. They must be movable, of course. And if there were not something along the ramps' upper surface to hold them, they would slide down, carrying the observer most uncomfortably with them. I should, therefore, have holes cut out along the tops of the ramps at convenient distances; the holes on one side being exactly opposite those on the other. A set of cross benches should then be made, with projections corresponding to these holes. Then a bench could be set wherever it was wanted, or several at a time, so that different observers might watch the same transit across different parts of the field of view, as along p_1 p_2, q_1, q_2, and r_1, r_2. For some observations, indeed, such holes would serve yet another purpose. By means of them, screens could be set up by which to diminish the field of view and make the observations more exact. Or on such screens, images of the sun (showing the sun spots, be it remarked) could be thrown through a small opening on a screen, covering for the time the mouth of the gallery. For such observations the holes would be convenient, for the seats they would be absolutely essential.

Now no traces of the seats themselves, with their projections, cushions, &c., &c., have been found or were likely to be found. But holes in the ramps are there still; twenty-eight of them there were originally in each ramp, though now only twenty-six remain, owing to the destruction of a ramp stone. They are situated just as they should be to subserve the purposes I have mentioned—that is, at equal distances (of about 5½ feet), and each hole on the east side of the gallery is exactly opposite the corresponding hole on the left side.

THE TRUE STORY OF THE MOON.*

GALILEO and Kepler, Huyghens and Hevelius, Cassini, the Herschels, and a host of other astronomers have tried in vain to interpret aright the telescopic aspect of the moon, during a period of about 270 years. Tired at length of being "une femme incomprise," the moon obtruded herself, Mr. Jones tells us, on his sight, "in so prominent a manner that she seemed to say, 'take a look at me,' and the night was so favourable, that" Mr. Jones "felt bound to accept the invitation." "Round went the tube, down went the eye, and instantly I telescopically gazed for the first time upon a scene of indescribable beauty; gazed and wondered, wondered and gazed, and for a time could do no other." Strange to say, the true meaning of the lunar scenery did not at once present itself to Mr. Jones's lively imagination. A second evening he observed her, and still he "felt that the lunar rings and plain walls were monuments of a departed greatness." But on the third occasion when the opportunity of observing the moon was embraced, "the moon was young, in crescent phase, and the structural character of the rings about the terminator came out beautifully. And now, O, volcanic theory, as commonly understood, thou art doomed. . . . Yes, there can be no mistake, *the ring mountains of the moon are the atolls of an ancient ocean which once overspread that luminary*, and the lunar walls, both of the ring mountains and walled plains, are organic structures, strictly analogous with the coral reefs of the terrestrial oceans, while the whole aspect of the lunar structures indicates that they are principally of similar carbonate of lime texture."

Mr. Jones is not only quick in forming novel views, but expects his readers to be equally quick in grasping them. He gives half a page more to a comparison between the lunar features and those described in Darwin's and Dana's books on Coral Reefs and Coral Islands, and, forthwith, "thinks that enough has been said to enable the reader to find out for himself that the craterology of the moon, and the theory which regards the lunar walls and reefs as direct products of eruption, is a *pure myth*."

Probably *we* have said enough to enable the reader to find out for himself that Mr. Jones's theory is pure nonsense. There is not the slightest resemblance between the lunar craters and coralline structures, whereas there is the closest possible resemblance between the lunar features—craters, mountain ranges, high tablelands, and level plains—and those terrestrial features which result from subterranean forces, or what Humboldt calls the reaction of the crust against the interior. Mr. Jones says there are some astronomers who have ventured to doubt the volcanic character of the lunar asperities, citing, as an instance, the Editor of KNOWLEDGE. He is as much mistaken in this as in his coralline theory (he could hardly be more). The remarks of the Editor, that some of the regions in which small craters are exceedingly numerous look as though they bore the marks of former meteoric showers, or, as Professor Newcomb puts it, "that the figures of these inequalities can be closely imitated by throwing pebbles upon the surface of some smooth plastic mass," bears no such interpretation. Neither Mr. Proctor nor Professor Newcomb has the least doubt that the volcanic theory of the lunar surface features is essentially true.

* "First Steps to Selenography." By John Jones. (John Leng & Co., Dundee.)

BABYLONIAN DISCOVERIES.

FOR some time past rumours have been current of great discoveries by an agent of the French Government in the Mesopotamian valley, and in the latter part of last year they took definite shape; the antiquities excavated were announced to be on their way to the Louvre, and the successful investigator proved to be M. de Sarzec, French Consul at Bussorah. The cases have recently been unpacked, and their contents so far fulfil the expectations created, that M. Oppert, at the "Academy des Inscriptions," has pronounced them to be the most priceless treasures of ancient art contributed to Europe since the great explorations of Layard and Botta.

In the *Gazette des Beaux Arts*, a preliminary account of some of the statues which form part of the "find" is given by M. Menant, an Assyriologist, accompanied by some exceedingly beautiful heliotypes of the objects themselves. This, and several other short notices in the French press, furnish these intensely interesting facts. The antiquities, which all come from one magnificent palace, are of all kinds—sculptured slabs, bas-reliefs, statues, fragments of terra-cotta, and numerous inscribed bricks, some of them with more than one hundred lines of cuneiform writing. Great honour is due to M. de Sarzec for rescuing these valuable remains, for they were buried beneath a part of Mesopotamia, close to the junction of its two great rivers, deep down in alluvial deposits, and their recovery required much greater exertions than that of relics in Assyria.

Had this collection only contained further additions to the fast-growing remains of Babylonia and Assyria, it would have been received with delight by archaeologists, but it fortunately presents us vestiges of another primitive people of Chaldea, the riches and importance of whom are probably at present quite unappreciated. The inscriptions (any full interpretation of which is as yet unattempted) are in very archaic forms of cuneiform characters, and embody a dialect quite distinct from the Semitic Assyrian, but whether closely allied to, or identical with, the so-called Accadian, cannot be pronounced from the fragments published.

Two statues of diorite, of which admirable facsimiles are given, so far from being inferior precursors of Assyrian sculptures, are, if anything, superior to the work of that people which they certainly preceded, proving a far advanced stage of art for the nation by whom they are executed. One is of a person seated, the other an upright figure, both, unfortunately, decapitated, a condition which seems to be that of all the statues exhumed. Each figure is clothed in a long robe reaching to the ankles, but the correct outline of the body is distinctly visible below the folds of raiment, as in the best periods of sculpture, and the delicate arrangement of the drapery is most pleasing. The feet, which are quite naked, are carefully executed. The whole lower front of the dress of the seated statue is covered with cuneiform writing of very old type, apparently closely allied to the extremely ancient texts, from which the Rev. W. Houghton proves the hieroglyphical origin of the cuneiform characters.

This seated figure appears to be that of an architect, for, on his lap, is a tablet inscribed with a plan of a building, and some instrument connected with architecture. The erect figure, if anything more correctly carved, has a few lines of writing on the right front of the robe and the right arm. The attitude of the arms is in

both precisely similar, and so, probably, conventional, but well suited to the character of repose given to the statues, they being crossed before the body, the right hand lower, and holding the left. The loss of the heads of these figures is greatly mitigated by the possession of the exquisite head (belonging to a statue not yet found), a copy of which is given. It bears an embroidered head-dress similar in shape to the old Cossack shako. This, and a fragment of ornament from a marble slab, completes the series of illustrations at present published.

As might be expected from a "savant," M. Menant concludes his monograph by a theory, and as it is one which, if correct, tends greatly to support his previous arguments, it need not be said he urges it with great confidence. For many years the advanced school of cuneiform decipherers had, without exciting much opposition, decisively declared the old Accadian tablets to be in a Turanian tongue, a language allied to that of the Tartar and Finnic families, but lately this has been called in question most determinedly by M. Halévy, one of his arguments being, that if this Accadian dialect were (instead of being, as he declared, merely an esoteric priestly writing, intended by the initiated to be unintelligible to ordinary readers) a language complete in itself, inherited from a prior civilisation, where are the remains of this primitive people? Especially were he and his followers dubious as to a Turanian civilisation, Turanians being celebrated in history rather by the destruction than evolution of culture.

Now, here are the complete remains of an advanced state of art and consequent wealth associated with numerous inscriptions of great difficulty in a writing allied to the alleged Turanian Accadian, or, at least, certainly separate from the Semitic Assyrian. To M. Menant, an advocate of pre-Turanian culture, the opportunity is too good to resist, and he triumphantly avers that here the "blow of a pickaxe" has presented the missing proof.

Do the monuments themselves offer support to either side? None; their evidence is only negative; still, it is decisive as far as it goes. The physical characteristics of the head are certainly non-Turanian, and as decidedly non-Semitic. The features are of a high type of beauty, allied to the Greek or Caucasian. Again, the statues have no analogy either with Assyrian, Egyptian, or Hittite art. If a resemblance must be sought, it would be found nearest in the figures from Branchidæ, obviously only a resemblance, not a real connection. To impartial observers this result is not a surprise, for whilst the Turanianists and Semiticists have been refuting each other, they remember that in the old ethnological list, never yet contradicted by research, Cush is said not to be a son either of them or of Japhet, but of Ham. These wonderful discoveries furnish one certain lesson, taught before in Egypt, that it is not an invariable rule that the greater the antiquity of relics of the past, the greater the inferiority of execution they present. For the last thousand years of its history, the architecture of the Nile valley presents only a decline; here, again, by the Euphrates and Tigris, the earliest appears in some respects to have been the better. Was there, then, a still higher art before this again; who shall say? Only a few years ago, Egypt and Chaldea were accounted the first of nations, and the existence of a great Hittite people only to be inferred from a casual statement by Masoudi, an Arab historian.

All that can be said is, that whatever wonders are still buried beneath the soil of Western Asia can only be revealed by the spade. M. de Sarzec has wielded it lavishly and to good purpose, and deserves the gratitude of scholars and all who desire to know the history of the human race, the world over.

INTELLIGENCE OF THE HOUSE MARTIN.

It is a common delusion, founded upon imperfect information, that animals guided by instinct do not modify their proceedings by reason, but persevere in a mechanical repetition of the same acts. Probably no creature with a complex nervous system that was observed with sufficient attention, under a variety of conditions, would be found so deficient in intelligence as this theory imagines. At any rate, it completely breaks down when applied to our common birds, and quite fails to explain the kind of facts to be narrated concerning the house martin. A cottage of many gables, situate on the slope of a wide heath, was for many years a favourite resort of this sociable bird, and in one season as many as thirteen nests were established. Now, according to the instinct theory, they ought to have been all alike, but in eleven cases there were obvious differences, some slight in appearance, but probably all-important for the stability of the erection or the comfort of its inhabitants. The simplest nest was quite open at the top, sheltered by projecting eaves, and very roughly finished at the margin. Another variety was built quite up to the woodwork, and had a side entrance left in the rough. Others had similar side entrances, neatly finished with a rounded border. On a north-western gable, quite on its top corner, repeated efforts had been made to construct a nest which would brave the storm winds, and after several failures and mendings, a sort of buttress was stuck on below, evidently a new idea. On the southern side, a favourite locality was under a projecting window, sufficiently high above the sill of a lower window that no cat could reach it by a jump. In this situation the birds built twin nests—semi-attached houses, and they placed their doorways close to the wall on opposite sides, so that when looking at them, the left abode had its entrance on the extreme left, and the right one on the extreme right. If the entrances had been in any other position, the birds might have jostled in going in and out. The walls of the cottage being rough cast, offered a good foundation, but there is no tenacious clay near, and the martin architects were never quite successful with two of the highest gables, possibly on that account. Mischievous sparrows occasionally stole a nest, but the right birds were generally very comfortable, and reared their broods prosperously. It was, therefore, a matter of surprise that, after coming for many successive years, repairing old nests, and making new ones, they merely looked at the place, and did nothing in the summer of 1881. The weather was unfavourable, the birds arrived late, and prepared houses some way off, perhaps from their offering more sheltered situations. Towards the close of the martin season, the custom of the old birds for many years was to give the young ones some building lessons, and lines of foundation, several feet long, were usually attached to the cottage walls. Some of them served for the commencement of nests in the following season, but most of them seemed merely school exercises. If these acts were all done under blind instinct, there is a kind of blindness much like seeing, and it may be doubted whether the mud huts of the poor Irishmen exhibit much more intelligence than the martin's homes.

Henry J. Slack.

INTELLIGENCE IN ANIMALS.

On reading the article "Intelligence in Animals," page 177, and also the previous one on "Brain Troubles," page 175, it struck me that human beings might, perhaps, lessen their "brain troubles" and improve their "intelligence" by trying to acquire a curious habit possessed by some animals, especially the dog. I allude to the way they have of saving themselves up, so to speak, when not on duty, which nearly everyone must have noticed, and which the following instance will illustrate: They have, at my father's house, a small black and tan terrier, Toby III., who has taken upon himself the duty of escorting all strangers to the door on their leaving the house. On the slightest sign of a departure, Toby, although lying on the sofa snoring and apparently fast asleep, instantly starts up in a fearful state of excitement, and with every appearance of undying fury and hatred, fairly screams the visitor out. In less than a quarter of a minute he is once more comfortably asleep. It would be interesting to know how dogs have acquired this enviable knack of disengaging their attention when not required; perhaps it is partly because they are, unlike "the literary gentleman," not "exposed to much anxiety respecting family matters."

Some time ago a friend brought us a small terrier, under the impression that it was our Toby that had got lost. It was an amiable little creature, and, unlike Toby, willing to make friends with anyone. On being noticed, it would look up, shake its head, and actually *laugh* with satisfaction. If laughter be a sign of intelligence—and it is an attribute generally supposed to be confined to the most intelligent of all animals, man—our little friend must have been quite an "infant phenomenon." This is the first instance I know about of a dog laughing; but my wife assures me they had a dog which, although bold and courageous, would, on being left in the house alone, cry "real tears," just like a child.

J. H.

GHOSTS.

I am asked by "T. D." [204 and 205] to explain the "War-Office Ghost," in which, he says, three friends, in different parts of England, saw a fourth friend at the corrected date of his death abroad. And Mr. Ebenezer Kelby cites the case of Lord Brougham (mentioned, if I mistake not, in his Autobiography), in which that illustrious statesman is said to have beheld a friend's "ghost;" the "ghost" appearing to him, by mutual pre-mortem agreement, as the spectre of the first deceased of the two. In reply, permit me briefly to say, that before one can form an opinion upon any such

apparently mysterious cases, one must have full and complete evidence, not only of times and seasons, but of all other circumstances connected with each case. There must be no shadow of discrepancy—no lack of complete and full agreement in every jot and tittle of evidence, before a scientist can take the case under his consideration.

To lay the explanation of such cases within the domain of the supernatural, because we may not be able exactly to satisfy others or ourselves of a rational cause for them, is, of course, but a sorry way of escape from our difficulties. But I have, at least, one idea to fall back upon in treating of so-called "warning dreams," and the appearance of apparitions at expected and unexpected times, and that is, the idea of *coincidences*. If a person tells me he dreamt of a person's death, and that the person can be proved to have died at the moment he dreamed of the event, or even if he tells me he saw the apparition of his deceased friend, I reply that he may be indulging in the fallacy of *post hoc ergo propter hoc*. I would further reply—being a disbeliever in "ghosts" of all kinds as visitations from the nether world, at least—that the explanation of these events does not lie outside the doctrine of coincidences. It is, in other words, a mere fortuitous circumstance that the dream or the "ghost" (*i.e.*, the *subjective* image in one's own brain) has appeared at the time (not always exact) of the person's death. If I can show that as startling coincidences occur in our waking life, I may claim to have, at least, shown the possibility and probability of their occurring in the case of dreams and ghosts. Here is one well-known coincidence, as startling to my mind as any ghost story I have ever heard. I quote from my recently published "Naturalist's Note-Book" (Chatto & Windus), page 39:—"The well-known case of Joseph Lesurques, whose misfortune forms the incident on which more than one melodrama and novel has been founded, has recently been brought anew under public notice through Mr. Henry Irving's performance in the 'Lyons Mail,' and by his assumption of the dual *rôle* of Lesurques and his villainous double. The case actually occurred in France in 1794, and its details are sufficiently well known to obviate the necessity for their repetition here. Charged with robbery and murder, the innocent Lesurques was recognised, identified, and sworn to as the real culprit by various disinterested witnesses. Notwithstanding strong exertions which were made to save his life, and, despite his previous high moral character and probity of conduct, Lesurques was sentenced to death, and executed. Soon afterwards, the real culprit, a man who bore the closest possible likeness to Lesurques, was brought to justice. It was then seen that the similarity in features, stature, build, and manner was so close as to have deceived the witnesses who gave evidence at the trial. On these grounds alone, and as a matter of common recognition and identification, the unfortunate resemblance of Lesurques to the real culprit had unwittingly led them into a 'Comedy of Errors,' which resulted in a legal tragedy as its *dénouement*. But more extraordinary to relate still is the incident, well-nigh unparalleled in the annals of coincidences, that Lesurques was marked by a scar on the forehead, and by another on the hand, whilst the real criminal likewise possessed similar markings. Surely "the grim irony of Fate" could no further go than this, in causing chance likeness to assume a form and to entail consequences so fatal and sad as in the case of Joseph Lesurques."

And, lastly, as to a "ghost" being seen by more than one person, or regarding the possibility of several persons being collectively deceived, let me relate the famous case of the Crystal Palace fire. When the wing of the Palace was burnt the animals in the menagerie were believed to have perished in the flames. But, as the flames progressed, the eager and excited crowd of spectators were horrified to behold the chimpanzee struggling to escape from a horrible death on one of the pinnacles of the building. With eager eyes the crowd followed every movement of the ape, and loud was the sympathy for the unfortunate animal. Imagine the sequel. When the chimpanzee was more nearly approached, the object which, to the eyes of thousands, had presented the exact reproduction of an ape, was discovered to be merely a fluttering rag of canvas, the movements of which had simulated in their eyes the attitudes of the monkey. After the occurrence of such an incident, I must be pardoned if I feel somewhat sceptical, even when the united testimony of two or three persons is hurled at my head by way of convincing me that a ghost was thereby necessarily proved to be no mere figment of the brain.

Andrew Wilson.

ARTIFICIAL INDIGO.

It may be interesting to many readers of this magazine to know something about the production of the dyestuff indigo by artificial means, for it is now to some extent obtained practically by the chemical process known as synthesis, from one of the constituents of the tar obtained from the distillation of coal for the production of gas.

Previous to the introduction of this colouring matter into Europe, about the middle of the sixteenth century, the indigo contained in woad (*Isatis tinctoria*) was employed for dyeing, although the Romans and Greeks used indigo for painting; up to the present time the name "wood" is still in vogue in many dyeworks, the vats in which the dyeing is carried on being called "wood vats" and the dye-house "wood-house."

The following is intended to give a short account of the manner in which this valuable colouring matter, so largely produced in India from the cultivation of the indigo plant, is built up by chemical processes. Indigo is composed of carbon, oxygen, hydrogen, and nitrogen, and is represented by the formula C_8H_5NO, showing the number of atoms of each of its elementary constituents. The naphtha obtained when coal tar is distilled, contains a number of chemical compounds—benzol, toluol, cumol, &c.; it is from the second of these (toluol, C_7H_8) that indigo is obtained. By adding an atom of oxygen to indigo, Erdmann and Laurent formed a compound named isatin ($C_8H_5NO_2$); and afterwards Baeyer succeeded in converting this compound back again into indigo by the reduction of its chloride; and from a knowledge of the constitution of this isatin, the two chemists, Claissen and Shadwell, have succeeded in building it up from a nitro compound of benzoic acid (called ortho-nitro-benzoic acid). It is pretty well known that this acid is contained in gum benzoin, from which it was exclusively obtained until within the last few years. Now, however, it is produced from toluol by simple but interesting chemical processes. The nitro-compound of benzoic acid has one of its hydrogen atoms displaced by chlorine, and on bringing this chloride in contact with silver cyanide, the chlorine and cyanide exchange places, forming the insoluble compound silver chloride and the nitrite. This nitrite, heated with potassium hydrate, exchanges the cyanogen for an atom of oxygen and hydrogen, producing ortho-nitro-phenyl-glyoxalic acid and potassium cyanide. The oxygen associated with the nitrogen forming the nitro group, is displaced by a similar process to one already largely employed for converting the nitro compounds of benzol, toluol, &c., into their corresponding amines or amido compounds (aniline toluidine); that is, by contact with nascent hydrogen by the abstraction of water from the amido compound just formed from ortho-nitro-phenyl-glyoxalic acid isatin is obtained, which, as we have already seen, can be converted into indigo by the process discovered by Baeyer.

This chemist has also succeeded in producing isatin by another process from toluol, first producing phenyl-acetic acid.

The colouring matter is obtained practically by Baeyer from a compound found in gum, benzoin, and other natural products, known as cinnamic-acid. This is the process employed:—The acid produced by natural means being too expensive, its synthesis is resorted to; toluol is also, in this instance, the starting-point; it is by the substitution of one of its atoms of hydrogen by chlorine, converted into a compound named benzyl chloride, which, by a proper treatment with nitric acid, is converted into oil of bitter almonds by the displacement of one atom each of the monatomic elements, hydrogen and chlorine, by the diatomic element oxygen. This oil is also called benzaldehyd. It was discovered in 1856 by Bertagnini that this compound, on treatment with acetyl-chloride, is converted into cinnamic-acid. W. H. Perkin, F.R.S., has, however, discovered a more practical and cheaper method for the synthesis of this acid. Two atoms of hydrogen in the toluol are substituted by two of chlorine, forming benzyl-dichloride, and this compound, heated with acetate of soda, yields cinnamic acid. Acting on this acid with nitric acid there is formed a nitro-compound—the ortho-nitro-cinnamic acid. This is caused to combine with two atoms of bromine, by which the dibrom-nitro-phenyl-propionic acid is obtained. By the treatment of this last-named compound with caustic soda or potash, the two atoms of bromine are removed, forming sodium bromide, whilst two atoms of hydrogen are also removed, forming a molecule of water, thus producing a new compound having two atoms of bromine and two of hydrogen less than the last-mentioned compound, the new product being ortho-nitro-phenyl-propiolic-acid, and this, by reduction with hydrogen, forms indigo, carbonic acid, and water. It is the ortho-nitro-phenyl-propiolic-acid which is supplied to the calico printers, who, on printing its alkaline solution with a reducing agent, form an indigo white on the fabric, and on steaming it is oxydised into the pure indigo blue. M. Rosentiehl says, "a mixture of gum water containing the above-

mentioned acid, along with carbonate of soda and glucose" is printed. "The design is scarcely visible at first, all the substances being colourless. But if the cloth is exposed for two minutes to a temperature bordering on 100° C the design appears, and the formation of indigotine (*i.e.* pure indigo) is so plentiful that the colour appears black. Washing with water removes the soluble matter, and indigo blue becomes visible with all its characters, and is intimately fixed upon the fibre." Although the manufacture of this interesting compound has been, according to the *Textile Manufacturer*, given up by one Continental factory, it undoubtedly only remains a matter of time for the further and more practical development of this new industry, and most probably it will become as successful a competitor with the natural product as alizarine is with madder, the cultivation of which has almost ceased, the beet being cultivated in its place for the manufacture of sugar.

SCIENCE AND RELIGION.

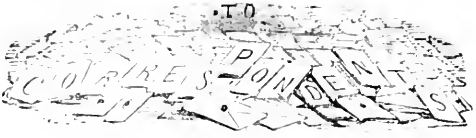
A CORRESPONDENT writes:—"I find fault with the *seeming* tendency of science to account for all 'physical' and 'chemical' laws as being merely due to certain fixed laws of nature. Scientific men may say that by nature they really mean God, or that nature was made by God; but the fact remains, that those who learn may or will say Nature does everything herself, there's no need for a God. Lecturers are too fond of such words as the following: 'These are the means by which Nature works. In this case Nature adopts such and such a course.' When some weak-minded people (and there are many such) are constantly hearing the one refrain of the whole law of existence, being merely a question of 'chemical' decay and 'chemical reproduction,' they say there is no God but these: they will perchance ask the question "Was there ever any beginning? Will there ever be any end?' One of our great men made use of the words that man was nothing but a 'shovelful of phosphates.' Such words spread quickly, not for good but for much evil. These, sir, are the points to which I would draw attention. I, for one, would gladly see a really good correspondence anent this matter. Yet even in this case, I would fear that some of the arguments advanced on the side of science would cause much mischief amongst those of weak minds or weak faith."

[We receive so many letters of this kind, that we think it well to admit so much as we have quoted of our correspondent's letter (all that is essential to the argument has been left): but it is only allowed to appear as the Helots were allowed by the Spartans to show the bad effects of indulgence. To the kind of correspondence which our correspondent invited (yet deprecates, though seeking to initiate it) our columns are emphatically not open. We can neither suffer scientific facts to be advanced as oppugning nor as supporting specific religious doctrines. If scientific statements were made here which seem, whether to "those of weak mind or of weak faith," or to able reasoners, to be opposed to religious doctrines which they hold, our correspondence columns would be open to scientific objections to such statements. They would be open to letters showing how such statements may be reconciled with the religious doctrines apparently oppugned, if they were open to suggestions on the other side. But the balance will be held fairly so far as lies in our power. We regard the wider questions of natural religion as within our scope, but those who wish to attack specific religious opinions from the side of science must seek some other arena; and so also must those who wish to attack science from the side of religion. Our purpose here is to seek for scientific truth. We are in no way concerned with the religious tenets of our contributors or correspondents. Those, on the one hand, who are unsatisfied with science unless used as a weapon wherewith to attack religious opponents; and those, on the other, who ask, first, not whether a scientific statement is true, but whether it can be reconciled with their religious views, will find science, as treated in these pages, altogether unsatisfactory to them. If there are few who do not belong either to one category or to the other, we shall have to admit that KNOWLEDGE is a mistake. But we should not change our plan; we should simply abandon our purpose.—ED.]

SEPARATE SOUNDS ON ONE WIRE.—M. Maiche has found by experiment that sounds of different characters produced from two separate sources can be sent simultaneously on one wire and received separately. He used at the receiving station two telephones of different resistances, and at the transmitting station caused a musical box to be set going on a microphone of small resistance, while an induction telephone transmitter was spoken into at the same time. The musical sounds were reproduced in the telephone which had the least resistance, and the vocal sounds in the other, so that with the two telephones to the ears, the music could be heard by one ear and the speech by the other.—*Scientific American*.

THE FRENCH SOCIAL PROBLEM.—At the beginning of the present century, with a population of not more than twenty-seven millions, there were actually more births in France than took place in the year 1880. M. Legrand, in his well-known essay on "Le Mariage et les Mœurs en France," states that between 1800 and 1815 the number of children born per marriage averaged 4·24; since then it had sunk gradually, and in 1860 averaged only 3·03 for the five preceding years. It rose again until 1865, but has since declined; and in the year 1871, the date of the Franco-German War, reached its lowest depth of 2·26. In 1872 the average rose to its highest for the last few years, namely 2·67, and in 1877 it was 2·55. M. Legrand asserts, on the strongest possible grounds, that this decrease in the birth-rate of his country continues, and is becoming more marked as the years go by. It is a noteworthy and, perhaps, ominous fact, that lately the number of marriages have not decreased. Indeed, there are actually more marriages per cent. in France than in England, the average per hundred being in the former ·88, and in the latter ·86.

ASBESTOS FIRE-PROOF PAINT.—A series of interesting experiments on a practical scale were recently carried out in the grounds of the Crystal Palace with asbestos paint, in order to test its qualities as a protective covering against fire. This paint is a new and special preparation of asbestos, and is being introduced by the United Asbestos Company, of 161, Queen Victoria-street, E.C. The asbestos in a finely divided state is mixed with a fluid material, and is used in a similar manner to other paints. Unlike them, however, it is uninflammable, and not only so, but is capable of communicating this valuable attribute to such substances as it may be applied to. This applies alike to cotton fabrics and to timber or other inflammable materials used for constructive or decorative purposes. Hence its great value in connection with theatrical properties and appliances, especially those connected with the stage arrangements. It was to demonstrate this valuable feature that the experiments were carried out, in the presence of the Lord Mayor and Lady Mayoress, the representative of the Lord Chamberlain, Captain Shaw, and a number of other ladies and gentlemen who had been specially invited, besides the visitors at the Palace generally. The first experiment consisted in submitting to the action of fire some linen, cotton, and gauze fabrics which had been partially treated with the paint. On setting fire to them, the unprotected portions quickly blazed away into tinder, the protected parts remaining intact. The next experiment consisted in placing on one part of a fierce fire some blocks of wood painted with asbestos paint, and on another part similar blocks of wood not painted. In the course of a short time the unpainted blocks were entirely consumed, while those which were painted resisted the action of fire for a long time without showing signs of deterioration. At length, however, the fierce heat of the fire raised some blisters, which on bursting admitted the intense heat, which charred the wood, the external coating of paint, however, being greatly preserved. In the final experiments, four timber erections were employed, two being about 12 ft. wide by 8 ft. deep and 10 ft. high, and representing theatrical stages, with ropes, curtains, and effects. The other two were open timber sheds, about 6 ft. square in plan and 8 ft. high. One of each of these two classes of structures was protected with the asbestos paint, the other two being of plain timber. Piles of shavings and other inflammable materials were placed under and upon the floor of each structure, and lights were applied to all simultaneously. The unprotected stage quickly caught fire, and in about twelve minutes it was a heap of blazing ruins. The unprotected shed, being open-sided, did not take fire so soon nor burn so rapidly, but the flames eventually got hold of it. Both the protected stage and shed resisted the effects of fire to the end most successfully, although inflammable materials, including naphtha, were occasionally employed. In the course of half-an-hour some portions of the fittings were found to be smouldering away, but at no time was there any outburst of flame from the protected materials. The interior of the woodwork, however, was well blistered, but the wonder is that it showed so little evidence of damage. The gauze and lighter fabrics disappeared at an early stage, but only by crumbling gradually away in an incandescent condition, and never once by bursting into flame. These results are highly satisfactory, and fully demonstrate the value of the asbestos paint as a fire-resisting medium in respect of its application to theatrical stages and effects, or, in fact, to any other structures or their fittings. On returning to the palace after the experiments the visitors were gratified by a private view of the concert-room, which was beautifully illuminated for the first time by the Edison electric light. The demonstration was distinctly not a public one, but was only the engineer's experimental trial of the engines and Edison machines, which have just been got in position.



Letters to the Editor.

The Editor does not hold himself responsible for the opinions of his correspondents. He cannot undertake to return manuscripts or to correspond with their writers. All communications should be as short as possible, consistently with full and clear statements of the writer's meaning.]

All Editorial communications should be addressed to the Editor of KNOWLEDGE; *all Business communications to the Publishers, at the Office, 74, Great Queen-street, W.C.*

All Remittances, Cheques, and Post-Office Orders should be made payable to Messrs. Wyman & Sons.

•.• All letters to the Editor will be Numbered. For convenience of reference, correspondents, when referring to any letter, will oblige by mentioning its number and the page on which it appears.

All Letters or Queries to the Editor which require attention in the current issue of KNOWLEDGE, *should reach the Publishing Office not later than the Saturday preceding the day of publication.*

"In knowledge, that man only is to be contemned and despised who is not in a state of transition. . . . . Nor is there anything more adverse to accuracy than fixity of opinion."—*Faraday.*

"There is no harm in making a mistake, but great harm in making none. Show me a man who makes no mistakes, and I will show you a man who has done nothing."—*Liebig.*

CHINESE CALCULATION.

DURING my first visit to America, in the winter of 1873-74, a Chinese calculating man gave some remarkable proofs of the rapidity with which the persons of his profession in China can execute some of the common processes of calculation. His rapidity in executing long sums, or what with most would be long sums, in addition, was remarkable. A series of numbers, each of four digits, were named to him as fast as they could be entered by a clerk, and when the last of some thirty had been called out, he was told to add them together. "It is already done," he said, naming the total. When the numbers as entered by the clerk had been carefully added together, it was found that the total so named was correct in every figure. It seems to me that there is something in this feat which, though akin to the power some of our banking clerks possess of adding in a single operation numbers of four digits, yet so far surpasses that power as to indicate the use of some entirely different system of arithmetical training, for I am given to understand that what the Chinese calculator did, though it seemed so remarkable, fell far short of what many Chinese computers could do. In fact, I was told he was only an ordinary computer. Can any of our readers give any account of Chinese arithmetic, or of their processes of rapid calculation? ED.]

MIND-DOCTORS.

[224]—What Molière ridiculed in the doctors of his age is true, to some degree, of the mind-doctors of the present time; there is a tendency among them to threaten all manner of evil consequences from quite ordinary and familiar symptoms, unless their aid is quickly called in. It occurs to me, by-the-way (my momentary forgetfulness on the point is one of the slight symptoms in question, and not, I venture to assure myself, a sign of approaching mania), that in "Monsieur de Pourceaugnac," Molière has satirized the very tendency with which we are here specially dealing: "Qu'ainsi ne soit," says the First Doctor to the Second, speaking of the unfortunate De Pourceaugnac, "pour diagnostique incontestable de ce que je vous dis, vous n'avez qu'à considérer ce grand sérieux que vous voyez, cette tristesse accompagnée de crainte et de défiance, signes pathognomoniques et individuels de cette maladie, si bien marquée chez le divin Hippocrate; cette physionomie, ces yeux rouges et hagards, cette grande barbe, cette habitude du corps, menue, grêle, noire et velue, lesquels signes le dénotent très-affecté de cette maladie, procédante du vice des hypocondres; laquelle maladie, par laps de temps, naturalisée, envieillie, habituée et ayant pris droit de bourgeoisie chez lui, pourroit bien dégénérer ou en manie, ou en phthisie, ou en apoplexie, ou même en fine frénésie et fureur. Tout ceci supposé, puisqu'une maladie bien connue est à demi guérie, car, *ignoti nulla est curatio morbi*, il ne vous sera pas difficile de convenir des remèdes que vous devons faire à monsieur," and so forth. CEREBRUM.

SEA SERPENT, OR SEAWEED?

225 If I am rightly informed you are a believer in the sea serpent. The following extract from a daily paper may serve to change your ideas on that subject. "A good sea serpent story—rather better than those which are often published about this time of year—comes from Madras, in the shape of reminiscences of Captain Taylor when lying at anchor in Table Bay some years ago. One day an 'enormous monster,' about a hundred feet in length, was seen advancing with snake-like motion round Green Point into the harbour. The head appeared to be crowned with long hair, and the keener sighted amongst the observers could see the eyes and distinguish the features of the monster. The military were called out, and after peppering the object at a distance of five hundred yards, and making several palpable hits, it was observed to become quite still, and boats ventured off to complete the destruction. The 'sea serpent' proved to be a mass of gigantic seaweed, which had been undulated by the ground swell, and had become quiescent when it reached the still waters of the bay. Probably if mariners would attack the 'monster' in the same manner whenever it is seen, we should hear little more of the sea-serpent." I am, sir, yours &c." J. DAWKINS.

[Mr. Dawkins appears to think that we have never heard of sea weed being mistaken for sea serpents. The following extract from an essay on Strange Sea Creatures, p. 223 of "Pleasant Ways in Science," may change his views in that respect:—"When the British ship *Brazilian* was becalmed . . . Mr. Herriman, the commander, perceived something right abeam, about half a mile to the westward, stretched along the water to the length of about 25 or 30 feet, and perceptibly moving from the ship with a steady, sinuous motion. The head, which seemed to be lifted several feet above the waters, had something resembling a mane, running down to the floating portion, and within about 6 feet of the tail, it forked out into a sort of double fin. Mr. Herriman, his first mate Mr. Long, and several of the passengers, after surveying the object for some time, came to the unanimous conclusion that it must be a sea-serpent. As the *Brazilian* was making no headway, Mr. Herriman, determining to bring all doubt to an issue, had a boat lowered down, and taking two hands on board, together with Mr. Boyd, of Peterhead, near Aberdeen, one of the passengers, who acted as steersman under the direction of the captain, they approached the monster, Captain Herriman standing on the bow of the boat, armed with a harpoon to commence the onslaught. The combat, however, was not attended with the danger which those on board apprehended; for, on coming close to the object, it was found to be nothing more than an immense piece of seaweed, evidently detached from a coral reef, and drifting with the current, which sets constantly to the westward in this latitude, and which, together with the swell left by the subsidence of the gale, gave it the sinuous, snake-like motion."

As a mere matter of detail, it may be remarked that there is some difference between the distance of half a mile in this case, of 500 yards in the other case, and in yet another case of a sea weed sea serpent 800 yards, and the distance of 200 yards at which Captain M'Quhae, and other officers of the frigate *Dædalus*, saw what they stated to be "beyond all question a living animal, moving rapidly through the water against a cross sea and within five points of a fresh breeze, with such velocity, that the water was surging against its chest as it passed along at a rate probably of ten miles per hour." Captain M'Quhae would not go after *his* seaweed because he saw he had no chance of overhauling it, so that for seaweed, travelling against the wind, it was tolerably active. Albeit Mr. Dawkins will not find a word in the essay above-named implying that we believe in the sea serpent. A paddling, long-necked sea creature, probably akin to the *Plesiosaurus*, seems suggested by that portion of the multitudinous evidence relating to supposed sea serpents which is trustworthy. Such a creature would not be a sea serpent, however.—ED.]

COLD SATURATED SOLUTION.—MARINE BOILERS.

[226]—In answer to query 185, Thorpe, in *Journ. Chem. Soc.* for October, 1881, gives a method for estimating total salts in water. In the same Journal, Page & Keightley [2], X. 566, give amounts of nitrate and chloride of K. and Na. in cold saturated solution. Can find no reference to methods in *Dic. Chem.*. If Messrs. G. & S. want a method for separate salts, there is no better way than adding excess of salt, heating and shaking, then cooling to 60° (this applies equally for common salt); or, if salt less soluble in hot water, saturate the solution at a lower temperature, and let it rise to 60° Then take 250 c.c. and make volumetric analyses. W. G. must be wrong in assuming that grease is present in boiler crust. Dust, or any substance that will not wet, make water spheroidal.

C. T. B.

INTELLIGENCE IN ANIMALS.

[227]—Reading to an old sportsman your article on this subject in No. 6, and the correspondence which followed, he related to me how he used to accompany a friend possessing a pointer (bitch), who, when her master missed three consecutive shots, would slink home, heedless of any calls to remain in the field. The friend alluded to was a first-rate shot, and rarely missed his mark, except after an evening's extra glass.

In thus administering a rebuke to her master, the animal, I think, exhibited a rare amount of humour. It could not be said that the dog herself was unmindful of her own duties, for on one occasion, when her master went home to lunch, returning after two hours' absence, she was found at the same spot where left, pointing to a hare lying at the bottom of a hedge. This, of course, was due to good training, but her conduct in the former instance must have been the result of reasoning. A. GAUBERT.

ELECTRICAL IMAGES.

[228]—Having been lately reading Maxwell's "Elementary Treatise on Electricity," I have been able to follow the reasoning and do all the mathematics except one part on page 85 relating to electrical images. The difficulty is to obtain his results without a clumsy and laborious process of multiplying. He says: "If we now write—

$$qaa = a + \frac{a^2 b}{c^2 - b^2} + etc.$$

$$qab = \frac{-ab}{c} - \frac{a^2 b^2}{c\,(c^2 - a^2 - b^2)} - etc.$$

$$qbb = b + \frac{ab^2}{c^2 - a^2} + etc.$$

the whole charge on the sphere a will be

$$Ea = qaa\,Pa + qab\,Pb,$$

and that of the sphere b will be

$$Eb = qab\,Pa + qbb\,Pb."$$

That is all clear enough. But he goes on to say: "From these results we may calculate the potentials of the two spheres when their charges are given, and if we neglect terms involving ^3b, we find—

$$Pa = \frac{1}{a}\,Ea + \frac{1}{c}\,Eb$$

$$Pb = \frac{1}{c}\,Ea + \left(\frac{1}{b} - \frac{a^3}{c^2\,(c^2 - a^2)}\right) Eb."$$

The second result, I cannot for the life of me make out, though I have tried lots of times. On page 186, Fig. 48, it seems to me that the direction of the current in the branch $C\,O$, should be from C to O, and not, as in the figure, from O to C, the battery being placed at E. It occurs in the large treatise as in the elementary one. Surely the Editor should have seen that such an important matter as Wheatstone's Bridge should have been correctly represented. He is not reputed to be over merciful towards the blunders of other minor planets. A STUDENT.

MORTALITY FROM CANCER.

[229]—In an article on the "Duration of Life" (KNOWLEDGE, No. XI., p. 228), Mr. Allinson states that diseases of more advanced life, "such as cancer," are increasing in fatality. Is it a fact that cancer is increasing, or is there only an increase in the number of recorded cases, due to a readier diagnosis on the part of medical men? In the Registrar-General's Report for 1879, the total average mortality from cancer is stated at 0·5 per 1,000 of population. If this is correct, my neighbourhood contrasts badly with the country in general. In the south-western suburb of London, in which I live, there have been in my own small circle of acquaintance within the past year five cases of cancer in elderly persons, in four instances abdominal. Can Mr. Allinson point to any trustworthy statistics in support of his statement, which my experience latterly goes far to confirm? It seems to me a question of great interest whether the occurrence of this most frightful disease is influenced by locality. H. A. EVEREST.

RICHTER'S DREAM.
